# ESTRO 36 CONTENT

## SATURDAY 6 MAY 2017

### Teaching Lecture

The role of radiotherapy in small cell lung cancer -current status and future developments .....	Abs. 1
Immunotherapy .....	Abs. 2
MRI for RO physicists: what is what? QA geometrical distortions .....	Abs. 3
Cavity Theory: separating the facts from the myths .....	Abs. 5
High tech or low tech for metastatic disease, how does one decide and what is the cost-benefit? .....	Abs. 6
Gene editing: How this technique can be used to study radiation responses? .....	Abs. 7
Target delineation and target definition for PBI .....	Abs. 8-9

### Joint Symposium

ESTRO-ASTRO: Cutting edge combined modality therapies (Focus on NSCLC) .....	Abs. 10-13
--	------------

### Symposium with Proffered Papers

Radiotherapy plus immunotherapy combination: rationale and results so far .....	Abs. 14-18
---	------------

### Joint symposium

ESTRO-AAPM: New technological and computational developments in particle therapy .....	Abs. 19-21
--	------------

### Symposium

CT imaging, new developments .....	Abs. 22-24
High tech or low tech for metastatic disease, how does one decide and what is the cost-benefit? .....	Abs. 25-27

### Symposium with Proffered Papers

Novel approaches in heart / lung matters .....	Abs. 28-31
--	------------

### Symposium

Expanding brachytherapy indications .....	Abs. 32-34
---	------------

### Proffered Papers

Radiobiological modeling .....	Abs. 35-41
--------------------------------	------------

### Poster Viewing

Session 1: Haematology / Paediatrics / Sarcoma .....	Abs. 42-50
--	------------

### Proffered Papers

Joint Clinical - GEC ESTRO on cervix cancer .....	Abs. 51-56
---	------------

### Symposium

Response adapted treatment .....	Abs. 57-59
----------------------------------	------------

### Proffered Papers

Dosimetry and detector development for particle therapy .....	Abs. 60-65
Quantitative and functional imaging .....	Abs. 66-71
Improvements in positioning and motion management .....	Abs. 72-77

### Symposium with Proffered Papers

Novel approaches in gut matters .....	Abs. 78-80
---------------------------------------	------------

### Proffered Papers

Skin .....	Abs. 81-86
------------	------------

### Poster Viewing

Session 2: Palliative and health services research .....	Abs. 87-93
--	------------

### Award Lecture

Van der Schueren Award lecture .....	Abs. 94
Iridium Award Lecture .....	Abs. 95
Honorary Physicist Award Lecture .....	Abs. 96

### Symposium

The optimal approach to treat oligometastatic disease: different ways to handle an indication quickly gaining acceptance .....	Abs. 97-100
--	-------------

### Symposium with Proffered Papers

Targeting tumour heterogeneity .....	Abs. 101-105
--------------------------------------	--------------

### Symposium

Innovations in ion beam therapy .....	Abs. 106-108
Imaging for therapeutic response / toxicity evaluation .....	Abs. 109-111
Comprehensive motion management and immobilisation solutions in radiation therapy .....	Abs. 112-114

**Symposium with Proffered Papers**

Novel approaches in brain matters .....Abs. 115-119

**Symposium**

Brachytherapy pays .....Abs. 120-123

**Proffered Papers**

Prostate .....Abs. 124-130

**Poster Viewing**

Session 3: Treatment planning .....Abs. 131-138

**Proffered Papers**

Lung .....Abs. 139-144

**Joint Symposium**

ESTRO-JASTRO: Oligometastatic disease .....Abs. 145-148

**Proffered Papers**

Best of particles .....Abs. 149-154

Imaging and image analysis .....Abs. 155-160

Novelties in image guidance .....Abs. 161-166

**Symposium**

Novel approaches in particle biology .....Abs. 167-170

**Proffered Papers**

Prostate 1 .....Abs. 171-176

Breast .....Abs. 177-182

**Poster Viewing**

Session 4: Brachytherapy miscellaneous .....Abs. 183-190

**Award Lecture**

Honorary Members' Award Lectures .....Abs. 191-193

**SUNDAY 7 MAY 2017****Teaching Lecture**

Role of radiotherapy in extranodal lymphomas ..... Abs. 194

Strategies to increase safety in radiation oncology: how to make accidents  
less likely to occur ..... Abs. 195

Automated planning, knowledge-based planning and other novel developments  
in treatment planning - how do they work and perform? ..... Abs. 196

Building of NTCP models that contain non-dosimetric parameters ..... Abs. 197

Particle therapy: how to start up and carry out daily clinical practice ..... Abs. 198

Three-dimensional organoid culture system ..... Abs. 199

Commissioning of dose calculations in brachytherapy TPS ..... Abs. 200

**Symposium**

New developments in Personalised Radiation Oncology (PRO) .....Abs. 201-204

Safety and clinical and cost effectiveness of multi-modality IGRT and ART .....Abs. 205-208

Robust optimisation in protons and photons .....Abs. 209-211

Ultra fast online therapy adaptation (replanning, dose accumulation QA) .....Abs. 212-214

Particle therapy: how to start up and carry out daily clinical practice .....Abs. 215-217

**Symposium with Proffered Papers**

Combining tumour and normal tissue models .....Abs. 218-222

**Symposium**

Paediatric brachytherapy .....Abs. 223-225

**Proffered Papers**

Dose measurement and dose calculations .....Abs. 226-232

**Poster Viewing**

Session 5: Lung and breast .....Abs. 233-241

**Proffered Papers**

Understanding RBE and its relevance in vivo .....Abs. 242-246

**Joint Symposium**

ESTRO-CARO: Waiting times and QA .....Abs. 247-250

**Proffered Papers**

Automated and robust treatment planning .....	Abs. 251-256
Best of online MRI-guided radiotherapy .....	Abs. 257-262
Variabilities in volume definition .....	Abs. 263-268

**Proffered Papers**

Prostate 2 .....	Abs. 269-274
Physics treatment verification .....	Abs. 275-280

**Poster Viewing**

Session 6: Imaging .....	Abs. 281-287
--------------------------	--------------

**Presidential Symposium**

Presidential Symposium .....	Abs. 288
------------------------------	----------

**Award Lecture**

Jens Overgaard Legacy Award	
Regaud Award Lecture .....	Abs. 290

**Symposium**

New paradigm in HNSCC .....	Abs. 291-293
-----------------------------	--------------

**Symposium with Proffered Papers**

Costs and value of radiotherapy innovations: how to assess .....	Abs. 294-297
--	--------------

**Debate**

This house believes that proton guided photons (online MR guided therapy) will be superior to photon guided protons (CBCT proton therapy) .....	Abs. 298-299
---	--------------

**Proffered Papers**

Intra-fraction motion management .....	Abs. 300-306
--	--------------

**Symposium**

Focus on ART: the clinical difficulties .....	Abs. 307-309
---	--------------

**Symposium**

Registration and fusion techniques .....	Abs. 310-312
--	--------------

**Proffered Papers**

Breast and gynaecology .....	Abs. 313-319
------------------------------	--------------

**Poster Viewing**

Session 7: Upper and lower GI .....	Abs. 320-328
-------------------------------------	--------------

**Proffered Papers**

Head and Neck .....	Abs. 329-334
---------------------	--------------

**Symposium**

GTFRCC .....	Abs. 335-338
--------------	--------------

**Proffered Papers**

Dose measurement and dose calculation for proton beams .....	Abs. 339-344
Treatment planning applications .....	Abs. 345-350
Adaptive strategies .....	Abs. 351-356

**Proffered Papers**

Physics Dosimetry .....	Abs. 357-362
Eye/GYN .....	Abs. 363-368

**Poster Viewing**

Session 8: Radiobiology .....	Abs. 369-374
-------------------------------	--------------

**Award Lecture**

Jack Fowler University of Wisconsin Award .....	Abs. 375
Company Award Lectures .....	Abs. 376-377

**MONDAY 8 MAY 2017****Teaching lecture**

State of the art multimodality treatment of rectal cancer .....	Abs. 378
SBRT for spine and non-spine bone metastases: what role in routine practice? .....	Abs. 379
Challenges in proton radiotherapy .....	Abs. 380-381
Targeting histones and epigenetic mechanisms in radiation biology and oncology .....	Abs. 382
State of the art and future improvements in in-room cone beam CT image quality .....	Abs. 383
Radiomics for physicists – understanding feature extraction, modelling, performance validation and applications of radiomics .....	Abs. 384

Focus on lung cancer: What a radiotherapy department should offer their patients .....	Abs. 385
How to write a research proposal for a grant? .....	Abs. 386
<b>Symposium</b>	
Rectal cancer – prediction and individualisation .....	Abs. 387-389
Radiotherapy of brain tumours .....	Abs. 390-392
MR guided radiotherapy: the new standard of care in 10 years time .....	Abs. 393-396
<b>Symposium with Proffered Papers</b>	
Novel approaches in head and neck tumour control .....	Abs. 397-400
<b>Symposium</b>	
Experimental therapies .....	Abs. 401-403
Adaptive radiotherapy (both anatomical and 'functional' changes) .....	Abs. 404-406
Focus on lung cancer: What a radiotherapy department should offer their patients .....	Abs. 407-409
Education and research grants .....	Abs. 410-414
<b>Poster Viewing</b>	
Session 9: Dosimetry .....	Abs. 415-423
<b>Proffered Papers</b>	
Upper and Lower GI .....	Abs. 424-429
<b>Joint Symposium</b>	
ESTRO-ESR: Radiomics and imaging databases for precision radiation oncology .....	Abs. 430-433
<b>Symposium with Proffered Papers</b>	
Novel approaches in prostate tumour control .....	Abs. 434-436
<b>Proffered Papers</b>	
New technologies for imaging and therapy .....	Abs. 437-442
Optimisation algorithms for treatment planning .....	Abs. 443-448
Planning and quality assurance .....	Abs. 449-454
<b>Poster Viewing</b>	
Session 10: RTT .....	Abs. 456-462
<b>Award Lecture</b>	
Donal Hollywood Award .....	Abs. 463
<b>Proffered Papers</b>	
Highlights of proffered papers .....	Abs. 464-467
<b>Symposium</b>	
Non-rectal GI tumours: key open questions to be answered from (and for) the radiation oncologist! .....	Abs. 469-471
<b>Joint Symposium</b>	
ESTRO-RANZCR: Big data to better radiotherapy .....	Abs. 472-475
<b>Symposium</b>	
Locally advanced breast cancer .....	Abs. 476-478
<b>Symposium with Proffered Papers</b>	
Novel approaches in thoracic tumour treatment .....	Abs. 479-482
<b>Proffered Papers</b>	
Inter-fraction motion management .....	Abs. 483-491
<b>Symposium</b>	
Focus on prostate cancer: what is the best of radiotherapy we need to treat our patients with .....	Abs. 492-494
Young ESTRO meets ESTRO School .....	Abs. 495-501
<b>Poster Viewing</b>	
Session 11: Head and neck and CNS .....	Abs. 502-511
<b>Proffered Papers</b>	
CNS .....	Abs. 512-517
<b>Symposium</b>	
Patient Reported Outcomes (PROs) in radiotherapy .....	Abs. 518-520
<b>Proffered Papers</b>	
Oligometastatic disease .....	Abs. 521-526
<b>Symposium with Proffered Papers</b>	
Novel approaches in colorectal tumour control .....	Abs. 527-529

### Proffered Papers

Dosimetry and detector development .....	Abs. 530-535
Novel methods for auditing .....	Abs. 536-541
Patient safety and treatment outcome .....	Abs. 542-547

### Poster Viewing

Session 12: Gynaecology and prostate .....	Abs. 548-554
--	--------------

## TUESDAY 9 MAY 2017

### Teaching lecture

New radiotherapeutic horizons in soft tissue sarcoma treatment .....	Abs. 555
Clinical evidence for hypofractionation in prostate cancer what is the optimum? .....	Abs. 556
Extracellular vesicles in radiation oncology .....	Abs. 557
Update on molecular radiotherapy .....	Abs. 558
Basics, implementations, limitations, ... of Monte Carlo dose calculation algorithms .....	Abs. 559
RTTs roles and responsibilities to support future practice .....	Abs. 560

### Symposium

Radiotherapy in the elderly .....	Abs. 561-564
-----------------------------------	--------------

### Symposium with Proffered Papers

Selection of patients and radiotherapy technique for APBI in the light of new phase III trial data .....	Abs. 565-569
Novel approaches in poor tumour control sites .....	Abs. 570-573

### Symposium

4D imaging and tracked delivery .....	Abs. 574-576
Modelling and treatment customisation .....	Abs. 577-579
RT is technology driven. How to keep the patient involved? .....	Abs. 580-582
Hypofractionation in prostate cancer .....	Abs. 583-585
Is there any ground for boost brachytherapy in the time of high precision IGRT/IMRT? .....	Abs. 586-588

### Symposium with Proffered Papers

Novel approaches in tumour control .....	Abs. 589-591
--	--------------

### Symposium

Applications and challenges in dosimetry for MR-linacs .....	Abs. 592-594
Novel approaches for combining imaging and non-imaging data for radiotherapy response prediction .....	Abs. 595-597

### Debate

Debate: Precision in radiotherapy: mission complete! .....	Abs. 598
--	----------

## POSTERS

Clinical track: Head and Neck .....	Abs. 603-621
Clinical track: CNS .....	Abs. 622-644
Clinical track: Haematology .....	Abs. 645-648
Clinical track: Breast .....	Abs. 649-665
Clinical track: Lung .....	Abs. 666-678
Clinical track: Upper GI (oesophagus, stomach, pancreas, liver) .....	Abs. 679-701
Clinical track: Lower GI (colon, rectum, anus) .....	Abs. 702-707
Clinical track: Gynaecological (endometrium, cervix, vagina, vulva) .....	Abs. 708-722
Clinical track: Prostate .....	Abs. 723-739
Clinical track: Skin cancer / malignant melanoma .....	Abs. 740-741
Clinical track: Sarcoma .....	Abs. 742-744
Clinical track: Palliation .....	Abs. 745-747
Clinical track: Elderly .....	Abs. 748-749
Clinical track: Health services research / health economics .....	Abs. 750-751
Clinical track: Other .....	Abs. 752-755
Physics track: Basic dosimetry and phantom and detector development .....	Abs. 756-784
Physics track: Dose measurement and dose calculation .....	Abs. 785-812
Physics track: Radiation protection, secondary tumour induction and low dose (incl. imaging) .....	Abs. 813-815
Physics track: Treatment plan optimisation: algorithms .....	Abs. 816-823
Physics track: Treatment planning: applications .....	Abs. 824-845
Physics track: (Radio)biological modelling .....	Abs. 846-855
Physics track: Intra-fraction motion management .....	Abs. 856-865
Physics track: Inter-fraction motion management (excl. adaptive radiotherapy) .....	Abs. 866-874
Physics track: Adaptive radiotherapy for inter-fraction motion management .....	Abs. 875-880

Physics track: CT Imaging for treatment preparation .....	Abs. 881-884
Physics track: (Quantitative) functional and biological imaging .....	Abs. 885-891
Physics track: Images and analyses .....	Abs. 892-906
Physics track: Implementation of new technology, techniques, clinical protocols or trials (including QA and audit) .....	Abs. 907-921
Brachytherapy: Breast .....	Abs. 922-925
Brachytherapy: Prostate .....	Abs. 926-932
Brachytherapy: Gynaecology .....	Abs. 933-941
Brachytherapy: Physics .....	Abs. 942-947
Brachytherapy: Miscellaneous .....	Abs. 948-951
Radiobiology track: Normal tissue biology of the heart .....	Abs. 952
Radiobiology track: Radiobiology of the intestinal track .....	Abs. 953-955
Radiobiology track: Normal tissue radiobiology (others) .....	Abs. 956-959
Radiobiology track: Radiobiology of proton and heavy ions .....	Abs. 960-963
Radiobiology track: Radiobiology of head and neck cancer .....	Abs. 964-969
Radiobiology track: Radiobiology of prostate cancer .....	Abs. 970
Radiobiology track: Radiobiology of breast cancer .....	Abs. 971-974
Radiobiology track: Radiobiology of lung cancer .....	Abs. 975
Radiobiology track: Radiobiology of colorectal cancer .....	Abs. 976-978
Radiobiology track: Radiobiology of cancer (others) .....	Abs. 979-995
RTT track: Patient preparation, positioning and immobilisation .....	Abs. 996-1000
RTT track: Imaging acquisition and registration, OAR and target definition .....	Abs. 1001-1006
RTT track: Treatment planning and dose calculation / QC and QA .....	Abs. 1007-1008
RTT track: Image guided radiotherapy and verification protocols .....	Abs. 1009-1012
RTT track: Motion management and adaptive strategies .....	Abs. 1013-1017
RTT track: Patient care, side effects and communication .....	Abs. 1018-1020
RTT track: Risk management/quality management .....	Abs. 1021-1025

## **ELECTRONIC POSTERS**

Clinical track: Head and Neck .....	Abs. 1026-1100
Clinical track: CNS .....	Abs. 1101-1133
Clinical track: Haematology .....	Abs. 1134-1138
Clinical track: Breast .....	Abs. 1139-1198
Clinical track: Lung .....	Abs. 1199-1237
Clinical track: Upper GI (oesophagus, stomach, pancreas, liver) .....	Abs. 1238-1256
Clinical track: Lower GI (colon, rectum, anus) .....	Abs. 1257-1284
Clinical track: Gynaecological (endometrium, cervix, vagina, vulva) .....	Abs. 1285-1307
Clinical track: Prostate .....	Abs. 1308-1365
Clinical track: Urology-non-prostate .....	Abs. 1366-1370
Clinical track: Skin cancer / malignant melanoma .....	Abs. 1371-1374
Clinical track: Sarcoma .....	Abs. 1375-1378
Clinical track: Paediatric tumours .....	Abs. 1379-1382
Clinical track: Palliation .....	Abs. 1383-1406
Clinical track: Elderly .....	Abs. 1407-1411
Clinical track: Other .....	Abs. 1412-1432
Physics track: Basic dosimetry and phantom and detector development .....	Abs. 1433-1447
Physics track: Dose measurement and dose calculation .....	Abs. 1448-1513
Physics track: Radiation protection, secondary tumour induction and low dose (incl. imaging) .....	Abs. 1514-1518
Physics track: Treatment plan optimisation: algorithms .....	Abs. 1519-1539
Physics track: Treatment planning: applications .....	Abs. 1540-1592
Physics track: (Radio)biological modelling .....	Abs. 1593-1615
Physics track: Intra-fraction motion management .....	Abs. 1616-1639
Physics track: Inter-fraction motion management (excl. adaptive radiotherapy) .....	Abs. 1640-1657
Physics track: Adaptive radiotherapy for inter-fraction motion management .....	Abs. 1658-1671
Physics track: CT Imaging for treatment preparation .....	Abs. 1672-1676
Physics track: (Quantitative) functional and biological imaging .....	Abs. 1677-1702
Physics track: Images and analyses .....	Abs. 1703-1728
Physics track: Implementation of new technology, techniques, clinical protocols or trials (including QA and audit) .....	Abs. 1729-1765
Brachytherapy: Breast .....	Abs. 1766-1767
Brachytherapy: Prostate .....	Abs. 1768-1775
Brachytherapy: Gynaecology .....	Abs. 1776-1789
Brachytherapy: Anorectal .....	Abs. 1790
Brachytherapy: Head and neck .....	Abs. 1791-1793
Brachytherapy: Physics .....	Abs. 1794-1800
Brachytherapy: Miscellaneous .....	Abs. 1801-1806

Radiobiology track: Normal tissue biology of the heart .....	Abs. 1807
Radiobiology track: Normal tissue radiobiology (others) .....	Abs. 1808-1809
Radiobiology track: Radiobiology of cancer (others) .....	Abs. 1810
RTT track: Patient preparation, positioning and immobilisation .....	Abs. 1811-1817
RTT track: Imaging acquisition and registration, OAR and target definition .....	Abs. 1818-1819
RTT track: Treatment planning and dose calculation / QC and QA .....	Abs. 1820-1836
RTT track: Image guided radiotherapy and verification protocols .....	Abs. 1837-1843
RTT track: Motion management and adaptive strategies .....	Abs. 1844-1849
RTT track: Patient care, side effects and communication .....	Abs. 1850-1857
RTT track: Education and training/role development .....	Abs. 1858-1859
RTT track: Risk management/quality management .....	Abs. 1860-1865

---

SP-0005 Cavity Theory: separating the facts from the myths.

A. Nahum<sup>1</sup>

<sup>1</sup>*University of Liverpool, Physics, Henley-on-Thames, United Kingdom*

Cavity Theory (CVTY) is intended to yield the factor converting the reading of a dose-measuring instrument (or 'dosimeter') placed in an irradiated medium to the dose to that medium *in the absence of the instrument* i.e.  $D_{med}/D_{det}$ . All trainee medical physicists have been subjected to lectures on CVTY and may even have had to answer exam questions on it (and possibly some radiation oncologists and radiographers too!). This talk will attempt to sort out the facts from the misconceptions about CVTY. Many of the following statements will be examined critically:

- Ion chambers are the only instruments that act as Bragg-Gray (BG) cavities and they only do so in megavoltage photon beams
- BG theory does not require Charged-Particle Equilibrium (CPE) - the 'proof' is that it also works in electron beams
- The *density* of the detector plays no role in its response
- Expressions involving ratios of mass-energy absorption coefficients cannot be classed as cavity theory
- The Fano theorem is a particular type of 'cavity theory'
- Treatment planning algorithms do not involve CVTY concepts
- All analytical expressions for so-called 'perturbation factors' are approximate

- Monte-Carlo simulation makes cavity theory redundant
  - Today's Dose-to-Water Codes of Practice for Reference Dosimetry make CVTY unnecessary
  - Burlin or 'General' CVTY is hopelessly approximate and ought to be abandoned
  - Proton beam dosimetry requires the development of a new CVTY
  - Spencer-Attix CVTY removes the need for the BG assumption of negligible (secondary) electron fluence perturbation
  - Bragg-Gray theory breaks down in small-field megavoltage beams

Teaching Lecture: High tech or low tech for metastatic disease, how does one decide and what is the cost-benefit?

---

SP-0006 High tech or low tech for metastatic disease, how does one decide and what is the cost-benefit?

Y. Van der Linden<sup>1</sup>

<sup>1</sup>*Leiden University Medical Center LUMC, Department of Radiotherapy, Leiden, The Netherlands*

With ongoing improvements of the technical possibilities in radiation oncology and its widespread availability, the sky seems the limit, also for patients referred for palliative indications. But are these costly and time consuming protocols really helping our patients? In this talk, the necessity for high tech in palliative radiotherapy will be searched, comparing costs and benefits in terms of goals of palliative care, treatment outcome, quality of life, time consumption, and, also real costing.

Teaching Lecture: Gene editing: How this technique can be used to study radiation responses?

---

SP-0007 Gene editing: How this technique can be used to study radiation responses?

L. Marignol<sup>1</sup>

<sup>1</sup>*Trinity Translational Medicine Institute, Translational Radiobiology and Molecular Oncology- Applied Radiation Therapy Trinity- Discipline of Radiation Therapy, Dublin, Ireland*

The personalisation of radiation therapy relies on the discovery of novel biomarkers predictive of treatment outcomes. The molecular classification of cancer with microarray and next generation sequencing have reduced time and costs associated with the generation of genetic profiles - but also the amount of genetic material required. Gene editing approaches using single-stranded RNA or DNA and/or CRISPR/Cas9 to disrupt or modify the DNA sequence of selected genes are attractive: the engineering of radioresistant cancer models enables the direct evaluation of the function of specific genes and regulatory elements in the radiation response. This approach has been particularly useful in the characterisation of the radiation-induced DNA damage response. Our increased ability to transfer these models into small animals and deliver highly conformal image guided irradiation further enable the robust evaluation of candidate markers. This lecture will discuss the potential and limitations of gene editing approaches in the identification of novel biomarkers of radioresistance.

---

Teaching Lecture: Target delineation and target definition for Partial Breast Irradiation after closed cavity surgery and oncoplastic surgery

---

### SP-0008 Target delineation and target definition for Partial Breast Irradiation after closed cavity surgery and oncoplastic surgery

V. Strnad<sup>1</sup>

<sup>1</sup>University Clinic Erlangen, Dept. Radiation Oncology, Erlangen, Germany

**Objective:** To define in CT images tissue structures inside the breast after a breast conserving surgery, which make possible reproducible delineate Clinical Target Volume (CTV) and Planning Target Volume (PTV). The results of deliberations of Breast Working Group of GEC-ESTRO and corresponding recommendations for target definition for APBI will be presented.

**Recommendations:** The Working Group Breast of GEC-ESTRO recommend to have for the correct delineation of CTV (PTV) appropriate knowledge's and to perform steps As follow:

1. To hold **DETAILED KNOWLEDGE'S** about anatomy of the breast of patient and of the tumor, about primary surgical procedure particularly type of surgery, use - number and location of surgical clips, position of the skin scar ), of pathological report (particularly size of resection margins in at least 6 directions, of preoperative mammography, MRI and ultrasound.
2. Identification of the **TUMOR LOCALIZATION** before breast conserving surgery inside the breast and translate this information in current CT imaging data set.
3. Calculation of the size of **SAFETY MARGINS** needed to cover CTV in all 6 directions. The appropriate size of safety margins (surgical resection margins and adapted safety margins) should be at least 2 cm.
4. **DEFINITION OF TARGET**
5. **DELINEATION OF THE TARGET** according defined rules. We recommend following seven steps for target delineation after closed cavity surgery:
  - a. Perform a CT.
  - b. Delineation of clips.
  - c. Delineation of surgical bed - whole surgical scar (WS) inside breast.
  - d. Delineation of ImTV (Imaging correlated Target Volume).
  - e. Delineation of ETB (Estimated Tumour Bed).
  - f. Delineation of CTV (Clinical Target Volume).
  - g. Delineation of PTV (Planning Target Volume).

For target definition after oncoplastic surgery dissident from recommendation for target definition after "closed cavity surgery" the Clinical target volume (CTV) is defined as the sum of the relevant clipped area (RCA). **Conclusion:** Presented guidelines makes possible a reproducible and robust definition of CTV (PTV) for Accelerated Partial Breast Irradiation (APBI) or boost irradiation after breast conserving closed cavity or oncoplastic surgery.

### SP-0009 Target delineation and target definition for PBI after open cavity surgery

T. Major<sup>1</sup>, C. Polgár<sup>1</sup>

<sup>1</sup>National Institute of Oncology, Radiotherapy Centre, Budapest, Hungary

**Objective:** To present guidelines for target definition and delineations after open cavity breast conserving surgery in accelerated partial breast irradiations or boost treatments using multicatheter interstitial brachytherapy based on the consensus of the GEC-ESTRO Breast Cancer Working Group.

**Method:** As a first step a contouring study with two phases was conducted by the Working Group. Contours of cavity and PTV on pre- and postimplant CT images were delineated. In Phase 1 nine radiation oncologists defined the target volumes of five patients without any instructions, while in Phase 2 four observers draw the contours of four patients applying simple contouring rules. The delineations were compared between the two phases,

the impact of guidelines was assessed and cavity visualization score was related to consistency of delineations. Following the study on interobserver variations of target volume delineation and a number of discussions in consensus meetings guidelines were worked out by experts on the field.

**Recommendations:** (1) Consistent windowing has to be used for proper cavity visualization. (2) The cavity visualization score has to be at least 3 in order to minimize the interobserver variations of target definition. (3) At delineation of surgical cavity only the homogeneous part of the postoperative seroma has to be included in the contours and protrusions or sharp irregularities have to be excluded. When surgical clips are present, they have to be surrounded by the contour with close contact. (4) CTV is created from the outlined surgical cavity with a non-isotropic geometrical extension. In each direction the safety margin is calculated by taking into account the size of free resection margin. The total size of safety margin is always 20 mm which is the sum of the surgical and added safety margins. CTV is limited to chest wall/pectoral muscles and 5 mm below the skin surface. **Conclusion:** It has been demonstrated that simple rules on defining the lumpectomy cavity significantly increased the consistency of contouring. Reliable consistency of target volume definition can be expected only for good cavity visibility. Following the GEC-ESTRO guidelines it is expected that the target volume definition in breast brachytherapy after open cavity surgery will be accomplished with more consistent way among radiation oncologists with low interobserver variations.

### Joint Symposium: ESTRO-ASTRO: Cutting edge combined modality therapies (Focus on NSCLC)

#### SP-0010 The gains to be made by combined modality treatment in NSCLC: setting the scene of new possibilities

M. Stuschke<sup>1</sup>, C. Poettgen<sup>1</sup>

<sup>1</sup>Universitätsklinikum Essen, Radiotherapy, Essen, Germany

Concurrent radiochemotherapy or combined modality treatments including surgery are standard options for stage IIIA NSCLC and stage IIIB patients treated with curative intent. Cumulative incidences of loco-regional recurrences approach 30% at 5 years following standard concurrent 60 Gy radiochemotherapy with conventional fractionation, while tri-modality schedules showed loco-regional recurrences of about 15%. Dose escalation using conventional fractionation and concurrent platin-based chemotherapy within the RTOG 0617 trial has failed to show a benefit in survival or local control. Passive scattering Proton therapy did not show a reduction in the rate of radiation pneumonitis in comparison to intensity modulated photon radiotherapy at the same total dose according to the NCT 00915005 trial. So where are the promising ways to improve survival of patients with locally advanced lung cancer by technological advances in radiotherapy?

More sensitive methods are needed to detect tumor spread and beyond FDG-PET/CT. Systematic endobronchial ultrasound-guided transbronchial needle aspiration can improve sensitivity to detect lymph node metastases. Prognostic factors for tumor control and toxicity after concurrent radiochemotherapy are being established to individualize dose escalation. PET-response, tumor volume, and dose volume histogram parameters are examples. More selective radiotherapy techniques are being tested in large trials including gating or tracking techniques together with IMRT or intensity modulated proton therapy. Including surgery may improve the therapeutic ratio in selected patients, if lobectomy is

adequate. Large treatment volumes were successfully treated by dose escalated hyperfractionated and accelerated radiotherapy schedules in patients with locally advanced lung cancer together with concurrent chemotherapy. Limited volume hypofractionation at the primary tumor site and limited hilum or mediastinum is another way to overcome repopulation. Adenocarcinomas with druggable driver mutations have a considerably better prognosis than tumors without. Targeted therapies are attractive partners for radiotherapy to inhibit repopulation and perhaps repair. New concepts emerge for using genetic vulnerabilities of tumor cells other than driver mutations for drug-induced synthetic lethality resulting in a highly selective treatment of tumor cells in combination with radiotherapy. For relapsing patients or patients with synchronous oligometastatic disease, stereotactic ablative radiotherapy RT to various sites can offer long term control complementing better systemic therapy options. Immunotherapy is now an established second line treatment in metastatic NSCLC and an interesting combination partner for radiotherapy whereas the latter can increase expression of tumor-associated antigens.

These advantages will be bundled into new radiotherapeutic concepts that have to be tested against standard conventionally fractionated radiotherapy and concurrent chemotherapy in future well designed randomized trials.

#### **SP-0011 The use of biomarkers for individualized treatment in NSCLC**

*J. Belderbos<sup>1</sup>*

<sup>1</sup>*Netherlands Cancer Institute Antoni van Leeuwenhoek Hospital, Amsterdam, The Netherlands*

A biomarker is a biological substance, that can be detected by a laboratory or imaging technique allowing an assessment of the disease presence and/or progression. Blood samples to analyze biomarkers have the advantage that they are fast, minimal invasive and easy to obtain. Blood-biomarkers may be related to hypoxia (osteopontin (OPN), carbonic anhydrase IX (CA-IX)), inflammation (Transforming growth factor beta1 (TGF-β1), interleukin-6 (IL-6), IL-8, and C-reactive protein (CRP)), tumour load (carcinoembryonic antigen (CEA), and cytokeratin fragment 21-1 (Cyfra 21-1)) or growth factors (vascular endothelial growth factor(VEGF)). Besides clinical factors like patient characteristics (age, gender, WHO-PS, weight loss) and tumor characteristics (tumor volume, stage, lymph nodes) several biomarkers have been shown to be associated with disease progression and survival of NSCLC patients treated with radio(chemo)therapy. In addition to dosimetric parameters biomarkers may also be helpful to predict toxicity or radio-resistance.

Blood-biomarkers to predict the risk of normal tissue damage by radio(chemo)therapy pre-, during and post-radio(chemo)therapy:

Inflammatory cytokines are made by many cells within the lung, including the alveolar macrophages, Type II pneumocytes, T lymphocytes and lung fibroblasts. Transforming growth factor beta1 (TGF-β1) is a cytokine that has been extensively studied as a marker predictive of radiation pneumonitis (RP). Patients with NSCLC have increased pre-treatment levels of TGFβ1 and that increased levels were associated with a higher mean lung dose (MLD) and a higher incidence of RP. But especially the observation of an increasing ratio of pre- to intra-treatment TGFβ1 for Stage III NSCLC treated with definitive radio(chemo)therapy was predictive of RP. More recently single nucleotide polymorphism rs1982073:T869C of the TGF-β1 gene was reported to be associated with the risk of RP in NSCLC patients treated with definitive radio(chemo)therapy. Therefore genotype rs1982073:T869C of the TGF-β1 gene may serve as a reliable predictor of RP (Yuan JCO 2009). Certain

polymorphisms of the VEGF gene have also been correlated with the incidence and severity of RP. Circulating interleukin-6 (IL-6) and interleukin-8 (IL-8) levels pre-, during and post-RT have been correlated with an increased risk of RP as well. Blood-biomarkers associated with disease progression and survival of NSCLC patients treated with radio(chemo)therapy:

A prediction model for 2-year survival was developed for NSCLC patients treated with curative intent with radio(chemo)therapy using different blood-biomarkers related to hypoxia, inflammation, immune response and tumour load by the MAASTRO group (Dehing-Oberije IJROBP 2011). They concluded that biomarkers CEA and interleukin-6 (IL-6) have an added prognostic value for survival of NSCLC patients. More recently the same group demonstrated and validated in two large cohorts of NSCLC patients the added value of blood-biomarkers related to hypoxia (OPN) and tumour load (Cyfra 21-1) (Carvalho Radiother Oncol, 2016) on survival.

Blood-biomarkers associated with radio-resistance: Deletion of KEAP1 has been linked with tumor aggressiveness, metastasis and resistance to oxidative stress and radiotherapy in lung squamous cell carcinomas. Using the pre-RT plasma samples KEAP1/NRF2 mutations increased radio-resistance in a small group of patients with NSCLC and predicted local tumor recurrence in radiotherapy patients (Jeong Cancer Discovery 2017). These recent findings are of potential clinical relevance and could lead to personalized treatment strategies for tumors with KEAP1/NRF2 mutations.

Conclusion: Combining blood-biomarkers and established prediction parameters into a single model is expected to improve the ability to predict normal tissue damage and treatment response as compared to either variable alone and could lead to personalized treatment strategies.

#### **SP-0012 Abscopal responses in metastatic non-small cell lung cancer (NSCLC): a phase II study of combined radiotherapy and ipilimumab**

*S. Formenti<sup>1</sup>* E. Golden, A. Chachoua, K. Pilonis, S.

Demaria

<sup>1</sup>*Weill Cornell Medical Center of Cornell University, New York- NY, USA*

CTLA-4 immune checkpoint blockade in metastatic and locally advanced NSCLC patients has demonstrated disappointing results (J Clin Oncol 2009, 27: suppl; abstr 8071). Conversely, our group has generated extensive pre-clinical evidence that the combination of CTLA-4 blockade and local radiotherapy induces responses outside the radiation field (abscopal effect) in syngeneic models of metastatic cancer (Clin Cancer Research 2005, 11: 728-734). We also reported a dramatic abscopal response in a patient with refractory metastatic NSCLC treated with combined radiotherapy (RT) and ipilimumab, a monoclonal antibody against CTLA-4, (Cancer Immunol Res 2013, 1: 365-372), who remains alive and disease free five years later, without any other additional treatment. We have conducted a phase I-II trial to investigate effectiveness and safety of ipilimumab and localized RT to a metastasis in patients with metastatic NSCLC, to elicit an individualized vaccine, that is effective systemically, as reflected by objective abscopal responses (Formenti and Demaria, JNCI 2013). Patients with chemo-refractory metastatic NSCLC, PS 0-2, and  $\geq 2$  measurable lesions ( $\geq 1$ cm) were eligible. Patients received ipilimumab (3mg/kg i.v.) within 24 hrs of starting RT (6Gy x5 or 9.5GyX3 daily fractions) to one lesion. Ipi was repeated every 21 days x3. Optional biopsies and serial blood draws were obtained for immune monitoring. Patients were evaluated for abscopal responses with baseline and post-treatment (day 88) PET/CTs. Metastases outside the RT field were measured on axial CTs in 2 perpendicular dimensions. The products of the measurements (l x w) in

all abscopal lesions were summed. Baseline and post-treatment measurements of abscopal lesions were compared. Abscopal responses were reported as: CR - complete resolution, PR - decrease in size  $\geq 30\%$ , PD - increase in size  $\geq 20\%$ , or SD - insufficient shrinkage or growth to qualify for PR/CR or PD. Toxicities were reported according to the common terminology criteria for adverse events version 4.0. Thirty-nine patients accrued. Based on intent to treat abscopal response rate was 18%. Seven of the 21 patients who completed the 4 cycles of ipilimumab had an abscopal response (33%). At median follow up of 16 months the achievement of an initial abscopal response to the regimen remains associated with better survival (HR=9.174, log-rank test  $p=0.061$ ) (Figure). Expression of PD-L1  $>10\%$  in pre-treatment tumor biopsies was observed among patients who achieved complete and partial abscopal responses, suggesting that T cells activated by RT and CTLA-4 blockade can reject PDL-1 positive tumors. Finally, marked changes in peripheral blood T cell clonality 3 weeks after combined treatment was demonstrated in the patients who developed abscopal responses but not in non responders. In a patient with complete response and sufficient tumor material for TCR Vbeta deep sequencing a T cell clone found in the tumor at low levels before treatment appeared in the blood at 3 weeks and persisted after completion of treatment. In conclusion, objective abscopal responses were common in NSCLC patients treated with local RT and ipilimumab, independently from initial PD-L1 expression. Immunologic characterization of tumor infiltrating lymphocytes and tumor antigen-specific T- and B-cell responses in treated patients is ongoing [clinicaltrials.gov NCT02221739].

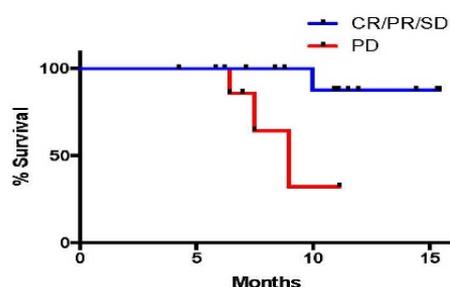

Figure.  
Percentage of surviving patients based on abscopal response after ipilimumab and radiotherapy, in a trial of 39 chemo-refractory metastatic NSCLC patients

#### SP-0013 The use of novel technologies (e.g. protons) in NSCLC

Z. Liao<sup>1</sup>

<sup>1</sup>UT MD Anderson Cancer Center Radiation Physics, Houston- TX, USA

Technological innovations during the last 2 decades has revolutionized photon radiotherapy and resulted in improved clinical outcomes of lung cancer patients in terms of reduced radiation toxicity and increased tumor control and survival. These innovations include intensity modulated radiation, volumetric modulated arc therapy, image guided radiation therapy. Proton therapy can offer substantial clinical advantage over the photon therapy because protons have unique depth-dose characteristics that can potentially significantly reduce normal tissue doses proximal and distal to the target volume and allow escalation of tumor doses. Lung cancer is one of the many cancer types that could benefit from proton therapy. Treatment planning and plan evaluation of PSPT and IMPT

demonstrated significant reduction of mean lung dose and mean heart dose. Results from retrospective studies from our institution and others were promising. However, the results of the first adaptive randomization trial comparing passively scattered proton therapy (PSPT) with intensity-modulated (photon) radiotherapy (IMRT), both with concurrent chemotherapy, for patients with inoperable lung cancer showed no statistically significant differences in the primary endpoint (radiation pneumonitis or local failure) were found between IMRT vs. PSPT. Higher-than-expected RP in the PSPT arm may have reflected larger high-dose volumes and a steeper learning curve for practitioners treating with protons. The results also suggest that the dose constraints used to guide IMRT may not be applicable for protons. The most current evidence and challenges in using protons for lung cancer will be reviewed in this symposium.

#### Symposium with Proffered Papers: Radiotherapy plus immunotherapy combination: rationale and results so far

##### SP-0014 In situ Cancer Vaccines: Tumor destruction and immune stimulation for local and systemic tumor control.

G. Adema<sup>1,2</sup>, M. Den Brok<sup>1,2</sup>, R. Van den Bijgaart<sup>1,2</sup>, M. Wassink<sup>1,2</sup>, M. Hoogenboom<sup>2</sup>, J. Bussink<sup>1,2</sup>, J. Futterer<sup>2</sup>  
<sup>1</sup>Radiotherapy & Oncology lab, Dept. of Radiation Oncology, Nijmegen, The Netherlands  
<sup>2</sup>RadboudUMC, Nijmegen, The Netherlands

In situ Cancer Vaccines: Tumor destruction and immune stimulation for local and systemic tumor control. Tumor ablation techniques are successfully applied for the treatment of cancer. These techniques use e.g. radiation, heat or cold to locally destruct often inoperable tumor masses. After ablation tumor antigens become instantly available for antigen presenting cells, and the procedure itself creates an inflammatory environment that will effect the immune system and hence anti-tumor immunity. Despite the reported enhanced presence of key immunological correlates, strong immune responses (abscopal effect) have only rarely been observed after tumor ablation as monotherapy. As a result, patients often succumb to tumor micro-metastases being already present prior to treatment. Therefore, there is a strong need for systemic adjuvant therapy, like immunotherapy, targeting these residual tumor cells. To obtain robust immunity we showed in murine models that ablation should be combined with immune modulation using adjuvants or immune checkpoint blockade mAbs. Moreover, we showed the involvement of mature lymph node dendritic cells, actively scavenging and cross-presenting antigens from the tumor. This yielded long-lasting memory immune responses and protection against a tumor rechallenge and even pre-existing metastasis. It is currently not fully understood how immune responses following radiotherapy can be optimally initiated and regulated. More importantly, the most effective immune stimulating compounds for Immuno-radiotherapy are not known. We will discuss our ongoing research program to uncover the potency of RT in combination with immune based strategies to eliminate tumor cells and their microenvironment for both local and systemic tumor control.

##### SP-0015 The impact of tumour infiltrating lymphocytes on clinical outcome after (chemo)radiotherapy

J. Galon

<sup>1</sup>Cordeliers Research Center (CRC), Paris, France

Abstract not received

### SP-0016 Radiotherapy and immunotherapy combination: paradigm changing or just hype?

S.J. Dovedi<sup>1</sup>

<sup>1</sup>The University of Manchester, Targeted Therapy Group, Manchester, United Kingdom

Radiotherapy (RT) is a highly effective anti-cancer treatment forming part of the standard of care for the majority of patients. In addition to the direct cytoreductive effect of RT there is increasing evidence that this treatment may also be immunogenic; however, the contribution and mechanisms of RT induced immune responses are unknown. Moreover, as a monotherapy, RT is rarely able to generate to abscopal responses outside of the treatment field, suggesting that any immune response generated may be suboptimal.

Longitudinal profiling of the tumour microenvironment following RT in syngeneic mouse models, which have a fully competent immune system, reveals the impact of local RT on both the innate and adaptive components of the immune system. Using next-generation sequencing of the T-cell receptor repertoire (TCR) we show that treatment with daily low-dose fractionated RT leads to a T-cell response that is dominated by polyclonal expansion of pre-existing T-cell clones. Moreover, we show that both local and distal tumour control following RT can be improved by combination with immunotherapies that target both immunosuppressive checkpoints (such as the PD-1/PD-L1 axis) and immune-stimulatory pathways to ultimately enhance anti-tumour activity by CD8<sup>+</sup> T-cells. Importantly, preclinical data suggests that RT dose, fractionation and scheduling with immunotherapy may impact tumour control.

In this presentation we will review the data from preclinical models and emerging clinical studies to explore the immunological effects of RT and how these insights may be used to guide clinical translation.

### OC-0017 Combined High Dose Radiation and Ipilimumab in Metastatic Melanoma, a Phase I Dose Escalation Trial.

K. De Wolf<sup>1</sup>, V. Kruse<sup>2</sup>, L. Brochez<sup>3</sup>, N. Sundahl<sup>1</sup>, M. Van Gele<sup>3</sup>, R. Speeckaert<sup>3</sup>, P. Ost<sup>1</sup>

<sup>1</sup>University Hospital Ghent, radiotherapy and oncology, Gent, Belgium

<sup>2</sup>University Hospital Ghent, medical oncology, Gent, Belgium

<sup>3</sup>University Hospital Ghent, dermatology, Gent, Belgium

Ipilimumab, a CTLA-4 blocking monoclonal antibody, induces durable, potentially curative, tumour regressions in some patients with metastatic melanoma, but unfortunately the majority of patients do not have long-term benefit from ipilimumab monotherapy. Preclinical data and early clinical data suggest synergistic antitumor activity between ipilimumab and high-dose radiotherapy (e.g. doses higher than 8 Gy per fraction). Therefore, the combination of ipilimumab with high-dose radiotherapy holds substantial promise for improving clinical benefit. We conducted a phase I trial to determine the safety and tumour responses of this combination.

**Material and Methods** Patients with metastatic melanoma, with at least three distinct measurable sites of disease, received four infusions of ipilimumab every three weeks at 3 mg/kg in combination with dose-escalated stereotactic body radiotherapy to one lesion after the second infusion of ipilimumab (level 1: 24 Gy in 8 Gy per fraction, level 2: 30 Gy in 10 Gy per fraction and level 3: 36 Gy in 12 Gy per fraction). For the patient randomization, a time-to-event continual reassessment method was used. The primary endpoint was to determine the maximum tolerated radiotherapy doses. Secondary endpoints were local control and tumour response as per RECIST 1.1. Clinical benefit was defined as complete response, partial response or stable disease.

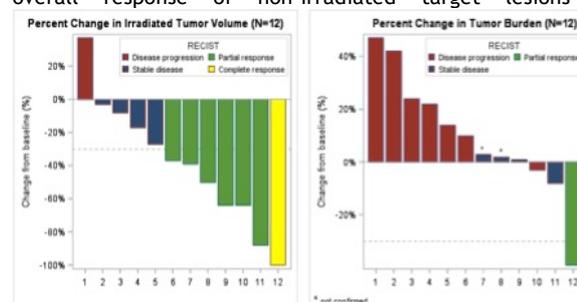

**Results** From March 18, 2015, to April 7, 2016, 13 patients with metastatic melanoma were enrolled. Median age was 68 years (range 23 - 80), with 58% male and 42% female patients. One patient experienced disease progression before receiving radiotherapy and was not eligible for evaluation. No dose-limiting toxicities were noted at dose levels 1, 2 or 3. Grade 3 or 4 ipilimumab-related adverse events (AEs) occurred in 25% of patients. Treatment-related AEs are shown in Table 1.

Table 1: Treatment-related adverse events

	24 Gy n = 5	30 Gy n = 1	36 Gy n = 6	ALL n = 12
<b>Laboratory abnormalities, any grade</b>				
Lymphopenia	0	0	3	3
Platelet count decreased	0	0	1	1
Hemoglobin decreased	0	0	1	1
Hyperkalemia	3	0	0	3
Alkaline phosphatase increased	1	0	1	2
Alanine aminotransferase increased	0	0	2	2
Aspartate aminotransferase increased	1	0	2	3
TSH decreased	3	0	1	4
<b>AEs, any grade</b>				
diarrhea	5	0	3	8
colitis	0	0	2	2
pruritus	1	0	1	2
dry skin	2	0	0	2
rash	0	0	0	0
insomnia	0	1	1	2
fatigue	2	1	1	4
decreased appetite	2	0	0	2
dysgeusia	2	0	1	3
dry mouth	2	0	1	3
nausea	3	0	1	4
weight loss	3	0	2	5
dyspnoea	1	0	1	2
cough	1	0	1	2
<b>AEs, grade 3-4</b>				
diarrhea	1	0	0	1
colitis	0	0	2	2
<b>AEs leading to ipilimumab discontinuation</b>				
diarrhea	1	0	0	1
colitis	0	0	2	2

Local control of the irradiated lesions was achieved in 11 of 12 patients. There was a complete local response in 1 irradiated lesion (8%), a partial response in 6 irradiated lesions (46%), stable disease in 4 irradiated lesions (31%), and progressive disease in 1 irradiated lesion (8%). Evaluation of the non-irradiated lesions demonstrated that 3 patients (24%) experienced clinical benefit (one patient (8%) developed a confirmed partial response and 2 patients (16%) had confirmed stable disease).

Figure 1: Best local response of irradiated lesions and overall response of non-irradiated target lesions

### Conclusion

Ipilimumab 3 mg/kg with concurrent high-dose radiotherapy can be delivered safely in patients with metastatic melanoma with excellent local control and indications of systemic antitumor responses in a subset of patients.

### OC-0018 Chemoradiation-induced altered profile of PD-L1 and CD8<sup>+</sup> TILs indicated prognosis in rectal cancer

Y.J. Lim<sup>1</sup>, J. Koh<sup>2</sup>, S. Kim<sup>2</sup>, S.R. Jeon<sup>3</sup>, E.K. Chie<sup>1</sup>, K. Kim<sup>4</sup>, G.H. Kang<sup>2</sup>, S.W. Han<sup>5</sup>, T.Y. Kim<sup>5</sup>, S.Y. Jeong<sup>6</sup>, K.J. Park<sup>6</sup>, H.G. Wu<sup>1</sup>

**Purpose or Objective** Cytotoxic chemoradiotherapy (CRT)-induced impact on the programmed death-1 (PD-1)/programmed death-ligand 1 (PD-L1) checkpoint activity in human cancers has not been much explored. This study evaluated CRT-induced changes in the expression levels of PD-L1 and CD8<sup>+</sup> tumor-infiltrating lymphocytes (TILs) and prognostic associations in rectal cancer.

**Material and Methods** We analyzed pre-CRT biopsies and the corresponding post-CRT resected tissues of 123 rectal cancer patients undergoing preoperative CRT followed by surgery between 2005 and 2012. Immunohistochemical staining of PD-L1 and CD8 was performed for the paired specimens.

**Results** The median values of PD-L1 H-score and density of CD8<sup>+</sup> TILs for pre and post-CRT tissues were 0 and 100, and 319.66 and 787.05 cells/mm<sup>2</sup>, respectively. CRT induced increases in the expression levels of PD-L1 and CD8<sup>+</sup> TILs ( $P < 0.001$  for both), and patients with sustained high level of PD-L1 both at pre and post-CRT showed less increase in the density of CD8<sup>+</sup> TILs than the others ( $P = 0.020$ ). Defining the low or high level of the PD-L1 and CD8<sup>+</sup> TILs before and after CRT, patients with high-to-high level of PD-L1 had poorer overall survival (OS) and disease-free interval (DFI) ( $P = 0.018$  and  $0.029$ , respectively), whereas the low-to-low density of CD8<sup>+</sup> TILs was associated with inferior DFI ( $P = 0.010$ ). Considering the existence or non-existence of the high-to-high PD-L1 level or low-to-low density of CD8<sup>+</sup> TILs, patients with one or more of the factors showed significantly worse OS and DFI ( $P = 0.020$  and  $0.002$ , respectively).

**Conclusion** This study verified that preoperative CRT resulted in the immunologic shift toward increases in the PD-L1 expression and density of CD8<sup>+</sup> TILs in rectal cancer. The poor prognostic subset was identified based on the CRT-induced change profiles, suggesting the potential candidates who can benefit from combining checkpoint inhibitors and CRT.

### Joint symposium ESTRO-AAPM: New technological and computational developments in particle therapy

#### SP-0019 Scaling down proton therapy facilities to fit into photon vaults

T. Bortfeld<sup>1</sup>, S. Yan<sup>1</sup>, B. Clasié<sup>1</sup>

<sup>1</sup>Mass. General Hospital, Radiation Oncology, Boston-MA, USA

Proton therapy technology is rapidly evolving. Newer designs exhibit substantial reduction in size, weight and cost compared to the first generation. In the first part of this talk, we will review state of the art compact proton therapy systems. We will focus particularly on single room solutions and highlight the physics and technology behind solutions that enable the size reduction of accelerator and gantry designs.

In spite of the already achieved and remarkable progress towards more compact and affordable proton therapy systems, all current systems require construction of dedicated buildings to house them which are significantly larger (and more costly) than conventional treatment rooms for photon therapy.

In the second part of this talk, we will explore the potential to build even more compact proton systems. We will first review a project that is underway at the Massachusetts General Hospital where we retrofit a proton therapy system into two neighboring photon vaults within an existing building. The system is almost installed and awaiting testing and commissioning. The progress and challenges with this approach will be discussed. Finally, we will give an outlook with possible designs that enable a proton therapy system to be installed in a single conventional photon therapy vault. We will discuss the technical hurdles that need to be overcome to realize this vision. These ultra-compact solutions will likely not include a gantry but rather a fixed beamline with advanced robotics and imaging solutions for patient positioning.

#### SP-0020 Integrating CBCT in ion beam therapy: challenges and opportunities beyond anatomical guidance

K. Teo<sup>1</sup>

<sup>1</sup>Hospital of the University of Pennsylvania, Department of Radiation Oncology TRC 2 West, Philadelphia- PA, USA

Cone beam CT (CBCT) is an important imaging modality for image guided radiation therapy (IGRT). In ion beam therapy, volumetric imaging offered by CBCT has important potential applications beyond anatomical guidance. Ion beam therapy dose distribution is sensitive to daily setup variation, motion and anatomical change such as tumor response, atelectasis, pleural effusion, bowel gas and organ filling. While CBCT may be used to assess these variations in a qualitative manner, a more quantitative analysis requires accurate Hounsfield units (HUs) for conversion to ion stopping power. In this presentation, the methods to improve the accuracy of CBCT HUs are reviewed. These techniques will enable water equivalent thickness (WET) measurements and dose estimation to be performed using CBCT. We demonstrate both qualitative and quantitative analyses of CBCT for different treatment sites and discuss the development of tools that will streamline adaptive proton therapy. These include extraction of image and dosimetric features that are predictive of the need for replanning as well as online replanning tools.

#### SP-0021 New horizons in probabilistic and robust treatment planning in particle therapy

M. Alber<sup>1</sup>

<sup>1</sup>Alber Markus, Department of Radiation Oncology, Heidelberg, Germany

Treatment related uncertainties give rise to the risk of loss in all quality scores of a treatment plan. Risk mitigation strategies can be largely blind to the magnitude and frequency of losses, and still be effective, like the PTV concept in photon therapy. However, all risk mitigation in one quality score comes at a price in most others. In particular, risk mitigation of systematic errors (by treatment planning) can be costly, ineffective and even in the best case: unfair. For example, whenever a protocol requires that a larger volume than the CTV is irradiated because some patients need this, all other patients pay the price. Ultimately, the precise quantification of loss-risk-distributions becomes a necessity. The term "robust optimization" is commonly used to express that the source of the uncertainty is directly considered during dose optimization instead of solving a substitute problem that is construed to yield a robust result (such as the PTV

concept). The method that currently receives most interest is the worst-case scenario, which aims to ensure that the target volume receives a minimum dose under a reasonable number of displacements and range uncertainties. Although this approach is greatly superior to the PTV concept for particle beams, it shares the similarity that it makes no assumptions about the frequencies with which uncertainties occur. In other words, all scenarios are equally likely, which is contrary to intuition (and good practice!) and increases the price for target dose robustness in a population. Probabilistic planning adds the quantification of risks to robust optimization and therefore requires assumptions about the frequencies of uncertainties as input. A number of probabilistic planning concepts have been proposed for photon therapy, which all rely in some way or other on approximations and assumptions that will not hold for particle beams, primarily because the geometric changes disturb the dose distributions too much. In order to keep the problems manageable and the number of scenarios realistically high, new methods for dose evaluation in terms of loss-risk distributions need to be deployed. New formulations of the optimization problem can be devised that take advantage of these distributions. Numerical complexity is only a secondary issue on current computer hardware. A primary problem is the dependence on assumptions about the frequency of uncertainties, and the patient-individual component of these frequency distributions. Hence, it is to be expected that reality demands a restricted use of such approaches.

#### Symposium: CT imaging, new developments

---

##### SP-0022 Current status and potential of dual energy and spectral CT

J. Andersson<sup>1</sup>

<sup>1</sup>Norrlands Universitetssjukhus, Department of Radiation Sciences- Radiation Physics, Umea, Sweden

Conventionally, Computed Tomography (CT) images are reconstructed with data that has been collected using a single X-ray tube potential during a scan. CT images are presented in the Hounsfield scale, which is based on linear attenuation coefficients that have intrinsic energy dependence.

A method for Dual Energy Computed Tomography (DECT) imaging was first proposed in the 1970's, where two sets of data are collected with different radiation qualities. These two data sets are used to draw conclusions about the material that has been scanned by analysing the energy dependence of the linear attenuation coefficients. In recent years, the major CT manufacturers have adopted DECT and several technological solutions are available on the market, including CT scanners with two X-ray tubes, X-ray tubes with rapid tube voltage switching and detectors with two layers that provide an energy separation of the incoming photon spectrum. One of the major benefits of using DECT is that materials can be viewed in terms of composition and mass density. Further benefits of DECT include mitigation of specific artefacts in the CT images using virtual monochromatic reconstructions. Challenges for the application of DECT include temporal resolution of the data collection, image noise, scattered radiation in wide volume scanning and patient dose considerations. From an engineering viewpoint these challenges translate to X-ray tube and detector technology, as well as computer processing speed and optimization. In radiology DECT has become routine tool for certain imaging tasks where material characterization and quantification is important for diagnostics.

##### SP-0023 CT image quality: Using a model observer for clinically relevant optimisation

N. Ryckx<sup>1</sup>, D. Racine<sup>1</sup>, A. Ba<sup>1</sup>, A. Viry<sup>1</sup>, F. Bochud<sup>1</sup>, F.R. Verdun<sup>1</sup>

<sup>1</sup>CHUV - Institute of Radiation Physics IRA, Department of Radiology, Lausanne, Switzerland

#### Introduction

The number of computed tomography (CT) examinations has been increasing steadily in the last twenty years, and this trend does not seem to slow down. For example, the number of diagnostic CT examinations has increased by 17% between 2008 and 2013 in Switzerland. Furthermore, the purpose of a CT has been extended to further diagnostic and/or therapeutic procedures: Attenuation correction for molecular imaging in nuclear medicine, interventional CT fluoroscopy procedures and radiation therapy treatment planning. Recently, the introduction of iterative reconstruction algorithms allows for a potential dose reduction by artificially removing image noise. However, the risk of reducing radiation dose too low is to potentially remove vital diagnostic information while conserving the subjective visual aspect (especially in terms of image noise) of images acquired at higher dose but without iterative reconstruction. Finally, the usual image quality metrics (CNR, MTF, NPS) are less pertinent within the iterative reconstruction paradigm, because these reconstructions are highly non-linear and non-stationary.

#### Materials and methods

We seek to adapt image quality using clinically relevant metrics. For this purpose, we use model observers, that are in-silico image observers based on psychophysics and statistical decision theory. The four cornerstones of a model observer are the following:

- A clinically relevant task (lesion detection, lesion localisation, etc.)
- An observer (human or in-silico)
- An adequate set of images, with a representative statistical fluctuation
- A figure of merit (FOM) to quantify the observer performance

In our approach, we evaluate CT image quality using a CHO (channelized Hotelling observer) with dense difference of Gaussian (DDoG) channels for low-contrast spherical lesion detection in the abdominal region (e.g. focal liver lesions) or a NPWE (non-pre-whitening matched filter with eye filter) observer for high contrast lesion (e.g. renal stone) detection. The images used for quality assessment are CT axial slices performed on either an anatomical abdomen phantom (QRM, Moehrendorf, Germany) with low-contrast spherical targets of known size (5 and 8 mm diameter) and contrast (-10 or -20 HU) or a home-made high-contrast phantom, consisting of three cylinders (diam. 10 cm) of different materials - Teflon for bone, polyethylene for fat and PMMA for soft tissue - immersed in a cylindrical water tank. The FOM used for quality assessment is either the area under the ROC (receiver operating characteristic) curve (AUC) or a detectability index  $d'$ . These assessments were performed on 70 CT units in Switzerland.

#### Results and discussion

For abdominal low contrast targets, no significant differences in AUC were noted between images reconstructed by standard filtered back-projection (FBP) and iterative reconstruction, but the dose-slice thickness product (DSP, used as a normalised dose metric) varied from 2.6 to 61 mGy mm, with reconstructed slice thicknesses ranging from 2 to 5 mm. For the 5mm/20HU target, 49% of the CT units gathered around an AUC range of 0.86-0.98 for a DSP range of 5-20 mGy mm. Nevertheless, 10% of the CTs were outliers because of relatively high dose levels and limited AUC scores, for which a more thorough investigation is probably needed. For the high contrast detection task, the FOM used for this task ( $d'$  of a NPWE model) yields results that are way too

sensitive to the NPS, and work on improving the FOM is currently being performed.

#### Conclusion

The use of a model observer for objective and clinical task-based metrics might tackle the current problems encountered with iterative CT image reconstruction, for which the classical physical metrics are less pertinent. However, tuning model observer performance in order to estimate human observer performance remains cumbersome, in particular because it relies on the introduction of internal noise mimicking human uncertainty in decision taking. One improvement would be the use of Gabor channels (rather than DDoG), which are even more anthropomorphic. The CHO model showed that the majority of units assessed using this method performed reasonably well when searching focal liver lesions. However, the limited spread in objective image quality was associated with a large spread in the chosen dose indicator. On the other hand, high contrast detection still suffers from conceptual flaws that will have to be improved. Ultimately, the goal is to set up an open web server where users could upload their images, the CHO or NPWE calculation being performed online, for immediate objective image quality assessment and thus continuous immediate dose optimisation.

#### SP-0024 The potential of new CT technologies for radiotherapy with photons and protons

W. Van Elmpt<sup>1</sup>

<sup>1</sup>MAASTRO Clinic, Department of Radiation Oncology, Maastricht, The Netherlands

Computed tomography (CT) imaging is the core of the radiotherapy process: diagnosis, delineation, treatment planning and follow-up imaging. New CT techniques are introduced at many radiology departments such as Dual Energy CT (DECT) scanners, iterative CT reconstructions and automated selection of tube potential and imaging dose. These techniques are also finding their way towards radiotherapy departments. In this presentation a focus will be on the developments in CT imaging that have an application for radiotherapy purposes. To improve delineation accuracy, mono-energetic reconstructions from DECT imaging are being investigated, metal artifact reduction techniques are employed to reduce scatter from metal implants and iterative reconstruction improve image quality that could allow better contouring. For dose calculation in treatment planning, various options are becoming available that reconstruct electron or mass density images directly from the CT scanner or reduce the uncertainty in stopping power ratios (SPR) for proton therapy dose calculations by using DECT imaging.

#### Symposium: High tech or low tech for metastatic disease, how does one decide and what is the cost-benefit?

#### SP-0025 High tech approaches for curative treatment, when is enough enough?

J. Kazmierska<sup>1</sup>

<sup>1</sup>Greater Poland Cancer Centre, Radiotherapy Dept, Poznan, Poland

The idea to cure metastatic disease using local ablative treatment is compelling, especially in an era of fast technological progress in imaging and radiotherapy allowing for delivering high radiation doses with high precision. However, there are still important open questions regarding the rationale for such treatment, integration with systemic treatment and toxicity. Results of ablative treatment of metastatic disease are encouraging but variable so far, due to heterogeneity of patients' group, lack of clear differentiation between

oligometastatic and disseminated disease and different endpoints of studies: from overall survival to stabilization of the disease. Nevertheless, SBRT is now accepted, valuable solution for these patients, despite its limitation. Yet still there is a need to define, factors that will help clinicians to keep the balance between the benefit for patients and overtreatment. Finding biomarkers, patient, disease and technology related parameters would be of value for decision-making process and selection those who benefit most from ablative treatment.

#### SP-0026 Optimizing the workflow of palliative treatment using Lean Six Sigma methodology

M. Kamphuis<sup>1</sup>

<sup>1</sup>Academic Medical Center, Department of Radiation Therapy, Amsterdam, The Netherlands

#### Introduction

Palliative radiotherapy for painful bony metastases is mostly performed with a simple one or two field treatment technique. Nowadays this procedure is performed based on CT-images and is often time consuming. At the AMC in Amsterdam the procedure is during working hours organized in a so called "one stop shop" (OSS). This means that patients are seen by the radiation oncologist, simulated and being treated in one day. The processing time (PT) of the whole procedure is 4:30 hours on average, but in about 15 % of the cases more than 6 hours is necessary. The PT was considered undesirable, especially since patients are often in a poor condition. The aim of this study was to decrease the average length of the procedure by at least two hours.

#### Methods

Lean Six Sigma methodology was used to improve the OSS protocol. First, a baseline time measurement was performed in 30 patients to quantify the performance of the different steps of the procedure. At the same time factors influencing the length of the procedure were registered (e.g. the treatment techniques used, the number of RTTs involved and the number of sites being treated). Patients were asked to fill in a form measuring the perceived quality of the OSS.

A multidisciplinary working group created an extensive list of influencing factors. Different techniques like Failure Mode and Effect Analysis were used. Most important influencing factors were identified e.g. using statistical analyses on the baseline time measurement. Based on these insights, the process was of the One Stop Shop was redesigned. The redesigned process was tested in a pilot study.

#### Results

In the baseline measurement, the PT ranged from 2:16h to 7:00h. In the analysis of influencing factors, the vital few could be identified: number of RTTs involved in the whole procedure, the use of a treatment planning instead of a manual calculation, as well as the fact that patients were scheduled of a fixed time slot on the treatment machine. Different important factors, not foreseen at forehand, could be identified using the methodology.

The redesigned process consisted of a small team existing of two RTTs and one or two MDs performing the OSS. Team composition was determined the day before the OSS procedure, taking educational level and experience into account. This team was responsible for the whole process. The fixed time slot on the treatment was abolished, patients were being treated as soon as the preparations were finished and space was available on the treatment machine. Results of the pilot study will be presented during the conference.

**Conclusion** Lean Six Sigma methodology provided the tools to quantify, analyze and re-optimize the One Stop Shop procedure. Furthermore, the methodology provided possibilities for improvement that were not foreseen at forehand.

**SP-0027 Evaluation of time, attendance of medical staff, and resources during stereotactic radiotherapy/radiosurgery: QUIRO-DEGRO trial**

A. Zabel-du Bois<sup>1</sup>, S. Milker-Zabel<sup>1</sup>, W. Popp<sup>2</sup>, J. Debus<sup>1</sup>, H. Sack<sup>3</sup>, R. Engenhardt-Cabillic<sup>4</sup>

<sup>1</sup>University Hospital Heidelberg, Radiooncology and Radiotherapy, Heidelberg, Germany

<sup>2</sup>Prime Networks AG, Prime Networks AG, Basel, Switzerland

<sup>3</sup>University of Essen, Department of Radiation Oncology, Essen, Germany

<sup>4</sup>Philipps-University Marburg, Department of Radiotherapy and Radiation Oncology, Marburg, Germany

**Purpose:** The German Society of Radiation Oncology (DEGRO) initiated a multicenter trial to develop and evaluate adequate modules to assert core processes and subprocesses in radiotherapy. Aim of this prospective evaluation was to methodically assess the required resources (technical equipment and medical staff) for stereotactic radiotherapy/ radiosurgery.

**Methods and Materials:** At two radiotherapy centers of excellence (University Hospitals of Heidelberg and Marburg/ Giessen) the manpower and time required for the implementation of intra- and extracranial stereotactic radiotherapy was prospectively collected consistently over a 3 months period. The data were collected using specific developed process acquisition tools and standard forms and were evaluated using specific process analysis tools.

**Results:** For intracranial (extracranial) fractionated stereotactic radiotherapy (FSRT) and radiosurgery (RS), a total of 1925 (270) and 199 (36) records could be evaluated, respectively. The approx. time needed to customize the immobilization device was median 37 min (89 min) for FRST and 31 min (26 min) for RS, for the contrast enhanced planning studies 22 and 27 min (25 and 28 min), for physical treatment planning 122 and 59 min (187 and 27 min), for the first and routine radiotherapy sessions for FSRT 40 and 13 min (58 and 31 min), respectively. The median time needed for the RS session was 58 min (45 min). The corresponding minimal manpower needed was two technicians for customization of the immobilization device, 2½ technicians and one consultant for the contrast-enhanced planning studies, one consultant, ½ resident and ⅓ physicist for physical treatment planning, as well as one consultant, ½ resident and 2½ technicians for the first radiotherapy treatment and 2½ technicians for routine radiotherapy sessions.

**Conclusion:** For the first time, the resource requirements for a radiotherapy department for the maintenance, protection and optimization of operational readiness for the application of intra- and extracranial stereotactic radiotherapy was determined methodically.

**Symposium with Proffered Papers: Novel approaches in heart / lung matters**

**SP-0028 State of the art in heart effects**

M.C. Vozenin<sup>1</sup>

<sup>1</sup>Centre Hospitalier Universitaire Vaudois, Department of Radiation Oncology, Lausanne Vaud, Switzerland

The therapeutic management of cancer has improved during the past decade and is today characterized by a significant increase in survival rates. Although effective on cure rates, both locoregional and systemic treatments present some concerns related to the development of chronic toxicities. The social impact of both acute and chronic toxicities of treatments is fully recognized and a specific attention is today paid to the toxicities induced by anti-cancer treatments as they impact on patients'

quality of life. About fifty percent of cancer patients are treated with radiotherapy (RT) which is, after surgery, the most important technique involved in curing cancer. Based on major technical advances in physics, imaging and ballistics, a high precision RT dose delivery safely reduces the volume of irradiated normal tissue and significantly decrease complications. These technological improvements make it possible to avoid organs at risk, such as the heart. This means that today radiation-induced cardiac toxicity is decreasing but in the mean time the evolution of treatment's standards towards combined therapies suggests that heart toxicity will remain a major concern within the next years. More specifically, cardiac toxicity is known to occur in patients treated with combination of RT with anthracycline or taxanes and targeted therapies; but appropriate biological evaluation of acute and chronic toxicities induced by these bi- or tri-therapies are lacking. Our previous work, suggest differential activation of 2 members of the small GTPase pathway, *i.e.* Epac-1 and RhoB, in the pathogenesis of radiation-induced cardiac toxicity. These targets are currently investigated in mice treated with RT+Paclitaxel+Heceptine. In addition, several inflammatory mediators are release by dying cancer cells in the course of anti-cancer treatments and the contribution of such factors to cardiac toxicity is currently under investigation, models and first results will be presented.

**SP-0029 Pharmacological modulation of cardiac radiation injury**

M. Boerma<sup>1</sup>

<sup>1</sup>University of Arkansas for Medical Sciences, Other, Little Rock, USA

For several decades, clinical and epidemiological studies have identified early and late manifestations of cardiac radiation injury in cancer patients who received a relatively high dose of radiation to all or part of the heart. Radiation therapy has undergone many improvements in treatment planning and radiation delivery. Nonetheless, in a subset of patients with thoracic cancers the heart is still partly exposed, and with the rapid increase in the number of long-term cancer survivors late side effects of cancer therapy such as those in the heart are still of concern. Current treatment of radiation-induced heart disease is no different from heart disease due to other causes, and there is no available pharmacological modulation that prevents or mitigates cardiac injury from radiation exposure. However, several potential pharmacological interventions such as anti-oxidant strategies, angiotensin converting enzyme inhibitors and transforming growth factor receptor inhibitors have been tested in pre-clinical models of cardiac radiation injury. This presentation gives an overview of some of these recent pre-clinical studies.

**OC-0030 In vitro study of FLASH vs. conventional dose-rate irradiation: Cell viability and DNA damage repair**

A. Beddok<sup>1</sup>, C. Fouillade<sup>1</sup>, E. Quelennec<sup>1</sup>, V. Favaudon<sup>1</sup>

<sup>1</sup>Institut Curie, Inserm U 1021 - CNRS UMR 3347, Orsay, France

**Purpose or Objective**

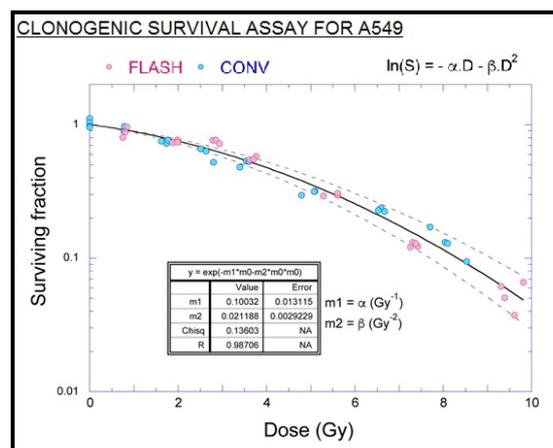

Favaudon et al. recently reported that high dose-rate (> 40Gy/s), 'FLASH' irradiation allows sparing C57BL/6J mice from radiation-induced pulmonary fibrosis. The mechanisms which underlie this difference are still elusive. The purpose of this study was to assess, on the one hand the cell viability and on the other hand the activation of two DNA damage response proteins (γH2AX and 53BP1) after FLASH vs. conventional dose-rate irradiation (CONV, 0.03 Gy/s).

## Material and Methods

We used two non-transformed human lung fibroblasts, MRC5 and IMR 90 and one human lung cancer cell line, A549. Cells were grown on coverslips and given 5 Gy with the same LINAC (4.5 MeV electrons) in the FLASH or CONV mode 24 h after seeding. EBT3 Gafchromic films were used to assess the dose received by each flask. Cell viability was evaluated 6 days post-irradiation (pi) by a MTT assay for the three cell lines and manual cell counting for the two fibroblastic cell lines. A clonogenic survival assay was also performed for A549 cells. For DNA damage response studies,  $\gamma$ H2AX and 53BP1 foci were detected by an immunofluorescence method. To quantify those foci, z-stack images across the nucleus were acquired on a SP5 Leica confocal microscope and foci analyzed using the 3D object counter software. The data came from 2 - 4 experiments performed under the same conditions and analysed with the same modalities. The statistical tests were Wilcoxon (cell viability) and Student (DNA damage response).

## Results

The MTT assay did not show any difference between CONV vs. FLASH modalities. For A549 cells, the median of the MTT signal was 86.6% after CONV vs. 78.8% after FLASH ( $p=0.7$ ); for MRC5, 61.3% (CONV) vs. 57% (FLASH,  $p=0.4$ ); and for IMR 90, 72.7% (CONV) vs. 72.5% (FLASH,  $p=1$ ). Cell counting did not find any difference too: for MRC5 cells, the median of the % of live cells was 20% (CONV) vs. 15.9% (FLASH,  $p=0.1$ ); for IMR 90, 15.8% (CONV) vs. 15.1% (FLASH,  $p=0.3$ ). The clonogenic survival assay did not show any difference for A549 after CONV vs. FLASH. For DNA damage study, the mean number of  $\gamma$ H2AX and 53BP1 foci was determined for the three cell lines, at 30 and 180 min pi. No statistically significant difference was observed between the two modalities of irradiation. For A549 cells, the mean number of  $\gamma$ H2AX foci, 30 min pi, was  $30 \pm 9$  after CONV vs.  $29 \pm 10$  after FLASH ( $p=0.6$ ); for MRC5,  $31 \pm 10$  for the two modalities of irradiation; and for IMR 90,  $37 \pm 11$  after CONV vs.  $39 \pm 15$  after FLASH ( $p=0.36$ ).

Mean number of  $\gamma$ H2AX and 53BP1 foci per nucleus for MRC5, IMR 90 and A549 cells

Number: mean number of foci per nucleus.

n: number of nuclei analyzed.

p: probability (Student t test).

NI: non-irradiated.

## Conclusion

This in vitro study did not elicit any significant difference, between CONV and FLASH, in both tumoral and non-tumoral cell lines with cell viability and foci of DNA damage repair proteins as endpoints. This suggests that the differences evidenced from in vivo studies result from the differences evidenced from in vivo studies result from the microenvironment and/or immune responses.

## OC-0031 Global changes in the glycosylation of irradiated endothelial cells with functional consequences

C. Jaillet<sup>1</sup>, W. Morelle<sup>2</sup>, M.C. Slomianny<sup>2</sup>, V. Paget<sup>1</sup>, G. Tarlet<sup>1</sup>, V. Buard<sup>1</sup>, S. Selbonne<sup>1</sup>, F. Caffin<sup>1</sup>, E. Rannou<sup>1</sup>, P. Martinez<sup>2</sup>, A. François<sup>1</sup>, F. Foulquier<sup>2</sup>, F. Allain<sup>2</sup>, F. Milliat<sup>1</sup>, O. Guipaud<sup>1</sup>

<sup>1</sup>Institute for Radiological Protection and Nuclear Safety, PRP-HOM, Fontenay aux Roses, France

<sup>2</sup>University of Lille, UGSF, Lille, France

## Purpose or Objective

Altered by ionizing radiation, the vascular network is considered as a prime target to limit normal tissue damages and improve tumor control in the context of radiotherapy. Irradiation activates endothelial cells which then participate in the recruitment of circulating cells, especially by overexpressing cell adhesion molecules but also by other yet unknown mechanisms. In this study, we aimed to determine whether irradiation modifies the endothelium glycosylation pattern and to investigate the impact of these changes on the adhesion of circulating cells.

### Material and Methods

Primary Human Umbilical Vein Endothelial Cells (HUVECs) were irradiated at 20 Gy ( $^{137}\text{Cs}$  source) and studied from 12 hours to 21 days. Glycosylation was studied by fluorescence microscopy and flow cytometry using a set of fluorescent lectins to specifically quantify different types of sugar. The overall N-glycan pattern was studied by MALDI-TOF mass spectrometry. Glycosaminoglycans were studied by the uronic acid dosage. Interactions of endothelial cells with fluorescent THP-1 monocytes were analyzed under flow conditions by fluorescence videomicroscopy. Radiation enteropathy of C57BL/6 mice was induced by exposure of an intestinal segment to 19 Gy of radiation (LINAC, 4 MV) and studied at day 3, 7 and 42. The mRNA levels of 84 genes encoding proteins involved in glycosylation were measured in HUVECs and small intestine by real-time quantitative PCR using human or mouse glycosylation PCR array.

### Results

We show here that ionizing radiation induces an overexpression of high mannose-type N-glycans at the membrane surface of primary endothelial cells, while complex-type N-glycans decrease. We also show a decrease of the quantity of glycosaminoglycans upon radiation exposure, which may reflect a thinning of the glycocalyx. Using fluorescence videomicroscopy, we show that these changes contribute to increase monocyte adhesion on irradiated HUVECs under flow conditions. By a transcriptomics approach, we confirmed that genes involved in N-glycosylation are modulated by ionizing radiation. We also show that O-glycosylation is probably modified by radiation, which we validated by cell labeling experiments using fluorescent lectins. Finally, we studied the expression of a panel of genes involved in glycosylation in a radiation enteropathy mouse model, showing that a global modification of glycosylation gene expression occurs in the irradiated small intestine.

### Conclusion

Our results demonstrate the existence of radiation-induced changes of endothelial glycosylation *in vitro*, with functional consequences on the adhesion of monocytes. They also suggest that irradiation modifies the glycosylation pattern of the small intestine tissue. In the same way as in chronic disease such as atherosclerosis, the endothelium glycome therefore appears to be a therapeutic target for modulating the pathological inflammatory response observed after irradiation.

## Symposium: Expanding brachytherapy indications

---

### SP-0032 The technique for CT/MR guided hepatic implantations

N. Tselis<sup>1</sup>

<sup>1</sup>Department of Radiation Oncology, Klinikum Offenbach GmbH, Germany

Abstract not received

### SP-0033 Optical and tracking technologies for navigation in brachytherapy

R. Weersink<sup>1</sup>

<sup>1</sup>Princess Margaret Cancer Centre University Health Network, Physical Chemistry, Toronto, Canada

This presentation discusses two medical fields not normally associated with brachytherapy: optical imaging and image-guided navigation technologies. Both of these fields, especially in combination with each other, offer some new approaches to treatment planning and delivery in brachytherapy. To date, endoscopy and surgical navigation tools have had only limited roles in brachytherapy; electromagnetic (EM) tracking is under evaluation for catheter segmentation and quality

assurance while endoscopy is principally used to guide applicator insertion for lung and esophagus brachytherapy. This presentation will briefly discuss new techniques in endoscopy; introduce several evolving optical imaging modalities that are proving valuable in intraluminal disease detection.

For instance, white light endoscopy has long played a critical role in diagnostics and disease staging of cancer for many intraluminal sites. With the advent of laparoscopic surgery, endoscopy is also critical for minimally invasive surgery. Endoscopic microscopy is also offering new methods of visualizing disease at fields of view that are possibly relevant for brachytherapy. Fluorescence imaging, both with and without contrast agents, has been explored for disease detection in many disease sites. Advances in targeted contrast agents and imaging technology have created new opportunities in image guided surgery, in which fluorescence is used to detect microscopic levels of disease at tumour and surgical margins. and optical coherence tomography. Optical coherence tomography (OCT) provides almost pathology-like imaging for intraluminal sites that may be useful in assigning patient specific prescription depth information.

The presentation will also outline applications of EM navigation in other fields, such as bronchoscopic and endoscopic navigation. We discuss possible roles for endoscopic navigation in brachytherapy, such as applicator placement for intraluminal sites and improved contouring of superficial disease.

Navigation technologies have become commonplace in surgery and interventional radiology while endoscopic tracking integrated with volumetric imaging presents new "augmented" methods of visualizing clinical information. As applicators become more sophisticated improved methods of guiding their insertion are needed and navigation technologies are sure to play a role, not only in catheter reconstruction but also for placement guidance.

Given the small role that each of these technologies currently has in brachytherapy this presentation will be, by necessity, somewhat speculative but it is hoped that this encourages further consideration on how to implement these technologies in brachytherapy.

### SP-0034 Using multiparametric US to redefine target volumes in brachytherapy

H. Wijkstra<sup>1</sup>

<sup>1</sup>Eindhoven University of Technology / AMC University Hospital Amsterdam, Signal Processing Systems / Urology, Eindhoven / Amsterdam, The Netherlands

#### Introduction

Prostate cancer most often is characterised by multiple areas of malignant lesions that differ in size and morphologic appearance. The lesions can be divided in insignificant and dominant lesions (DLs). Using radiotherapy, identification of DLs would enable treatment of the whole prostate with a moderate dose and giving a boost on the DLs, which most probably will improve treatment outcome. To be able to localise DLs an accurate imaging technique is needed.

Multiparametric MRI (mpMRI) has been developed as an imaging technique to detect and localise prostate cancer. In mpMRI a combination of T2 imaging, diffusion-weighted imaging (DWI) and dynamic contrast enhanced MRI (DCE-MRI) is used. Expert centers published promising results, however, recent studies demonstrate that mpMRI is still missing up to ~20% of significant prostate cancer. mpMRI is currently the main modality for the (pre-)planning of therapy, however, real-time ultrasound is used during most therapeutic procedures (e.g. brachytherapy). As compared to (mp)MRI, ultrasound is cost-effective, practical and widely available. A relative new development is multi parametric ultrasound (mpUS).

#### Multi-parametric ultrasound

A recent review revealed that mpUS is not widely studied yet, but that early results are encouraging. mpUS might serve as a cost-effective and safe diagnostic tool to select patients for focal therapy and to plan treatment procedures. In mpUS different ultrasound modalities are combined, including contrast-enhanced ultrasound (CEUS), Doppler ultrasound, computerised transrectal ultrasound and elastography.

Transrectal greyscale ultrasound is currently the standard imaging tool for the prostate and is e.g. used for guiding seed placement in brachytherapy. The performance reported in the literature varies widely.

Several systems for computerised analysis of ultrasound images have been developed. The far best results published are from the artificial neural network/C-TRUS (ANNA/C-TRUS) system. The initial results for a different computerised analysis technique, histoscanning, were favourable, however, recent studies state that histoscanning is not recommended to reliably identify and characterise prostate cancer.

Cancer requires angiogenesis to develop into clinically significant disease. The increased perfusion in malignant tissue can be visualised by Doppler ultrasound imaging. Various authors reported additional value of the Doppler techniques. However, the hypervascularity detected by Doppler ultrasound is not based on true angiogenic perfusion but on flow in larger feeding vessels.

In contrast-enhanced ultrasound, gas filled microbubbles are administered intravenously during ultrasound imaging. The microbubbles were first used as additional reflectors in combination with Doppler techniques, increasing sensitivity. In the past years, contrast-enhanced ultrasound has emerged, and the technique now exploits the microbubbles nonlinear oscillations to extract a contrast specific image, sensitive enough to detect single microbubbles. Recently, quantification techniques are being developed that extract objective parameters from CEUS data to further improve interpretation. The latest developments focus on the assessment of the dispersion kinetics of the contrast agent passing through the microvasculature to image changes in the microvascular architecture resulting from cancer neoangiogenesis. Most prostate cancers are stiffer than normal prostatic tissue. Two variants of ultrasound elastography exploit this difference in stiffness: quasi-static or strain elastography and the novel shear wave elastography. The latter assesses stiffness by measuring the velocity at which a shear wave travels through the tissues. Shear wave elastography does not require manual cyclic compression of the prostate and quantification is possible because shear wave velocity is an absolute value.

#### Conclusion

The ultrasound modalities discussed above exploit different physical characteristics of (malignant) tissue. Combining the modalities has the potential to detect and localise accurately tumours and dominant lesions. Until now only limited data on the performance of combinations of ultrasound modalities have been published. Therefore, it is difficult to determine the exact value of mpUS in e.g. brachytherapy. Due to the advantages of ultrasound over MRI (i.e. more cost-effective, wider available, less time-consuming, more practical, more suitable for perioperative use and more easily combined with therapeutic devices), the frequent use of US modalities in therapy procedures, its enhanced performance in multiparametric fashion, it is expected that mpUS will become an increasingly interesting modality in also brachytherapy.

<sup>2</sup>Princess Margaret Cancer Centre, Cancer Clinical Research Unit, Toronto, Canada

<sup>3</sup>Radboud University Medical Center Nijmegen, Radiation Oncology, Nijmegen, The Netherlands

<sup>4</sup>VU University Medical Center, Otolaryngology/Head and Neck Surgery, Amsterdam, The Netherlands

#### Purpose or Objective

In order to facilitate a more personalized oncology, research into non-invasive tumor related biomarkers is essential. Radiomics, the comprehensive quantification of tumour phenotypes by extracting large numbers of quantitative image features, can capture intra-tumour heterogeneity and gene-expression patterns [1]. It has previously been shown that a radiomic signature may have high value for survival prediction in lung and head and neck cancer patients [1,2]. However, extensive analysis on the quality of this signature has yet to be done. In this project, we validate the existing radiomics signature in 5 validation sets. We hypothesize that the signature performs above the chance level, in terms of discrimination, on each validation set. Furthermore, we expect that high, medium and low risk patients can be identified using the radiomics signature.

#### Material and Methods

Five independent Lung and Head & Neck (H&N) cancer cohorts (in total 1418 patients) treated with (chemo-)radiation were used in this study. Radiomic features were extracted from the pre-treatment computed tomography (CT) images. The model was trained on the Institute 1 lung cohort (N=422) and validated on the other datasets (N=996). The outcome is two-year survival following treatment. An exponential curve was fitted to the radiomics signature predictions plotted against overall survival. Risk group allocation for the Kaplan-Meier curves was done by partitioning patients in 3 groups according to radiomics score.

#### Results

As can be observed in figure 1, an upward trend of radiomics signature response versus overall survival can be observed for each validation set. Risk groups can be identified using the radiomics signature in every dataset, as is shown in figure 2.

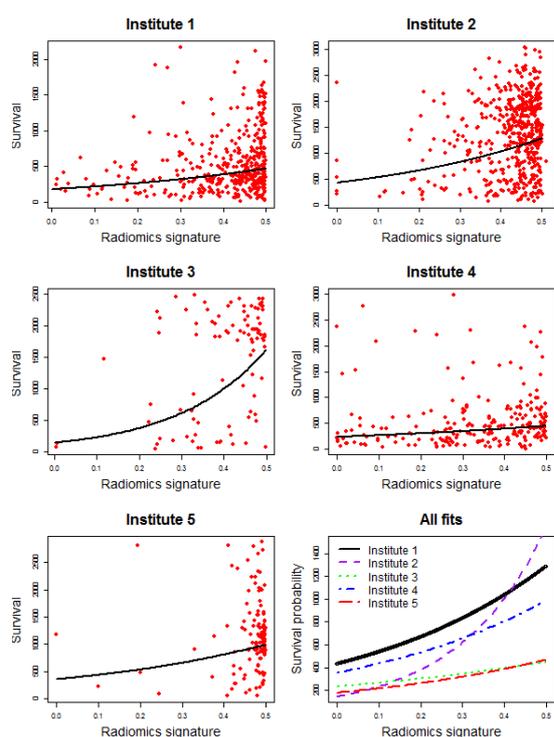

Figure 1: Exponential fit of radiomics signature score versus overall survival for different datasets.

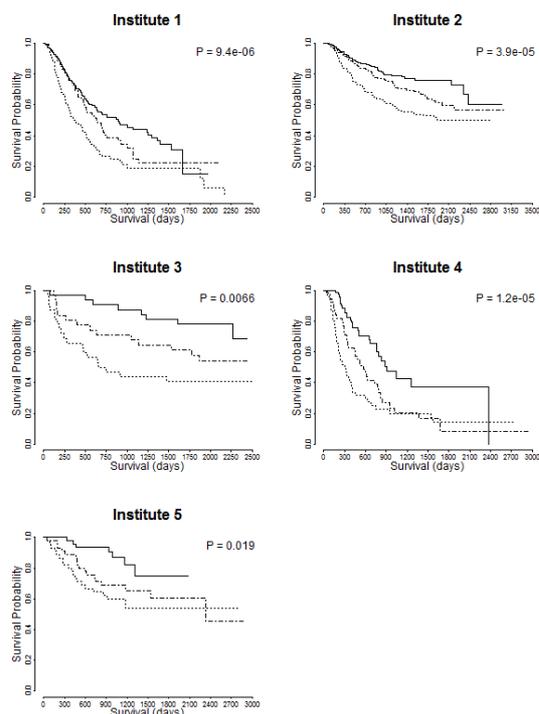

Figure 2: Risk group identification based on the radiomics signature score for each dataset.

### Conclusion

The radiomics signature model is able to predict two-year survival above the chance level in every validation cohort. Furthermore, the radiomics signature allows the identification of low, medium and high risk group patients. These findings indicate that the signature is robust and transferable across hospitals.

### OC-0036 Does androgen deprivation therapy result in lowering the alpha / beta values in prostate cancers?

N.R. Datta<sup>1</sup>, E. Stutz<sup>1</sup>, S. Rogers<sup>1</sup>, S. Bodis<sup>1</sup>  
<sup>1</sup>Kantonsspital Aarau, Radio-Onkologie, Aarau, Switzerland

### Purpose or Objective

Reports indicate that prostate cancers exhibit fractionation sensitivity with low  $a/B$  values similar to those of late-responding normal tissues. This has resulted in a number of hypofractionated (HRT) randomized clinical trials being undertaken in prostate cancer. Some of these have been reported to be isoeffective in terms of identical biochemical and/or clinical failure (BCF) rates. This allows estimation of the  $a/B$  values using the specified RT dose parameters, thus avoiding any uncertainty in choice of values for additional variables pertaining to tumour kinetics, repair and tumour control probability. The present study has been undertaken to estimate the  $a/B$  values for prostate cancer from randomized clinical trials of conventional (CRT) vs. HRT radiotherapy (RT) reporting similar 5-year BCF. The influence of various tumour and treatment variables on the  $a/B$  estimates was also examined.

### Material and Methods

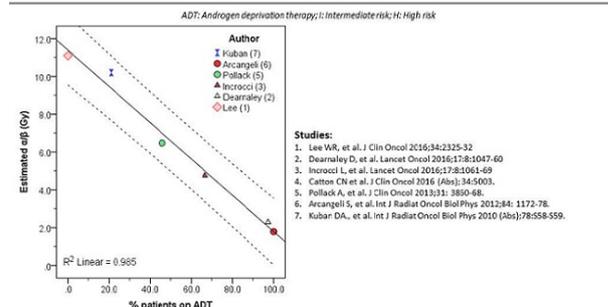

Randomized clinical trials with similar BCF following CRT or HRT for prostate cancer were collated following a detailed database search as per the PRISMA guidelines. The  $a/B$  value from each trial was derived using the linear-quadratic (L-Q) expression,  $a/B(\text{Gy}) = (d_{\text{HRT}} D_{\text{HRT}} - d_{\text{CRT}} D_{\text{CRT}}) / (D_{\text{CRT}} - D_{\text{HRT}})$  where, 'd' and 'D' indicate the dose/fraction and the total dose respectively of the corresponding HRT and CRT schedules (represented by subscripts). Prostate cancers being slow growing tumours, a time factor was not included in these calculations. RT dose/fraction (1.8-2Gy for CRT; 2.4-3.4Gy for HRT), total RT dose (73.8-80Gy in CRT; 60-72Gy in HRT), use of androgen deprivation therapy (ADT) and tumour risk categories were considered as possible covariates in a multivariate regression analysis for the estimated  $a/B$  value.

### Results

Seven randomized trials including 5,916 patients treated with CRT (n=2,949) or HRT (n=2,967) were available from 156 citations searched. Three trials recruited patients in a single risk category (one for each of low, intermediate or high-risk), 2 trials included both intermediate and high-risk patients and 2 trials included all risk categories. One study in low-risk patients did not use ADT while in others, 21%-100% patients were treated with ADT. The estimated  $a/B$  values ranged from 1.33-11.1Gy (5.41±4.0) (Table, Fig). On multivariate analysis, only %patients receiving ADT predicted the estimated  $a/B$  values (model  $R^2$ : 0.992; coefficient = -0.096,  $p < 0.001$ ).

**Table 1:** Details of the seven randomized trials between conventional (CRT) and hypofractionated (HRT) radiotherapy along with their computed  $\alpha/\beta$  values and the corresponding biologically effective doses (BED). Corresponding BED values have also been tabulated assuming  $\alpha/\beta$  of 1.5 Gy.

Author	Conventional fraction radiotherapy		Hypofractionated radiotherapy		Estimated $\alpha/\beta$ (Gy)	BED for CRT & HRT with estimated $\alpha/\beta$ (Gy)†	BED <sub>1.5</sub> (assuming $\alpha/\beta = 1.5$ ) (Gy)	BED <sub>1.5</sub> (assuming $\alpha/\beta = 1.5$ ) (Gy)	% difference in BED*	% patients with ADT	Risk group

Arcangeli et al (6)	2.00	80.00	3.10	62.00	1.79	169.44	186.67	190.13	1.86	100	High
Kuban et al (7)	1.80	75.60	2.40	72.00	10.20	88.94	166.32	187.20	12.5	21.0	All

## Conclusion

The clinically estimated  $\alpha/\beta$  values for prostate cancer from an isoeffective L-Q model were inversely related only to the proportion of patients receiving ADT. This is in accordance with *in vitro* and *in vivo* studies demonstrating ADT induced cell cycle arrest and induction of apoptosis in prostate cancer, both of which results in decelerating the tumour growth. Thus, ADT-primed prostate cancers cells could radiobiologically mimic late-responding normal tissues and display lower  $\alpha/\beta$  values. This suggests a possible selective benefit of ADT in cancer prostate patients on HRT treatment protocols.

## OC-0037 Low dose volume effect is a critical determinant for radiation-induced lung fibrosis

G. Defraene<sup>1</sup>, M. La Fontaine<sup>2</sup>, S. Van Kranen<sup>2</sup>, B. Reyms<sup>3</sup>, J. Belderbos<sup>2</sup>, J.J. Sonke<sup>2</sup>, D. De Ruyscher<sup>1,3</sup>

<sup>2</sup>Netherlands Cancer Institute, Department of Radiation Oncology, Amsterdam, The Netherlands

<sup>3</sup>Department of Radiation Oncology MAASTRO GROW - School for Oncology and Developmental Biology, Maastricht University Medical Centre, Maastricht, The Netherlands

## Purpose or Objective

Severe normal lung tissue damage after (chemo) radiotherapy, presenting as fibrotic changes, occurs in 20% of patients and often coincides with clinical symptoms. The mechanism of formation and/or propagation of these lung infiltrations is not well understood. The aim of this study was to quantify and explain lung tissue density increase assessed by CT scans as a surrogate of lung damage in a dataset in which unusually large prescription doses resulted in a wide range of lung tissue doses.

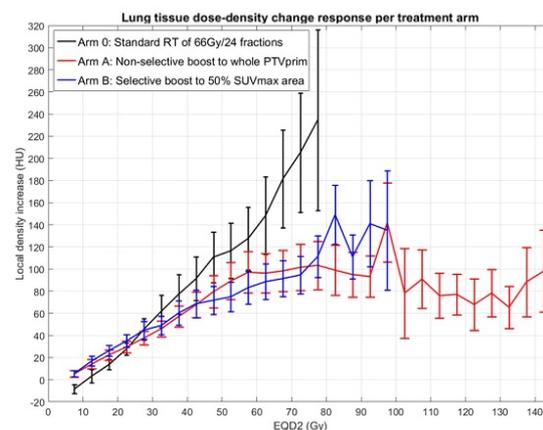

## Material and Methods

The dataset consisted of 75 stage I-III non-small cell lung cancer patients from 3 institutions treated in the PET-Boost trial: a randomized phase II study (NCT01024829). The randomization arms were a dose escalation to the primary tumour (PTV<sub>prim</sub>) as a whole (Arm A) and an integrated boost painted to the 50% FDG PET SUV<sub>max</sub> subregion of PTV<sub>prim</sub> (Arm B), both delivered in 24 fractions. When dose constraints prevented escalation  $\geq 72$  Gy, standard treatment of 66 Gy in 24 fractions was delivered (Arm 0). The planning CT (CT<sub>0</sub>), follow-up CT (CT<sub>3</sub>) +/- 3 months post RT and planned dose maps (IMRT or VMAT) corrected to equivalent doses in 2 Gy fractions

(EQD2,  $\alpha/\beta=3$ Gy) were collected. A deformable registration mapped CT<sub>3</sub> to CT<sub>0</sub> using a multiresolution B-spline algorithm with constraints on rigidity and smoothness to avoid reshaping of infiltrations on CT<sub>3</sub>. The median density change in Hounsfield Units ( $\Delta$ HU) within the 'lungs minus GTV' contour was then extracted per dose bin of 5 Gy from the difference image (HU<sub>3</sub>-HU<sub>0</sub>). Prognostic factors of  $\Delta$ HU were obtained through linear regression. The studied covariates were CT<sub>3</sub> timepoint (T<sub>3</sub>), total and ipsilateral lung volume (LV<sub>tot</sub> and LV<sub>ipsi</sub>), mean lung dose, lung volumes receiving 5 Gy, 20 Gy and 40 Gy (V<sub>5</sub>, V<sub>20</sub> and V<sub>40</sub>), mean heart dose (MHD), heart D<sub>max</sub> and PTV<sub>prim</sub> mean dose.

## Results

The average density change response curve per study arm is depicted in Figure 1. A saturation was only observed above 60Gy in Arm A. The higher response in Arm 0 above 40Gy suggested that local dose is not the only driver of local  $\Delta$ HU risk. Prognostic factors of individual patient response at 20-25Gy, 40-45Gy and 60-65Gy were therefore searched in the combined dataset. Table 1 shows the significant covariates. Lower LV<sub>ipsi</sub> was highly prognostic of  $\Delta$ HU in all dose bins. The dosimetric prognostic factors lung V<sub>5</sub> and MHD could explain the higher  $\Delta$ HU in Arm 0 (standard RT was only delivered in presence of limiting constraint(s)): V<sub>5</sub> was on average 78.9%, 64.6% and 62.8% in Arm 0, A and B, respectively, while MHD was on average 17.9Gy, 13.4Gy and 13.1Gy, respectively. In multivariate analysis, LV<sub>ipsi</sub>, V<sub>5</sub> and T<sub>3</sub> were independent prognostic factors for  $\Delta$ HU in the 40-45Gy and 60-65Gy dose bins.

**Figure 1** Population dose response curves for local density change of lung tissue 3 months post RT in Arm 0 (15 patients), Arm A (28 patients) and Arm B (32 patients). Average and standard error of mean (SEM) per 5 Gy dose bin. The data suggest there is no non-local impact of the highest lung doses in Arm A and B on the density increase of distant lung regions.

Covariate	Dose bin	20-25 Gy		40-45 Gy		60-65 Gy	
		p	$\beta$	p	$\beta$	p	$\beta$
Ipsilateral lung volume, LV <sub>ipsi</sub> (cc)		0.023	-0.011	0.0050	-0.031	0.0049	-0.045
Total lung volume, LV <sub>tot</sub> (cc)		/	/	0.017	-0.014	0.0023	-0.027
Total lung V <sub>5</sub> (%)		/	/	0.013	1.25	0.020	1.72
Mean heart dose, MHD (Gy)		/	/	0.023	1.73	0.034	2.37

**Table 1** Univariate linear regression p value and model coefficient  $\beta$  of the significant prognostic factors ( $p < 0.05$ ) of local density increase assessed within 3 different dose bins for the total dataset of 75 patients. For the dose bins 40-45 Gy and 60-65 Gy, a multivariate linear regression model with 3 independent prognostic factors ( $p < 0.10$ ) was obtained:  $\Delta$ HU<sub>40-45Gy} = -78.71 - 0.021 \cdot \text{LV}\_{ipsi} + 1.30 \cdot \text{V}\_5 + 24.30 \cdot \text{T}\_{3} ( $R^2=0.21$ ) and  $\Delta$ HU<sub>60-65Gy} = -65.42 - 0.032 \cdot \text{LV}\_{ipsi} + 1.64 \cdot \text{V}\_5 + 27.60 \cdot \text{T}\_{3} ( $R^2=0.17$ ), with T<sub>3</sub> in months.</sub></sub>

## Conclusion

This study indicates that the low dose volume effect is critical for the induction of severe lung fibrosis in high dose regions. This supports the hypothesis of the importance of residual lung volumes spared from low dose for optimal repair within the whole lung.

## OC-0038 Patterns in ano-rectal dose maps and the risk of late toxicity after prostate radiotherapy

<sup>6</sup>Istituto di Candiolo- Fondazione del Piemonte per l'Oncologia IRCCS, Radiotherapy, Candiolo, Italy

<sup>7</sup>Università degli Studi di Milano, Oncology and Hemato-Oncology, Milano, Italy

### Purpose or Objective

To explore which features of the dose distribution in the ano-rectal wall determine the risk of late rectal bleeding and late faecal incontinence following prostate cancer radiotherapy (RT).

### Material and Methods

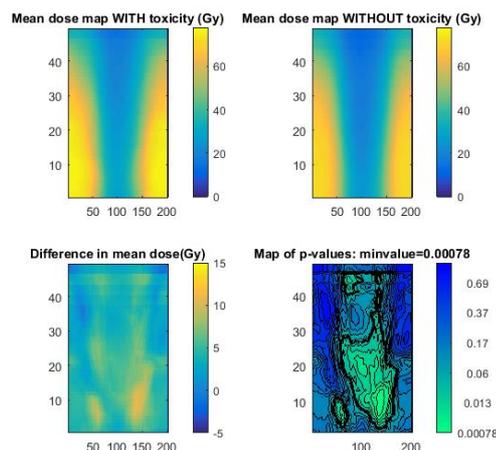

Patients from the DUE-01 study with available 3D dose distributions and follow-up data at 24 months after RT were included in this study. Patients with pre-treatment symptoms were excluded. An incidence of 22 in 152 was observed for a maximum grade  $\geq 2$  rectal bleeding, while 12 patients in 110 experienced a mean grade  $> 1$  faecal incontinence, calculated from at least 3 occasions from 6 to 24 months after RT.

Dose surface maps were extracted and converted to EQD2; structures considered were the rectum, anal canal and the combination of the two. For each endpoint, the mean of the dose surface maps in the group of patients with and without toxicity respectively were calculated. A t-test was performed on the mean values of each pixel to identify regions where the dose differed between patients with and without toxicity (i.e. with low p-value).

The lateral and longitudinal extent, and eccentricity, of EQD2 isodoses from 5 to 73 Gy were extracted from the dose maps. Univariate NTCP models using each parameter were fitted to the outcome data and the performance evaluated using AUC.

### Results

The patients who experienced rectal bleeding received higher dose to the posterior part of the rectal wall (see figure; dose map unfolded along anterior axis); the greatest difference was found when aligning all dose maps at the inferior border of the rectum. Patients with faecal incontinence had a higher dose in the posterior wall of the anal canal compared to patients without; here a greater difference was found when aligning the dose maps according to the centre of mass of the dose maps. For rectal bleeding, the highest AUC was found for the lateral extent of the 31-Gy isodose; this is in agreement with the difference in dose to the posterior wall in the toxicity vs. non-toxicity groups. For faecal incontinence, on the other hand, the model based on the lateral extent of the highest isodose (73 Gy) had the highest AUC.

### Conclusion

The dose received by the posterior part of the rectal wall is related to the risk of late rectal bleeding, and the lateral extent of the 31-Gy isodose is the best spatial parameter to include in an NTCP model. The risk of causing late faecal incontinence is related to the dose to the anal canal.

### OC-0039 Unique sparing of spatial memory in mice after whole brain irradiation with dose rates above 100Gy/s

K. Petersson<sup>1</sup>, P. Montay-Gruel<sup>2</sup>, M. Jaccard<sup>1</sup>, G. Boivin<sup>2</sup>, J. Germond<sup>1</sup>, B. Petit<sup>2</sup>, F. Bochud<sup>1</sup>, C. Bailat<sup>1</sup>, J. Bourhis<sup>2</sup>, M. Vozenin<sup>2</sup>

<sup>1</sup>Lausanne University Hospital, Institute of Radiation Physics IRA, Lausanne, Switzerland

<sup>2</sup>Lausanne University Hospital, Department of Radiation Oncology, Lausanne, Switzerland

### Purpose or Objective

Radiotherapy at ultra high dose rate (Flash-RT) has been suggested to increase the differential response between normal and tumor tissue compared to conventional radiotherapy. In order to further explore Flash-RT and to validate its protective effect on normal tissues, we decided to investigate brain response to Flash-RT as it is a well-defined and robust model in radiobiology.

### Material and Methods

10 Gy was used as the prescription dose for the whole brain irradiations (WBI). The irradiation settings, corresponding to the prescription dose, were defined according to film (Gafchromic™ EBT3), TLD (LiF-100), Alanine pellets, and ion-chamber (Advanced Markus, corrected for ion recombination) measurements at the surface of a solid water phantom, positioned behind a 1.7 cm in diameter aperture of a graphite applicator. The measurements and the subsequent mice WBI were performed for different dose rates, ranging from a conventional radiotherapy dose rate of 0.1 Gy/s to 10 Gy delivered in a single 1.8  $\mu$ s electron pulse. TLD were positioned inside the skull of a sacrificed mouse to validate the dose delivered to the brain during WBI for the highest and lowest dose rate setting. 75 Female C57BL/6J mice were used in the study. Dose rate effect on neuroprotection was evaluated by 'Novel Object Recognition test' two months post-irradiation. All the experiments were video-recorded. Analysis was performed blindly and the time the mice spent investigating each object was measured in order to calculate the Recognition Ratio (RR) such as: RR= (time spent investigating the novel object / time spent investigating the two objects).

### Results

The Film, TLD, Alanine, and ion-chamber measurements showed a similar delivered dose (10 Gy), regardless of the dose rate setting. The TLD measurements in the brain of the sacrificed mouse verified that the prescribed 10 Gy dose was delivered to the mouse brain, for a 10 Gy in 1.8  $\mu$ s and a 0.1 Gy/s dose rate delivery (10.06 and  $9.90 \pm 8.2\%$ ,  $k = 2$ , respectively). Our results showed spatial memory preservation in mice after 10 Gy WBI delivered in a single 1.8  $\mu$ s electron pulse, whereas 10 Gy WBI delivered with a dose rate similar to what is conventionally used in radiotherapy (0.1 Gy/s) impaired mice mid-term spatial memory. Using systematic dose rate escalation, 100 Gy/s was found to be the lower limit for full preservation of spatial memory functions after 10 Gy WBI.

#### Conclusion

This study shows for the first time that normal brain tissue toxicities after WBI can be reduced with increased dose rate. Spatial memory is preserved after WBI with mean dose rates above 100 Gy/s, whereas 10 Gy WBI at a conventional radiotherapy dose rate (0.1 Gy/s) totally impairs spatial memory. This radiobiological advantage, together with other practical considerations that benefit from rapid radiotherapy treatment delivery, such as minimizing intra-fractional motion, increased patient comfort, and improved treatment efficiency, makes Flash-RT a promising treatment modality.

#### OC-0040 Validation of prospective electronic toxicity registration to audit dose constraints

T.M. Janssen<sup>1</sup>, A. Dikstaal<sup>1</sup>, M. Kwint<sup>1</sup>, S. Marshall<sup>1</sup>, A.L. Wolf<sup>1</sup>, J. Kneegjens<sup>1</sup>, L. Moonen<sup>1</sup>, J. Belderbos<sup>1</sup>, J.J. Sonke<sup>1</sup>, M. Verheij<sup>1</sup>, C. Van Vliet-Vroegindeweij<sup>1</sup>  
<sup>1</sup>Netherlands Cancer Institute Antoni van Leeuwenhoek Hospital, Radiotherapy, Amsterdam, The Netherlands

#### Purpose or Objective

In 2012 we started with the prospective, electronic registration by the treating physician of all grade  $\geq 2$  toxicities (CTCAE v4.0) for all patients irradiated at our department. Simultaneously we set up an infrastructure to couple this data to dose and treatment parameters. The aim of this work is to assess the validity of the data and to show the feasibility of such an infrastructure to audit toxicity prediction models and dose constraints in daily clinical practice.

#### Material and Methods

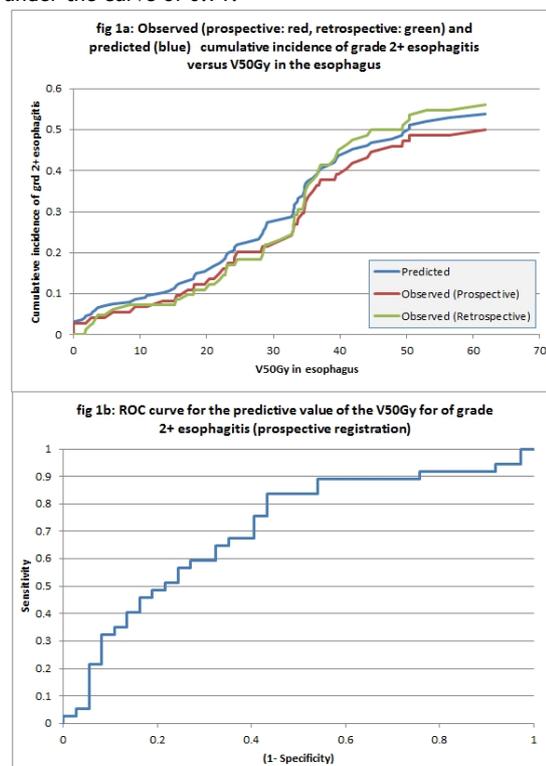

As a showcase we consider the relation between the esophagus V50Gy and grade  $\geq 2$  esophagitis in locally advanced NSCLC patients receiving concurrent chemoradiotherapy (CCRT; 24 x 2.75Gy, daily 6mg/m<sup>2</sup> cisplatin). Clinically we use V50Gy<50% as a dose constraint based on a previously developed NTCP model [1]. The applicability of this model to current clinical practice is not evident since dose criteria changed after publication and patients currently receive intravenous pre-hydration (1L, NaCl 0.9%) which was shown to decrease esophagitis

[2]. For all CCRT patients (excluding adaptive RT and re-irradiations) treated in 2014/2015, the planned V50Gy and the registered esophagitis  $\geq$  grade 2 were retrieved. Furthermore, a single observer retrospectively scored toxicity, based on the electronic health records. We calculated the incidence of grade  $\geq 2$  esophagitis per V50Gy and compared this with the expected incidence based upon the model by Kwint *et al.* using a  $\chi^2$  test. ROC analysis was performed to assess the predictive value of V50Gy.

#### Results

For 82 patients, 558 consultations were performed. Median follow up was 3.5 months and grade  $\geq 2$  esophagitis was prospectively (retrospectively) scored for 41 (46) patients. For 74 patients, retrospective and prospective scoring was identical and for 3 patients esophagitis was scored in both cases, but grades differed.

A comparison of the observed and predicted grade  $\geq 2$  esophagitis is shown in Figure 1a. The prospective (retrospective) observed incidence of grade  $\geq 2$  esophagitis was 50% (56%) while the model predicts 54%. Neither registrations differ from the model prediction (prospective  $p=0.78$ , retrospective  $p=0.91$ ). ROC analysis (figure 1b) of prospective registrations result in an area under the curve of 0.71.

#### Conclusion

Retrospective and prospective toxicity registration showed overlap in 90% of cases. Moreover, the observed dose-effect of grade  $\geq 2$  esophagitis was almost identical to the NTCP model. This implies 1) that the V50Gy accurately predicts toxicity for our current treatment protocol and 2) that our prospective toxicity registration results in valid data. Esophagitis incidence was expected to decrease due to pre-hydration. While this discrepancy requires further investigation, it does show that the electronic toxicity registration and connection to dose parameters appears to be a valuable tool to audit the applicability of dose constraints in daily clinical practice.

#### OC-0041 Predictors of asymptomatic radiation induced vascular damage to infradiaphragmatic vessels

L. Cella<sup>1</sup>, R. Liuzzi<sup>1</sup>, P. Romanelli<sup>2</sup>, M. Conson<sup>2</sup>, V. D'Avino<sup>1</sup>, M. Ottaviano<sup>3</sup>, V. Damiano<sup>3</sup>, G. Palmieri<sup>3</sup>, R. Pacelli<sup>2</sup>, M. Mancini<sup>1</sup>

<sup>1</sup>Institute of Biostructure and Bioimaging-CNR, National Council of Research, Napoli, Italy

<sup>2</sup>Federico II University School of Medicine, Department of Advanced Biomedical Sciences, Napoli, Italy

<sup>3</sup>Federico II University School of Medicine, Centro Riferimento Tumori Rari Regione Campania, Napoli, Italy

#### Purpose or Objective

Blood vessels may be damaged by radiation exposure and radiation therapy (RT) may have a negative impact on the vascular system by promoting accelerated atherosclerotic vascular complications. Aim of the present study is to identify predictors of asymptomatic radiation-induced

abdominal atherosclerosis in patients affected by testicular classic seminoma (CS) treated with RT and prospectively evaluated by abdominal vascular ultrasonography.

#### Material and Methods

Forty-two CS patients (median age 34 years, range 16-56) who had undergone radical inguinal orchiectomy were enrolled in this study. Twenty-six patients underwent post-surgery RT (median total dose 25.2 Gy, range 25.05-43.2), 2 of them also received chemotherapy (CHT), and 16 patients were treated with surgery alone or by surgery followed by CHT (control group). For RT group, dose volume histograms (DVHs) for contoured structures (abdominal arteries and kidneys) were extracted and near maximum dose ( $D_{2\%}$ ) and mean dose ( $D_{mean}$ ) metrics analyzed. The presence of stenosis in an abdominal vessel and renal resistive index (RRI) were evaluated by abdominal echo-color Doppler and considered as indicators of vascular damage. The presence and severity of stenosis was classified according to validated criteria reported in table 1.

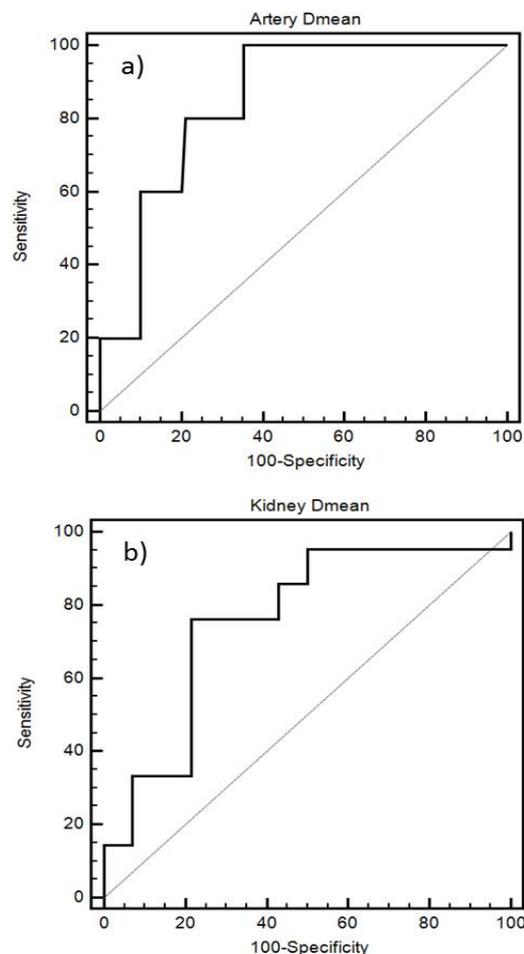

**Table 1.** Stenosis classification based on peak systolic (PSV), end-diastolic velocity (EDV), Iliac artery velocity ratio and renal artery velocity ratio

Stenosis classification	Artery	PSV (cm/sec)	EDV (cm/sec)	Velocity Ratio
<50% Diameter-reducing stenosis	Celiac	>200	<55	
	Superior mesenteric	>225	<60	
	Iliac	>150		<2 <sup>§</sup>
	(<60%) Renal	>180		< 3.5*
>50% Diameter-reducing stenosis	Celiac	>200	>55	
	Superior mesenteric	>225	>60	
	Iliac	>150		>2 <sup>§</sup>
	(>60%) Renal	>180		>3.5*

The average RRI (aRRI) over the left and right kidneys was also computed. Statistical analysis was performed first comparing RT group and control-group by Chi-square and Mann-Whitney tests. For RT group, univariate logistic regression analysis was performed by Spearman's rank correlation coefficient ( $R_s$ ) to evaluate correlations between different factors with the incidence of stenosis and with RRI. The impact of artery dosimetric factors was analyzed comparing the stenotic arteries versus normal ones. Similarly, the kidney dosimetric analysis was performed on each kidney separately. The area under the Receiver Operator Characteristic (ROC) curve (AUC) was used to evaluate the test accuracy.

#### Results

After a median follow-up of 77.4 months (range 48-120 months), stenosis was observed in 8 patients (31%) in the RT group but none in the control group ( $p=0.016$ ). A significantly higher median aRRI was also observed in the RT group compared with control group (0.63 vs 0.60,  $p=0.032$ ). Age at RT was the only clinical risk factor for stenosis ( $R_s=-0.529$ ,  $p=0.005$ ). Artery mean dose was correlated with stenosis [ $R_s=0.238$ ,  $p=0.008$ ,  $AUC=0.85$ , 95%CI 0.77-0.91] and kidney mean dose with dichotomized RRI variable using its mean value (0.62) [ $R_s=0.417$ ,  $p=0.013$ ,  $AUC=0.76$ , 95%CI 0.58-0.89], respectively. ROC curves are displayed in figure 1.a and 1.b.

#### Conclusion

Late vascular damage represents a potential effect of abdominal RT even at moderate-low radiation dose. Younger age at irradiation as well as artery and kidney mean doses are associated with increased risk. Ultrasound-based follow-up may allow for early detection of asymptomatic vascular radiation-induced damage, helping to prevent severe vascular events.

#### Purpose or Objective

Total-body irradiation (TBI) has an historical established role in preparative regimens used before allogeneic transplant in both acute lymphoblastic leukemia (ALL) and acute myeloid leukemia (AML). The most popular myeloablative conditioning consists of 12Gy delivered in 6 fractions (2Gy twice daily for 3 days) in combination with cyclophosphamide. This schedule of treatment delivery is, however, time-consuming and became less popular in the radiation oncology community in the era of development of new technologies. The aim of the SARAZIN study was to analyze the impact of the modified myeloablative fractionated TBI regimens as compared to the standard 6 fractions-schedule on outcome of patients undergoing allotransplant for ALL and AML.

#### Material and Methods

We retrospectively compared myeloablative TBI regimens of 3126 patients registered in the EBMT database transplanted between 2000 and 2014 for ALL (n=1783) or AML (n=1343). Pre-transplant chemotherapy consisted mainly of cyclophosphamide (Cy) in 92% and 97% of ALL and AML patients, respectively. TBI was delivered as either 12Gy in 6 fractions (group 1; ALL, n=1362 and AML, n=857), or single dose TBI (STBI) (group 2; ALL, n=54 and AML, n=79), or 9-12Gy in 2 fractions (group 3; ALL, n=173 and AML, n=256), or 12Gy in 3-4 fractions (group 4; ALL, n=194 and AML, n=151). The majority (70%-79%)\* of ALL and AML (57%-79%) patients were grafted in 1<sup>st</sup> complete remission (CR1). The rate of transplants from unrelated donors was higher in ALL (24%-50%) vs AML (20%-37%).

#### Results

The median follow-up was 61 months and 85 months in the ALL and AML patients, respectively. At 5 years, leukemia free survival (LFS), overall survival (OS), relapse incidence (RI) and non-relapse mortality (NRM) were 46.5%, 50.4%, 29%, 24.5% in ALL and 45.7%, 48%, 30.4% and 23.8%, respectively. LFS at 5y in AML and ALL patients were respectively: 48% and 45%, 32% and 45%, 45% and 53%, 42% and 50% in the 4 TBI groups (p=0.082 for AML and p=0.32 for ALL). Additionally, for both AML and ALL, no statistical significance was found between the 4 TBI groups for OS (p=0.82 in ALL; p=0.11 in AML), RI (p=0.29 in ALL; p=0.23 in AML) and for NRM (p=0.58 in ALL; p=0.12 in AML). In multivariate analyses of TBI schedules, comparing the different schedules to the standard 12Gy in 6 fractions (group 1 vs group 2; group 1 vs group 3; group 1 vs group 4), fractionation was not found as independent prognostic factor neither in ALL nor in AML patients for LFS, OS, RI or NRM.

#### Conclusion

The SARASIN study showed that using a TBI dose of 12Gy as pre allogeneic transplantation, fractionation has no impact on relapse or survival neither in ALL, nor in AML patients. The reduction of the number of fractions even in this rather high TBI dose level is not associated with increased risk of NRM. Altogether, our data suggests that 12Gy could be delivered safely in less than 6 fractions. This may lead to increase TBI availability as pre transplantation conditioning regimens in acute leukemia patients.

#### PV-0043 Radiotherapy to the mediastinum in Hodgkin's lymphoma: Is B-VMAT the only arc solution? C. Hanna<sup>1</sup>, C. Featherstone<sup>1</sup>, S. Smith<sup>2</sup>

<sup>1</sup>NHS Greater Glasgow and Clyde, Clinical Oncology, Glasgow, United Kingdom

<sup>2</sup>NHS Greater Glasgow and Clyde, Radiotherapy planning and imaging, Glasgow, United Kingdom

#### Purpose or Objective

Patients treated for Hodgkin's lymphoma have a long life expectancy. It is therefore essential to restrict dose to organs at risk (OARs) to reduce long-term toxicity when using consolidation radiotherapy treatment. Smaller volumes and lower doses have made an impact but it is also crucial that the correct radiotherapy technique is chosen. "Butterfly" arc therapy (B-VMAT) is a technique that has gained popularity with the claim of reducing dose to heart, lung and breast tissue. This project aims to assess if B-VMAT offers any advantage over 3D conformal or alternative arc techniques as a solution to reduce long-term toxicity in these patients.

#### Material and Methods

Review of case records and planning CT scans for 8 patients with mediastinal lymphoma treated with radiotherapy in the past 12 months. We produced a list of "aspirational" dose constraints (DCs) (Table 1) after review of current literature. These DCs were used to compare five different planning techniques (Figure 1) for each patient (Varian/Eclipse Version 13). Mean OAR dose values were calculated for each technique and a paired t-test was used to compare conformity of B-VMAT to the other techniques.

#### Results

Patients were aged between 20-42 years; 4 male and 4 female.

Heart Dmean of 15Gy was met for all plans except one (AP:PA) and 10Gy was mostly achievable. B-VMAT and ARC-A were the optimal plans in terms of OAR dose except for one patient when there was most overlap between heart and PTV. In this case the ARC-F was superior.

Lung-PTV Dmean of 12Gy was achieved in all but one plan (AP:PA). Arc therapies achieved better V20 doses compared to 3DCRT. Arc therapy, in general, did not generate high V5s except for ARC-F which failed to meet the V5 constraint for all patients.

Breast doses were similar for arc and 3D conformal plans except when using ARC-F which was inferior. Dmean of 2Gy was always met. V4 <5% was met for all plans except ARC-F.

Table 1 displays mean OAR doses for all 8 patients for each technique. ARC-A and B-VMAT both consistently outperform 3D-CRT, ARC-F and hybrid without a substantial increase in dose bathing. Conformation number (CN) was significantly better for ARC-F, significantly worse for AP:PA and equivalent for ARC-A and hybrid when compared to B-VMAT. Although superior or equivalent in conformity compared to B-VMAT, both ARC-F and hybrid techniques were nevertheless inferior in reducing OAR doses.

	Parameters (Units) (Standard Deviation (SD))	B-VMAT	AP-PA	ARC-F	ARC-A	Hybrid
Heart	Dose (15Gy mandatory; 10Gy optimal)	9.2 (1.6)	11.7 (3.0)	9.1 (1.4)	9.2 (1.9)	9.7 (2.1)
	V15 (<3%)	28 (6)	37 (10)	24 (3)	27 (8)	31 (10)
	V5 (<50%)	41 (7)	43 (10)	43 (13)	38 (9)	41 (8)
PTV	Dose (12Gy mandatory; 10Gy optimal)	8.9 (1.9)	8.8 (2.4)	8.5 (1.9)	7.3 (1.7)	7.9 (1.9)
	V20 (<20%)	12 (5)	22 (7)	10 (6)	12 (5)	17 (6)
	V5 (<50%)	37 (10)	36 (10)	52 (11)	40 (9)	39 (9)
Breast	Dose (2Gy mandatory; 0.5Gy optimal)	0.4 (0.28)	0.5 (0.26)	1.3 (0.79)	0.4 (0.29)	0.5 (0.26)
	V10 (<5%)	0.6 (0.66)	0.6 (0.66)	2.0 (2.21)	0.6 (0.66)	0.6 (0.66)
	V4 (<5%)	1.8 (2.20)	1.4 (1.80)	8.6 (5.35)	1.8 (2.18)	1.4 (1.76)
PTV	CN*(SD)	0.66 (0.1)	0.37 (0.13) (0.0902)	0.89 (0.04) (0.00003)	0.57 (0.1) (0.085)	0.57 (0.13) (0.09)
	Conformal index p-value)					
	IP6 (%)	92.5 (3.7)	94.5 (1.3)	95.0 (1.4)	92.8 (1.4)	93.6 (1.6)
	IP2 (%)	108.1 (2.30)	107.1 (1.87)	105.0 (1.41)	108.5 (2.33)	107.0 (1.90)
	Dose (%)	113.2 (3.3)	111.6 (4.3)	108.6 (1.6)	114.4 (2.9)	110.8 (3.6)

Table 1  
\*CN: Conformal number calculated using a reference isodose of 95%.

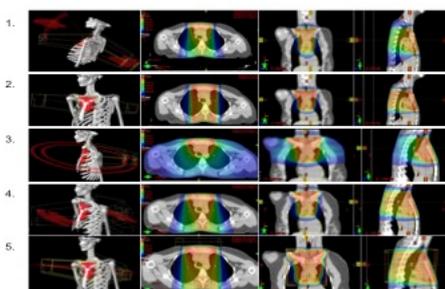

Figure 1:  
PTV outlined in red for all plans  
1. Butterfly VMAT (B-VMAT)  
2. 3D conformal 2 opposing fields (AP-PA)  
3. 2 full arcs (ARC-F)  
4. 2 full arcs with avoidance sectors (ARC-A)  
5. Hybrid plan combining ARC-A with AP-PA (Hybrid)

## Conclusion

Taking into account conformality and OAR dose reduction, ARC-A performed as well as B-VMAT. ARC-A does not require couch rotation, therefore reducing set-up error and making it easier to combine with DIBH apparatus compared to B-VMAT. It should be considered as a practical alternative to B-VMAT. We found it useful to have a list of "aspirational" DCs for this planning comparison. In practice, however, each patient's OARs should be set based on their clinical characteristics and disease location and the best plan should be chosen after comparison of at least two techniques.

## PV-0044 Is involved-node radiotherapy for Hodgkin lymphoma safe in routine?

A. Boros<sup>1</sup>, R. Sun<sup>1</sup>, J. Arfi Rouche<sup>2</sup>, J. Lazarovici<sup>3</sup>, D. Ghez<sup>3</sup>, J.M. Michot<sup>3</sup>, A. Beaudré<sup>4</sup>, A. Danu<sup>3</sup>, J. Bosq<sup>5</sup>, V. Ribrag<sup>3</sup>, R. Mazoni<sup>1</sup>

<sup>1</sup>Institut de Cancérologie Gustave Roussy, Radiation Oncology Department, Villejuif, France

<sup>2</sup>Institut de Cancérologie Gustave Roussy, Radiology Department, Villejuif, France

<sup>3</sup>Institut de Cancérologie Gustave Roussy, Oncology Department, Villejuif, France

<sup>4</sup>Institut de Cancérologie Gustave Roussy, Radiation Physicist, Villejuif, France

<sup>5</sup>Institut de Cancérologie Gustave Roussy, Pathology Department, Villejuif, France

## Purpose or Objective

Involved-node radiotherapy (INRT) answers the need for reducing the irradiated volumes in Hodgkin lymphoma patients, in promising to reduce the risk of late morbidity. However, this concept, combined with modern radiotherapy techniques, exposes to risks of geographic misses. The purpose was to evaluate the efficiency of INRT in daily routine.

## Material and Methods

The data from patients with limited Hodgkin diseases treated with a combined modality associating

chemotherapy and INRT were reviewed. Eligibility was restricted to those with Ann-Arbor stage I-II diseases, who had a PET-CT in treatment position prior to chemotherapy. Supra diaphragmatic recurrences were sorted according to radiotherapy fields as in or out-field and their belonging to a treated lymph nodes area was examined, with the aim to state if the target would have been included in an involved-field radiation therapy (IFRT). Distance relapse was defined as a recurrence located beyond the diaphragm.

## Results

Seventy-four consecutive patients were included. Histologic subtypes were nodular sclerosis in 91%, mixed cellularity in 7%, and lymphocyte depleted in 2%. Patients' mean age at diagnosis was 37.6±13.1 years; median follow-up, 40.6 months. Initially 88% of the patients had stage II diseases and the remaining 12%, stage I. According to the EORTC (European Organization for Research and Treatment of Cancer) criteria 70% had early unfavorable diseases and 30%, early favorable diseases. All patients received ABVD, administrated in 95% of the patients for 3-4 cycles, followed by BEACOPP after 2 cycles in 2%, or combined with brentuximab in 5%. The mean RT dose was 30.9±2.0 Gy delivered in 1.8±0.05 Gy fractions. IMRT was used in 42 %, and 3D conformal radiotherapy in 18%. Deep inspiration breath hold technique (DIBH) was used in 40%, with 3D conformal radiotherapy in all but one patient (IMRT).

A total of 4 patients experienced relapses (crude incidence: 5.4%), which resulted in 3- and 5-year disease free survival rates of 96.9% and 93.8%. Three- and 5-year overall survival rates were 100% and 97.4% respectively. All four patients had supra diaphragmatic recurrences. In two patients, they consisted in a mix of in- and out-field relapses. In-field relapses occurred in regions receiving 30.6 Gy and 32.4 Gy, respectively. In the remaining two patients, relapses were out-field on both side of the diaphragm. In 2 patients out of 4, relapses were located in lymph nodes regions partially irradiated with INRT (1 and 2 areas respectively).

## Conclusion

Although the 4 reported relapses comprised out-field areas, recurrences in partially irradiated lymph node areas, which would have been potentially covered by IFRT fields, occurred in 2 patients (2.7%). On the overall, INRT, implemented in routine, yielded satisfactory outcomes in regard to published series.

## PV-0045 Estimation of internal risk volume for coronary arteries after motion evaluation with ECG-gated CT

M. Levis<sup>1</sup>, C. Fiandra<sup>1</sup>, A.R. Filippi<sup>2</sup>, F. Cadoni<sup>1</sup>, V. De Luca<sup>1</sup>, A. Cannizzaro<sup>3</sup>, D. Garabello<sup>4</sup>, S. Veglia<sup>4</sup>, R. Ragona<sup>1</sup>, U. Ricardi<sup>1</sup>

<sup>1</sup>University of Torino, Radiation Oncology, Torino, Italy

<sup>2</sup>San Luigi Hospital, Radiation Oncology, Orbassano Torino, Italy

<sup>3</sup>University of Messina, Radiation Oncology, Messina, Italy

<sup>4</sup>A.O.U. Città della Salute e della Scienza, Radiology, Torino, Italy

## Purpose or Objective

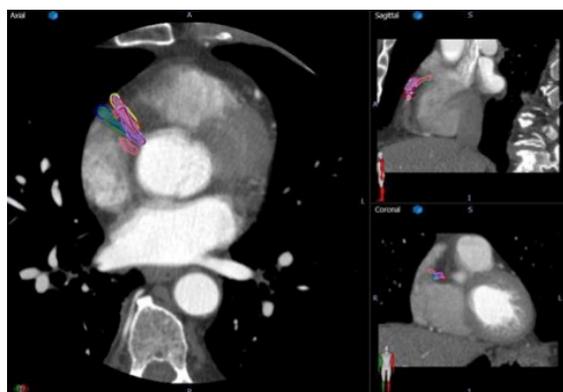

Retrospective studies in patients affected with Hodgkin lymphoma and breast cancer demonstrated a linear relationship between heart dose and the risk of coronary artery disease (CAD). In order to spare small structures such as coronary arteries (CA), a highly precise contouring is needed; however, heart motion represents an obstacle for a correct delineation. To date, the entity of motion-induced CA displacement and margins for internal risk volume (IRV) are poorly described. Aim of this study was to quantify CA displacement and then estimate IRV through the use of ECG-gated CT.

### Material and Methods

We enrolled 8 consecutive patients who were referred to the Radiological Department of our hospital for ECG-gated intravenous contrast enhanced CT. All scans were performed with the same multislice spiral CT (LIGHTSPEED, General Electric). Patients were asked to hold their breath after a mild hyperventilation. Reconstructions were performed in 10% steps over the entire R-R cycle with a dedicated retrospective ECG-gated algorithm. For all patients, 10 data sets were created and the following structures were delineated in the reconstructed sets: Left main trunk (LMT), left anterior descending (LAD), left circumflex artery (CX) and right coronary artery (RC). CA were contoured with inputs from an experienced radiologist. CA displacements across different phases of the heart cycle were evaluated in left-right (X), cranio-caudal (Y) and antero-posterior (Z) directions with the Van Herk formula ( $1.3\sigma + 0.5\sigma$ ).

### Results

The following coronary displacements were found in X, Y and Z co-ordinates, respectively: 3.6, 2.7 and 2.7 mm for LMT; 2.6, 5.0 and 6.8 mm for LAD; 3.5, 4.5 and 3.7 mm for CX; 3.6, 4.6 and 6.9 mm for RC. Figure 1 shows the axial, coronal and sagittal contours of a right coronary artery, all retrieved on one of the ten sets created for each patient.

### Conclusion

Our study shows that the CA displacement over the heart cycle ranges from 2.6 to 6.9 mm, suggesting the need for an IRV margin to accurately estimate the dose received by these structures during the planning of a thoracic irradiation. Based on these findings, we suggest to apply an isotropic margin of 3-4 mm for LMT and CX and an isotropic margin of 5-7 mm for LAD and RC.

### PV-0046 Comparison of respiratory-induced diaphragm motion during radiotherapy between children and adults

S. Huijskens<sup>1</sup>, I. Van Dijk<sup>1</sup>, J. Visser<sup>1</sup>, C. Rasch<sup>1</sup>, T. Alderliesten<sup>1</sup>, A. Bel<sup>1</sup>

<sup>1</sup>Academic Medical Center, Radiation Oncology, Amsterdam, The Netherlands

### Purpose or Objective

Respiratory motion during radiotherapy has been extensively studied in adults and often 4-dimensional computed tomography (4DCT) is used to quantify the respiratory motion prior to treatment in order to optimize safety margins. Similar data are not known for paediatric radiotherapy, and margins are therefore commonly based on adults data. The purpose of this study is to quantify and compare respiratory motion in children and adults.

### Material and Methods

Respiratory-induced diaphragmatic motion was retrospectively analysed on repeated Cone Beam CTs (CBCTs) acquired during the radiotherapy treatment course of 35 children (mean age 10.7; range 2.2-17.8) and 35 adults (mean age 59.6; range 34.0-93.0). Patients were

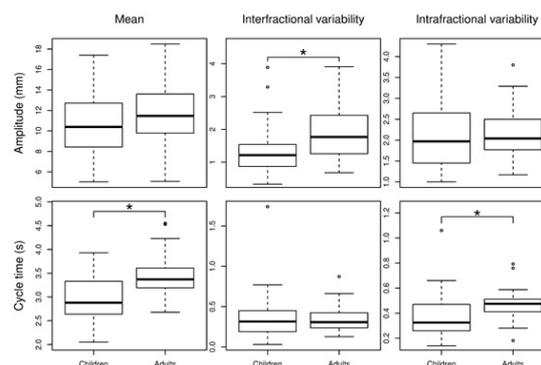

included when the diaphragm was visible on upper abdominal or thoracic free-breathing CBCTs, totaling 359 paediatric CBCTs and 374 CBCTs from adults (mean 12; range 2-33).

To measure respiratory-induced diaphragmatic motion, a two-dimensional Amsterdam Shroud image was created for each CBCT, allowing for selection of the cranio-caudal position of the end-exhale (EE) and end-inhale (EI) positions of the top of the right diaphragm. Pixel coordinates were corrected for the scanner geometry and translated into millimetres relative to the patients' isocentre.

The amplitude was defined as the displacement between EE and EI diaphragm positions. The cycle time described the time between two consecutive EI peaks. We analysed the variability of the intrafractional and interfractional respiratory motion. Differences between children and adults were tested with the Mann-Whitney-U-test, considering  $p < 0.05$  significant.

### Results

The differences in respiratory-induced diaphragmatic motion between children and adults are summarized in Figure 1. Although the mean amplitude was somewhat smaller in children than in adults (10.6 mm vs. 11.6 mm), the difference was small and insignificant. Interfractional variability in amplitude was significantly smaller in children compared to adults ( $p = 0.004$ ). Since children breath faster than adults, the cycle time was significantly briefer ( $p = 0.000$ ). Additionally, intrafractional variability in cycle time was also significantly smaller in children ( $p = 0.002$ ).

**Figure 1.** Boxplots showing the distributions of the individual means and standard deviations of respiratory-induced diaphragmatic motion in children and adults. Horizontal bars, boxes and whiskers represent median values, 50<sup>th</sup> and 90<sup>th</sup> percentiles, respectively. Circles denote outliers.

### Conclusion

We found significant, but small, differences in respiratory-induced diaphragmatic motion between children and adults. Large ranges of amplitude and cycle time in both children and adults confirm that respiratory motion is patient-specific and requires an individualised approach to account for. Unexpectedly, overall variability is smaller in children than in adults, suggesting that a pre-treatment 4DCT for planning purposes will be at least equally beneficial in children as it is in adults.

### PV-0047 Whole lung irradiation in patients with osteosarcoma and Ewing sarcoma: a systematic review

<sup>6</sup>*Fondazione di Ricerca e Cura "Giovanni Paolo II", Medical Physics Unit, Campobasso, Italy*

#### Purpose or Objective

Whole Lung Irradiation (WLI) represents a treatment option in patients with lung metastases from Ewing Sarcoma. However, prospective trials reporting impact of WLI on outcome and toxicity are few and discordant. Aim of our analysis was to systematically review the available literature to better define toxicity of WLI in patients with Ewing Sarcoma and Osteosarcoma. Secondary endpoints were overall survival (OS) and disease-free survival (DFS) analysis.

#### Material and Methods

A systematic review based on PRISMA methodology of papers reporting studies on prophylactic or curative bilateral WLI was performed using PubMed, Cochrane Library and Scopus. Combination with other treatment as chemotherapy and surgery was allowed. Only article published in English were considered.

#### Results

According to title and abstract 115 studies were screened and 12 of them met the inclusion criteria (4/12 were randomized controlled trials), reporting results on 649 patients. Clinical mild and moderate impairment as dyspnea and cough was reported in 49 patients (7.6%). Severe pneumonitis occurred in 13 patients (2.0%). Smoking significantly increased WLI toxicity and toxicity rates were higher in WLI combined with chemotherapy, surgery or radiotherapy boost. No impact of WLI on OS was described.

#### Conclusion

WLI produce a relatively low rate of radiation-induced severe effects. However, a positive impact on patients outcome was not demonstrated. New strategies to prevent or treat lung metastases have to be tested in these patients.

<sup>11</sup>*Istituto Scientifico Romagnolo per lo Studio e la Cura dei Tumori IRST- IRCCS, Radiotherapy Department, Meldola, Italy*

#### Purpose or Objective

To evaluate clinical-radiological response and outcome in patients with primary or recurrent soft tissue sarcomas (STS) of extremities treated with neoadjuvant chemoradiation.

#### Material and Methods

Sixty patients (median age 52 years, range: 23-87) with primary (54 patients, 90%) or recurrent (6 patients, 10%) STS, were treated with neoadjuvant chemotherapy (CHT) and pre-operative external beam radiotherapy (RT: 50 Gy in 25 daily fractions). Selection criteria were diseases of large dimension (> 5 cm) or in close proximity of critical structures such as nerves or vessels. The Gross Tumor Volume (GTV), defined as macroscopic disease visible in the T1-weighted sequences, was delineated based on MRI images. MRI images were merged with CT-simulation scans. For CTV definition we added a 4 cm margin in cranio-caudal direction and a 1 cm radial margin (except where anatomical barriers were present) to GTV. CTV to PTV margin was 1 cm added isotropically. All patients underwent CT scan and MRI of the interested anatomical region plus chest TC before and after RT (before surgery). For the aims of this analysis the tumor volume before and after RT was divided into quartiles.

#### Results

With a median FU of 58.5 months (range 12-116), only one patient had local relapse 24 months after surgery and was treated with surgical re-resection, with local control of the disease in the following radiological-clinical investigations. Fifteen patients (25%) developed metastases. Six out of 60 patients died (10%). Only 20 patients (33.3%) received postoperative RT-boost for marginal or intralesional margins. At preoperative MRI tumor volume showed an average reduction of 18% (range -90% to +191%). Patients with smaller tumors at diagnosis (volume < median) showed a trend for improved 5-year disease-free survival (DFS) (81.3% vs 64.3%; p=0.075). In patients with very large tumors at diagnosis (4th quartile), a significant volume reduction after RT was correlated with very high 5-year DFS (100%) and 5-year OS (100%). Patients presenting with smaller but volumetrically enlarged lesions showed worse 5-year DFS (50%) and 5-year OS (50%). Five-year DFS and OS of patients with volume of larger dimensions before and after RT (4th quartile) were 46.2% and 72.7%, respectively. Tumor reduction after neoadjuvant therapy was significantly correlated with DFS (p:0.002) and OS (p:0.027).

#### Conclusion

In this series of patients treated with preoperative RT a high LC rate was recorded. Pre-treatment and volumetric changes of tumor size significantly predicted patients outcome. Prospective studies on neoadjuvant setting of STS are necessary to improve outcome in high-risk groups.

#### PV-0049 Recurrent skull base and extra-cranial chordoma following proton therapy: clinical outcomes.

M. Kountouri<sup>1</sup>, M. Walsler<sup>1</sup>, R. Schneider<sup>1</sup>, A. Bolsi<sup>1</sup>, A. Lomax<sup>1</sup>, D. Weber<sup>1</sup>

<sup>1</sup>*Paul Scherrer Institute PSI, CPT, Villigen PSI, Switzerland*

#### Purpose or Objective

The aim of this study was to evaluate the clinical outcomes in patients diagnosed with a recurrence of a skull base or extra-cranial chordoma following treatment with pencil beam scanning (PBS) proton radiation therapy.

#### Material and Methods

Between November 1997 and December 2015, 77 patients with a mean age of 51.3 years (range 22.3 - 79.6 years) were treated for a skull base (N=38) or extra-cranial (N=39) chordoma with PBS proton therapy and later presented with a recurrence. Of those patients treated for

an extra-cranial chordoma, proton therapy was delivered as salvage treatment in 16 patients (41.6%) while the rest (58.4%) received adjuvant proton therapy. In skull base tumours, 15 patients (39.5%) were treated in salvage setting, 22 (57.9%) in adjuvant while 1 (2.6%) patient had definite proton therapy. The median administered dose was 74 Gy (RBE) (range 62 - 76 Gy (RBE)).

#### Results

Following a median follow up of 68 months (range 11.5 - 189.8 months), of those patients treated for a skull base tumour, all recurred locally except for one who presented a 'skip metastasis'. The median time to local recurrence in these patients was 31 months (range 4.4 to 152 months). In patients with skull base disease, half (N=19) were further treated with surgery, 4 patients (21%) of which had adjuvant chemotherapy, most commonly imatinib and one patient received further adjuvant radiotherapy. Of those patients who were not operated, they either received chemotherapy only (N=12), radiotherapy only (N=1) or no treatment at all (N=4) or there was no information of the treatment provided (N=3).

Of those patients treated for an extra-cranial chordoma, 13 patients (33%) presented with a distant failure and 38 patients (97%) had a local recurrence. The median time to local recurrence was 36.9 months (range 4.8 - 146.7 months). Half of these patients (N=19) were treated surgically, one of which had adjuvant chemotherapy and two radiotherapy. Of the patients who were not operated, 5 received chemotherapy only, 10 no treatment at all or there was lack of information (N=4).

Following PBS proton therapy in skull base and extra-cranial chordoma, 5-year actuarial local control (LC), distant disease free survival and overall survival (OS) following proton therapy were 19.5% (95%CI 10.7 - 28.3%), 75% (95%CI 64 - 75.1%) and 66.3% (95%CI 55.5 - 77.1%) respectively. The OS was not different if the patients were treated in the adjuvant or salvage setting, 68.6% (95%CI 54.9 - 82.3%) and 63% (95%CI 45.7 - 80.5%) respectively (p=0.96). The median time from the first recurrence after PBS proton therapy to the death was 24 months (range 0.7 - 142.3 months).

#### Conclusion

This data shows that patients diagnosed with a recurrence following spot scanning proton therapy for a skull base or extra-cranial chordoma can still have other treatment options available although once a recurrence is diagnosed the outcome is poor.

#### PV-0050 A randomised controlled study of decision aids to improve clinical trial decisions & recruitment

P. Sundaresan<sup>1,2</sup>, B. Ager<sup>3</sup>, P. Butow<sup>3</sup>, S. Tesson<sup>3</sup>, A. Kneebone<sup>2,4</sup>, D. Costa<sup>3</sup>, H. Woo<sup>2</sup>, M. Pearce<sup>3</sup>, I. Juraskova<sup>3</sup>, S. Turner<sup>2</sup>

<sup>1</sup>Crown Princess Mary Cancer Center- Westmead Hospital, Radiation Oncology, Sydney- NSW, Australia

<sup>2</sup>The University of Sydney, Sydney Medical School, Sydney, Australia

<sup>3</sup>The University of Sydney, Psycho-Oncology Co-operative Group PoCoG- School of Psychology-, Sydney, Australia

<sup>4</sup>Royal North Shore Hospital, Northern Sydney Cancer Centre, Sydney, Australia

<sup>5</sup>Auckland Hospital, Radiation Oncology, Auckland, New Zealand

#### Purpose or Objective

Randomised controlled clinical trials are considered the 'gold-standard' for evaluating medical treatments. However, recruitment to clinical trials is low overall, with both patients and clinicians reporting difficulties with the consent process. Decision Aids (DAs) may improve this process by ensuring patients weigh up the pros and cons of all their options and make informed value-sensitive decisions. DAs have demonstrated efficacy in improving knowledge and reducing decisional conflict during decision making about medical treatments. We aimed to

evaluate the utility of a DA for potential participants of a clinical trial (Trans-Tasman Radiation Oncology Group's RAVES 08.03), in reducing decisional conflict, improving knowledge and potentially improving informed trial recruitment.

#### Material and Methods

Potential participants for RAVES were identified by their urologist or radiation oncologist (RO) and invited to participate in the DA study. Participants received a pre-randomised package containing the standard RAVES participant information sheet and either the custom developed DA or a blank notebook. The packages were identical in appearance and both participant and recruiting clinician were blinded to the intervention. Questionnaire measures of decisional conflict and knowledge (including RAVES knowledge) were administered at baseline, one and six months. The primary outcome measure was decisional conflict. Secondary outcomes measured included knowledge about clinical trials and RAVES as well as recruitment to RAVES.

#### Results

127 men (median age = 63 years) were recruited through urologists (n = 91) and radiation oncologists (n = 36). 61 men were randomised to the DA arm and 66 to the control arm. Decisional conflict was significantly lower (p = 0.0476) and knowledge regarding RAVES was significantly higher (p = 0.033) in the DA arm. 18% of the DA arm (11 of 61) and 9% of the control arm (6 of 66) were recruited to RAVES. This difference did not reach statistical significance. Of the 5 men from the urologist sample who subsequently entered RAVES (5.5%), all 5 were from the DA arm (p=0.017). Of the 11 men from the RO sample who subsequently entered RAVES (30.5%), there was no significant difference in recruitment by the DA intervention (5 from DA arm vs from 6 control arm).

#### Conclusion

This study is the first to demonstrate the utility of a DA in reducing decisional conflict and improving trial knowledge in those with cancer making decisions regarding clinical trial participation. The DA also improved trial recruitment in a sub-group of patients.

#### Proffered Papers: Joint Clinical - GEC ESTRO on cervix cancer

##### OC-0051 Fatigue, insomnia, hot flashes (CTCAE) after definitive RCHT+IGABT for cervical cancer (EMBRACE)

<sup>7</sup>UZ Leuven, Department of Radiation Oncology, Leuven, Belgium

<sup>8</sup>Institute of Oncology Ljubljana, Department of Radiotherapy, Ljubljana, Slovenia

<sup>9</sup>Mount Vernon Hospital, Cancer Centre, London, United Kingdom

### Purpose or Objective

Advances in definitive treatment of locally advanced cervical cancer (LACC) have increased the number of long-time survivors and subsequently the likelihood of late and persisting treatment-related side effects.

Morbidity research has primarily focused on symptoms related to organs at risk, such as bladder, bowel, rectum or vagina. However, several patient reported outcome studies have pointed out the substantial impact of unspecific symptoms, such as fatigue, insomnia and hot flashes, on patients' quality of life.

The purpose of this descriptive report is to evaluate the pattern of development of these symptoms during the first years of follow-up within the prospective, observational, multi-center EMBRACE study (An international study on MRI-guided brachytherapy in locally advanced cervical cancer).

### Material and Methods

From 2008-2015, 1419 LACC patients were included in the study and treated with combined EBRT ± chemotherapy and MRI-guided brachytherapy following the GEC-ESTRO guidelines.

Fatigue, insomnia and hot flashes were prospectively assessed according to CTCAE v.3 at baseline, every 3 months (1<sup>st</sup> year), and every 6 months (2<sup>nd</sup>, 3<sup>rd</sup> year) and yearly thereafter. Analyses of crude incidence showing the maximum grade over all follow-ups, prevalence rates showing the proportion of grades in each follow-up and actuarial probabilities (Kaplan-Meier method) were performed.

### Results

In 1176 patients from 22 centers, information on morbidity was available at baseline and follow-up, with a median follow-up time of 27 months.

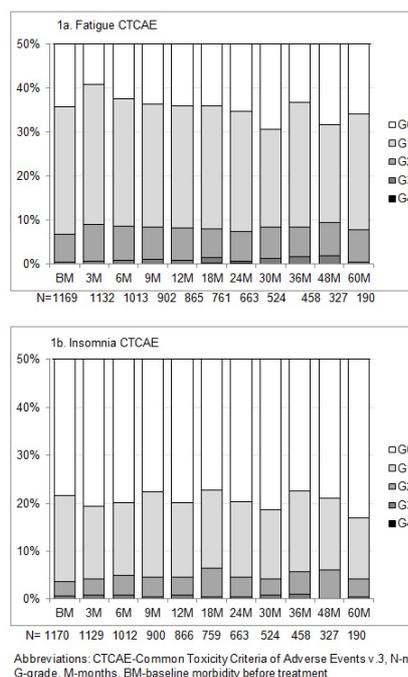

Crude incidence rates revealed disabling G4 fatigue in two patients. Furthermore, severe G3 morbidity occurred rarely (all ≤ 4%). Moderate G2 morbidity was shown in 15% (hot flashes), 11% (insomnia) and 20% (fatigue). However, mild G1 morbidity was pronounced with 33%, 29% and 40%, respectively. The actuarial estimates for G≥1 are summarized in table 1 and display consistently a high risk at 5 years for hot flashes (61.3%), insomnia (54%) and fatigue (72.8%).

The prevalence rates revealed that both fatigue and insomnia were already present at baseline and both symptoms did neither resolve nor worsen over time (figure 1a and 1b). The proportion of hot flashes increased considerably at the first follow-up after treatment and remained quite stable over time with only a small descriptive trend for improvement in G1 and G2.

**Table 1:** Actuarial estimates of fatigue, insomnia and hot flashes G≥1, G≥2, G≥3 at 3 and 5 years; crude incidence rate as maximum grading over all follow-ups.

Actuarial estimates Kaplan-Meier	Events	Total	3y estimates	5y estimates	Crude incidence rate
Fatigue G≥1	750	1170	70.9%	72.8%	G1: 40%
Fatigue G≥2	283	1170	28.9%	33.8%	G2: 20%
Fatigue G≥3	46	1170	5.0%	6.7%	G3: 4%
Insomnia G≥1	503	1168	51.4%	54%	G1: 29%
Insomnia G≥2	166	1168	17.3%	20.6%	G2: 11%
Insomnia G≥3	35	1168	4.1%	4.7%	G3: 3%
Hot flashes G≥1	584	1175	55.4%	61.3%	G1: 33%
Hot flashes G≥2	192	1175	20.4%	21.9%	G2: 15%
Hot flashes G≥3	18	1175	1.9%	2.2%	G3: 2%

**Figure 1a.** Prevalence rates of prospectively physician assessed fatigue and **1b.** insomnia according to CTCAE v.3.

### Conclusion

Fatigue, insomnia and hot flashes are prevalent after definitive treatment for LACC, mainly in the mild to moderate range, and do not resolve over time. Although both fatigue and insomnia are already present at baseline and seem to be not influenced by treatment, more research is needed to evaluate various risk factors in order to define intervention strategies which are available for hot flashes (hormonal replacement). In addition, the impact of these symptoms on patients' quality of life needs to be determined in future projects, taking also patient reported outcomes into account.

### OC-0052 Physician assessed and patient reported bladder morbidity after RCHT and IGABT for cervical cancer

<sup>3</sup>Gustave-Roussy, Department of Radiotherapy, Paris, France

<sup>4</sup>Tata Memorial Hospital, Department of Radiotherapy, Mumbai, India

<sup>5</sup>Utrecht University, Department of radiotherapy, Utrecht, The Netherlands

<sup>6</sup>Institute of Oncology Ljubljana, Department of

Oncology, Ljubljana, Slovenia

<sup>7</sup>Mount Vernon Cancer Centre, Department of Radiotherapy, Northwood, United Kingdom

#### Purpose or Objective

Bladder morbidity is a well known side effect to radiochemotherapy of locally advanced cervical cancer (LACC). The EMBRACE study is a prospective multi-institutional study with focus on MR image guided adaptive brachytherapy (IGABT) in LACC. The study includes registration of physician assessed morbidity and patient reported outcome (PRO). This analysis evaluates bladder morbidity with both assessment methods

#### Material and Methods

Out of 1419 patients recruited for the EMBRACE study, 1176 patients with assessment of bladder morbidity were analysed. Treatment included external beam radiotherapy with prescribed dose 45-50 Gy in 25-30 fx with concomitant cisplatin in 95% of the patients. IGABT was delivered with HDR BT (57%) or PDR BT (43%). Total mean  $D_{2cm3}$  to the bladder was 76.6 Gy. Median follow up (FU) was 27M (months). Morbidity and PRO was assessed according to the CTCAE v.3 and EORTC QLQ-CX24 at baseline (BL), every 3M (year 1), every 6M (year 2-3) and annually thereafter. Patients reporting "quite a bit" or "very much" bladder symptoms in EORTC were considered as clinically relevant endpoint analogue to CTCAE G2 and G3. Morbidity and PRO were analysed with crude incidence, prevalence rates, and actuarial estimates

#### Results

Prevalence of urinary frequency CTCAE G<sub>≥2</sub> ranges between 4-5%, irrespectively of FU time, PRO "frequent urination" ranges between 14-23%. Urinary incontinence CTCAE G<sub>≥2</sub> increases gradually from 3% (BL) to 5% at 60M, PRO "leaking of urine" increases from 5% (BL) to 11% at 60M. Prevalence of bladder bleeding CTCAE G<sub>≥1</sub> is reported in 1% (BL) and progresses to a maximum of 5% at 36M, followed by a reduction to 2% at 60M. This manifestation pattern is also seen for bladder cystitis CTCAE G<sub>≥2</sub> which increases from 1% (BL) to a maximum of 3% at 30M, and decreases slightly thereafter. PRO such as "difficulty emptying the bladder" is slightly increasing during FU, while disturbance during a "burning sensation during urination" is slightly reduced. Actuarial estimates at 5-year of CTCAE G<sub>≥2</sub> was 16.4%, 16.2% and 11.0% for incontinence, frequency, and cystitis, respectively. Severe bladder morbidity (ureter stenosis analysed separately) CTCAE G<sub>≥3</sub> was recorded in 39 patients (54 events), corresponding to an actuarial estimate of 4.7% risk at 5-years. G<sub>≥3</sub> morbidity was 2.1%, 1.9%, 1.5%, and 0.7% at 5-years, for incontinence, frequency, cystitis and bladder fistula, respectively. Ureter stenosis G<sub>≥3</sub> (19 patients) was found in 3.4% at 5-year (patients with BL ureter stenosis excluded). There was no G5 bladder morbidity

#### Conclusion

Bladder morbidity shows different manifestation patterns. Urinary frequency fluctuates during FU, while incontinence progresses. Bladder bleeding, cystitis and patient reported "burning sensation" progress to reach a maximum prevalence followed a tendency to resolve at later FU. Further studies have to explore these findings and relate them to patient and treatment parameters in order to find strategies to reduce bladder morbidity in future radiotherapy.

#### OC-0053 Physician assessed and patient reported limb edema after RCHT + IGABT for cervical cancer (EMBRACE)

D. Najjari Jamal<sup>1</sup>, S. Smet<sup>1</sup>, N. BK Jensen<sup>2</sup>, L. Fokdal<sup>2</sup>, J.C. Lindegaard<sup>2</sup>, C. Kirisits<sup>1</sup>, C. Chargari<sup>3</sup>, U. Mahantshetty<sup>4</sup>, I.M. Jügentliemk-Schulz<sup>5</sup>, B. Segedin<sup>6</sup>, P. Hoskin<sup>7</sup>, K. Tanderup<sup>2</sup>, R. Pötter<sup>1</sup>, K. Kirchheiner<sup>1</sup>  
<sup>1</sup>Medical University of Vienna / General Hospital of Vienna, Department of Radiation Oncology-

Comprehensive Cancer Center, Vienna, Austria

<sup>2</sup>Aarhus University Hospital, Department of Oncology, Aarhus, Denmark

<sup>3</sup>Gustave-Roussy, Department of Radiotherapy, Villejuif, France

<sup>4</sup>Tata Memorial Hospital, Department of Radiation Oncology, Mumbai, India

<sup>5</sup>University Medical Centre Utrecht, Department of Radiation Oncology, Utrecht, The Netherlands

<sup>6</sup>Institute of Oncology, Department of Radiotherapy, Ljubljana, Slovenia

<sup>7</sup>Mount Vernon Hospital, Cancer Centre, London, United Kingdom

#### Purpose or Objective

Treatment-related limb edema of the lower extremities after definitive radiochemotherapy for locally advanced cervical cancer has been reported to have a substantial impact on patients' well-being and body image. The aim of this report is to evaluate the manifestation pattern of limb edema during the first years of follow-up within the prospective, observational, multi-center EMBRACE study ([www.embracestudy.dk](http://www.embracestudy.dk)).

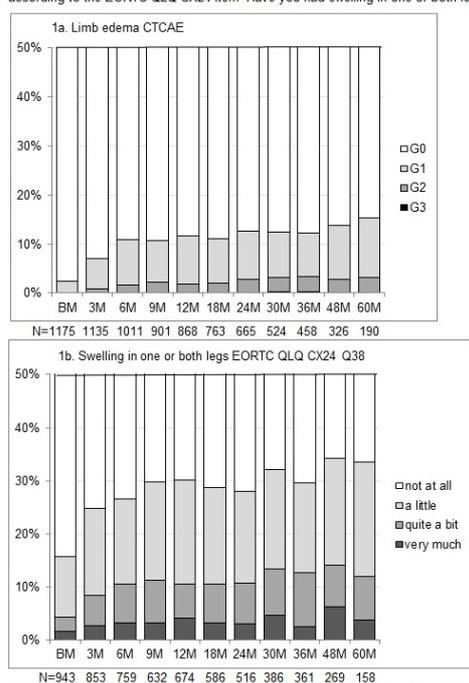

#### Material and Methods

The analysis was based on 1419 locally advanced cervical cancer patients enrolled from 2008-2015 who underwent combined external beam radiotherapy (either with 3D conformal technique or IMRT to 45-50Gy) ± concurrent chemotherapy and MRI-guided brachytherapy following the GEC-ESTRO guidelines. In case of pathological lymph nodes, a boost to 55-65Gy was applied. Limb edema was prospectively assessed with physician assessed common toxicity criteria for adverse events (CTCAE v.3) and patient reported EORTC quality of life questionnaire (module CX24, Q38) at baseline before treatment, every 3 months (1<sup>st</sup> year), and every 6 months (2<sup>nd</sup> and 3<sup>rd</sup> year) and yearly thereafter. Crude incidence rates, prevalence rates and actuarial estimates using the Kaplan-Meier method were analyzed.

#### Results

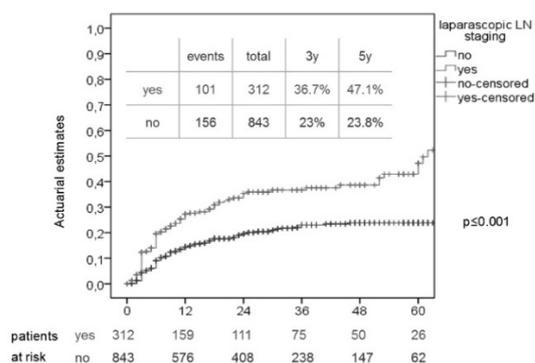

Information on limb edema at baseline and follow-up was available for analysis in 1176 patients regarding CTCAE (943 patients regarding EORTC) from 22 centers with a median follow-up of 27 months (range 1-85 months). Crude incidence rates of limb edema were 18% for CTCAE G1, 4% for G2 and <1% for G3 (n=4 patients); no G4 or G5 morbidity occurred. The progressive manifestation pattern of limb edema is reflected in the gradually increasing prevalence rates as shown in in figure 1a for CTCAE and 1b for EORTC outcome. Actuarial analyses revealed a 3-year/5-year probability of 0.5%/0.5% for G<sub>≥3</sub>, 6.1%/6.6% for G<sub>≥2</sub> and 26.5%/30.7% for G<sub>≥1</sub>. Laparoscopic lymph node staging increased the risk for the development of G<sub>≥1</sub> limb edema significantly (p<0.001) with an actuarial risk at 5 years of 23.8% versus 47.1% (figure 2).

**Figure 1a:** Prevalence rates of prospectively physician assessed limb edema, according to CTCAE v.3. **1b:** Prevalence rates of prospectively assessed patient reported limb edema, according to the EORTC QLQ CX24 item "Have you had swelling in one or both legs?"

Abbreviations: BM-baseline morbidity before treatment, M-months, N-number, G-grade

**Figure 2:** Impact of laparoscopic lymph node staging on CTCAE limb edema G $\geq$ 1

Abbreviations: LN-lymph node, y-year, G-grade

## Conclusion

Moderate to severe limb edema G $\geq$ 2 is limited in the first years after definitive radiochemotherapy including MRI-guided adaptive brachytherapy. Mainly mild limb edema CTCAE G1 with 5-10% inter-limb discrepancy in volume or circumference at point of greatest visible difference is observed. Nevertheless, a proportion of 8-14% of patients reports "quite a bit" and "very much" swelling of one or both legs during follow-up. Limb edema shows a progressive manifestation pattern over time both in the physician assessed and the patient reported outcome. Laparoscopic lymph node staging bears a considerable risk for the development of G $\geq$ 1 limb edema. Further investigations are needed to evaluate various specific risk factors in a multivariate model.

## OC-0054 Dynamics of patient reported QoL and symptoms after IGRT for locally advanced cervical cancer

S.T. Heijkoop<sup>1</sup>, R.A. Nout<sup>2</sup>, S. Quint<sup>1</sup>, J.W.M. Mens<sup>1</sup>, B.J.M. Heijmen<sup>1</sup>, M.S. Hoogeman<sup>1</sup>

<sup>1</sup>Erasmus MC Cancer Institute, Radiation Oncology, Rotterdam, The Netherlands

<sup>2</sup>Leiden University Medical Center, Radiation Oncology, Leiden, The Netherlands

## Purpose or Objective

In this study, locally advanced cervical cancer patients are treated with an online adaptive Plan-of-the-Day (PotD) protocol, using a daily CBCT to select the plan that best fits the observed anatomy of that day from a patient-specific plan library. The objective is to reduce unnecessary dose to healthy normal organs and to maintain a favorable Quality of Life (QoL). Patient reported health-related QoL and symptoms, during and in the first year after treatment, were prospectively scored. Results are reported here.

## Material and Methods

Between January 2012 and March 2016, all locally advanced cervical cancer patients treated with the PotD protocol and brachytherapy with or without chemotherapy or hyperthermia were eligible. QoL was assessed at baseline; weekly during the first five weeks of treatment; 1 week and 1, 3, 6 and 12 months after treatment, using the EORTC QLQ-C30 and the QLQ-CX24 questionnaires. Comparisons were made with an age-matched norm population.

## Results

From January 2012 until March 2016 a total of 167 locally advanced cervical cancer patients were treated with a PotD protocol, of which 123 (74%) were included as responders (baseline score and at least 1 additional questionnaire). Scores of EORTC QLQ-C30 functioning and global health scales are shown in figure 1. At baseline, scores of all functional scales except global health status were lower compared to the age-matched norm population. Global health and functioning were temporarily decreased and returned to a plateau at baseline level 3 months after treatment, except for cognitive functioning. Compared to the norm population all functioning scores, except global health showed either a small decrease or a medium decrease (cognitive functioning) 1 year after treatment.

Scores of symptoms and sexual functioning are provided in figure 2. Most symptoms showed a moderate-to-large increase, reaching a maximum at the end of treatment (5<sup>th</sup> week), or first week after treatment with a return to baseline at 3 months. However, several symptoms persisted during further follow-up (diarrhea, bowel cramps, dysuria, pain, fecal leakage, insomnia, tingling/numbness). While most symptoms gradually increased during the first five weeks, diarrhea and bowel cramps already markedly increased within the first three weeks to reach a plateau at the 5<sup>th</sup> week of treatment. Sexual/vaginal symptoms became apparent after treatment and increased in the first year after treatment. The increased vaginal symptoms were paralleled by increased sexual worrying and decreased sexual enjoyment.

Figure 1. Patient functioning scales (0 – 100) from the EORTC QLQ-C30. Mean  $\pm$  95% confidence intervals between 40 and 100 are shown. The dotted line indicates reference values from an age-matched Dutch female population cohort.

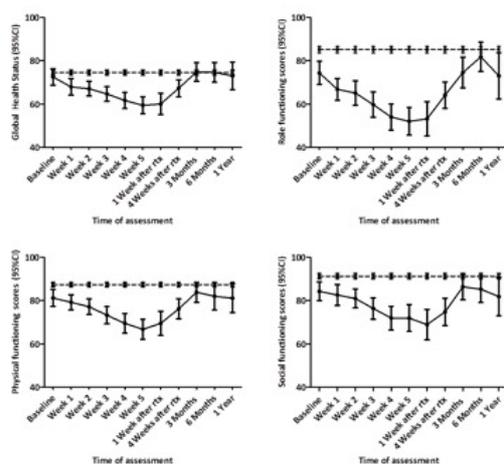

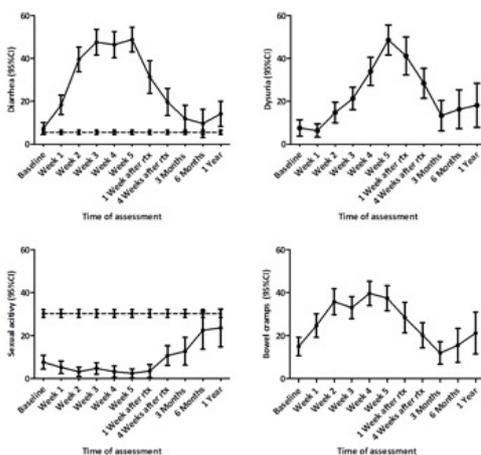

Figure 2. Symptom scales (0 – 100) from the EORTC QLQ-C30 and EORTC QLQ-CX24. Mean  $\pm$  95% confidence intervals between 0 and 60 are shown. The dotted line indicates reference values from an age-matched Dutch female population cohort.

## Conclusion

Treatment had a profound impact on QoL. For some systems this was temporarily, other symptoms persisted during further follow-up. End of external beam treatment is the most sensitive time point to measure future improvements in online adaptive radiotherapy with a PotD approach.

## OC-0055 Local failures after radiochemotherapy and MR-image-guided brachytherapy in cervical cancer patients

M. Schmid<sup>1</sup>, C. Haie-Meder<sup>2</sup>, U. Mahantshetty<sup>3</sup>, I.M. Jürgenliemk-Schulz<sup>4</sup>, B. Segedin<sup>5</sup>, P. Hoskin<sup>6</sup>, C. Kirisits<sup>7</sup>, J. Lindegaard<sup>8</sup>, K. Tanderup<sup>8</sup>, R. Pötter<sup>7</sup>

<sup>2</sup>Gustave Roussy, Department of Radiotherapy, Paris, France

<sup>3</sup>Tata Memorial Hospital, Department of Radiation Oncology, Mumbai, India

<sup>4</sup>Utrecht University, Department of Radiation Oncology, Utrecht, The Netherlands

<sup>5</sup>Institute of Oncology, Department of Oncology, Ljubljana, Slovenia

<sup>6</sup>Mount Vernon Cancer Center, Department of Radiotherapy, Northwood, United Kingdom

<sup>7</sup>Medical University of Vienna, Department of Radiation Oncology, Vienna, Austria

<sup>8</sup>Aarhus University Hospital, Department of Oncology, Aarhus, Denmark

## Purpose or Objective

To report patterns of local failure (LF) after radiochemotherapy and MR-image-guided adaptive brachytherapy (IGABT) in patients with locally advanced cervical cancer (LACC) observed within the international prospective observational multicenter study „EMBRACE“ (An international study on MRI-guided brachytherapy in locally advanced cervical cancer, [www.embracestudy.dk](http://www.embracestudy.dk)).

## Material and Methods

From 2008-2015, 1419 patients with LACC treated with radiochemotherapy and MR-IGABT (GEC-ESTRO recommendations) were included in the study. 1230 patients with completed treatment without major protocol violations (n=73) and with at least one follow up examination were available for this analysis (106 excluded). A LF was defined as incomplete remission in case of persistent disease 3 months after treatment which did not resolve at six months and as local recurrence after complete remission in case of recurrent disease. LFs were described based on their relation to (1) the clinical target volumes (CTV) and to (2) infiltrated organs / compartments.

## Results

After a median follow-up of 25 months 80 local failures (24 incomplete remissions and 56 local recurrences) were observed. Synchronous nodal or distant metastases were reported in 42 patients (52%, not reported: 5%). Median time to local recurrence was 11.5 months, 47 (86%) occurred within 24 months. Information about the location of LF was available in 63 patients (79%): The cervix and uterus were involved in 50 patients (80%), the proximal parametria in 8 patients (13%), the distal parametria/pelvic wall in 18 patients (29%), the vagina in 18 patients (29%), the urinary bladder in 12 patients (19%) and the rectum in 2 patients (3%), respectively (more than one location possible). An allocation to CTV was possible in 53 patients (66%): In 51% the LF were located inside the high risk (HR) CTV (n=27), in 17% inside the intermediate (IR) CTV (n=9) and in 30% inside the HR+IR CTV (n=16). 2% was not related to the CTVs (n=1).

## Conclusion

Local failures occur in a very limited number of patients after radiochemotherapy and IGABT. They are in about 50% synchronous with nodal or distant disease. The vast majority occurs within two years. Most patients fail locally within the HRCTV and IR CTV.

## OC-0056 Bowel morbidity in cervix cancer after RCHT+IGABT; physician and patient reported outcome - EMBRACE

N.B.K. Jensen<sup>1</sup>, K. Kirchheiner<sup>2</sup>, L.U. Fokdal<sup>1</sup>, J.C. Lindegaard<sup>1</sup>, C. Kirisits<sup>2</sup>, R. Mazon<sup>3</sup>, U. Mahantshetty<sup>4</sup>, B. Segedin<sup>5</sup>, I.M. Jürgenliemk-Schulz<sup>6</sup>, P.J. Hoskin<sup>7</sup>, R. Pötter<sup>2</sup>, K. Tanderup<sup>1</sup>

<sup>1</sup>Aarhus University Hospital, Department of Oncology, Aarhus C, Denmark

<sup>2</sup>Medical university of Vienna / General Hospital of Vienna, Department of Radiation Oncology-Comprehensive Cancer Center, Vienna, Austria

<sup>3</sup>Gustave-Roussy, Department of Radiotherapy, Villejuif, France

<sup>4</sup>Tata Memorial Hospital, Department of Radiation Oncology, Mumbai, India

<sup>5</sup>Institute of Oncology Ljubljana, Department of Radiotherapy, Ljubljana, Slovenia

<sup>6</sup>University Medical Centre Utrecht, Department of Radiation Oncology, Utrecht, The Netherlands

<sup>7</sup>Mount Vernon Hospital, Cancer Centre, London, United Kingdom

**Purpose or Objective**

To provide a descriptive overview of the prospectively collected physician assessed bowel morbidity and patient reported outcome (PRO) within the multicenter EMBRACE study, and to jointly evaluate the development of individual symptoms.

**Material and Methods**

The analysis was based on 1419 patients enrolled from 2008-2015. Treatment included image guided adaptive brachytherapy (IGABT) and EBRT delivered either by 3-D conformal technique or IMRT/VMAT and chemotherapy. Prescribed doses were 45-50Gy in 1.8-2.0Gy fractions. If pathological lymph nodes were present, a boost to 55-65Gy was given. Morbidity was assessed according to the CTCAE v.3 and PRO according to EORTC QLQ C30/CX24 at baseline, every 3 months (1<sup>st</sup> year), every 6 months (2<sup>nd</sup> and 3<sup>rd</sup> year) and yearly thereafter. Bowel endpoints evaluated were diarrhea, flatulence, incontinence, stenosis and fistula, all graded from 0 to 5 (flatulence G0-G2). The related PRO was included with following reportings; “a little”, “quite a bit” and “very much”. Relevant cut-off values were applied to report CTCAE and PRO: G<sub>≥</sub>2 and G<sub>≥</sub>1 versus “very much” and “≥”a little”. Crude incidences, prevalences and actuarial estimates were calculated.

**Results**

Baseline morbidity (BM) and follow up (FUP) information was available for 1176 patients (PRO 942). Median follow up was 27 months, 63% were treated with 3-D CRT and 37% with IMRT/VMAT. Figure 1 illustrates the bowel symptoms with prevalence rates at 5 years for diarrhea at 24% for G<sub>≥</sub>1, and 4% for G<sub>≥</sub>2 (CTCAE). According to PRO, any patient reported diarrhea was 35% and 3% for “very much”. Both reached a plateau at a certain level during FUP. Incontinence occurred in 9% as G<sub>≥</sub>1 and 2% as G<sub>≥</sub>2. For PRO any patient reported difficulty in controlling bowel was 29% and 3% for “very much”, both with increasing prevalence during FUP. Crude incidences of severe diarrhea and incontinence (G<sub>≥</sub>3, CTCAE) were 1.5% and 0.4%, respectively. Sigmoid, small bowel and colon stenosis G<sub>≥</sub>2 were present in 16 patients with 12 being G3/G4 with only one morbidity-related death because of necrotizing enteritis. Fistula G<sub>≥</sub>2 were present in 6 patients. Crude incidences and actuarial estimates are shown in table 1.

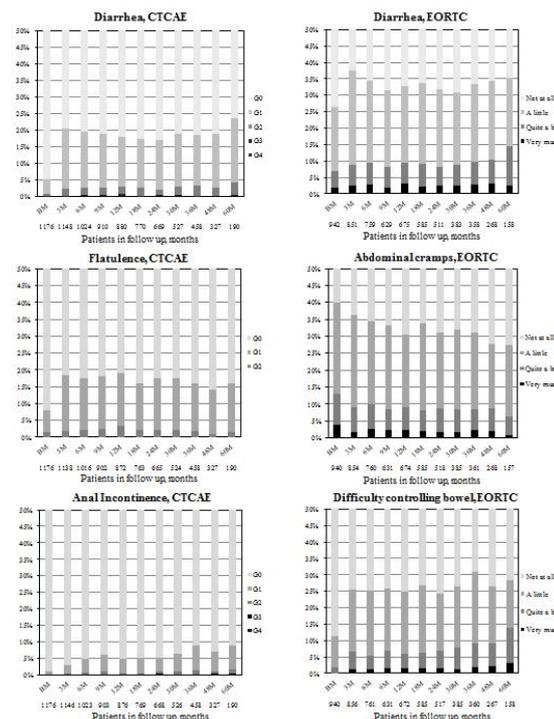

Figure 1. Prevalence rates for bowel endpoints at baseline and during 60 months of follow up. CTCAE v3.0 and PRO (EORTC GoL).

Bowel endpoints, CTCAE	BL N=1176	12M N=872- 880	24M N=665- 669	36M N=458	48M N=327	60M N=190	Crude incidence	60M Actuarial estimates

Table 1. Prevalence rates, crude incidences (up to 60M) and actuarial estimates of individual bowel endpoints; CTCAE v3.0 and PRO (EORTC GoL).

**Conclusion**

According to the data assessed within the EMBRACE study, bowel morbidity is overall frequently reported, however, severe morbidity is limited. The results indicate that patients report higher burden of bowel symptoms, however no direct correlation is possible between both assessment methods. The challenge is to find a practical way of interpreting the complementary information from PRO regarding morbidity. The data illustrate that different methodologies for quantification of morbidity provide different results, with actuarial analysis indicating higher magnitude than prevalence rates. In the future, better methods for quantifying relevance and burden of symptoms are warranted to further improve our morbidity profile in cervix cancer patients.

**SP-0057 Mechanisms and biomarkers of tumour response heterogeneity**
**S. Chopra<sup>1</sup>**
<sup>1</sup>*Advanced Centre for Treatment- Research and Education in Cancer- Mumbai, Radiation Oncology, Mumbai, India*

Heterogeneity of response to therapeutic radiation is a well-known phenomenon and is attributed to differential evolution of tumour subpopulations that may harbor resistant clones. Aberrant vasculature during early tumour growth results in heterogenous microenvironment. Tumour hypoxia and resultant acidic microenvironment therefore becomes an early event triggering various downstream pathways that support development and sustenance of aggressive tumour phenotype. Hypoxic environment is known to allow clonal evolution of stem cell phenotype through expression of stem cell genes like SOX-2/OCT-4/NANOG and increase in reactive oxygen species which may in turn lead to increased DNA damage repair and reduced cell kill after radiation, epithelial to mesenchymal transformation and distant metastasis. Recent research suggests that cancer stem cells may not be in a fixed but in a dynamic state of cellular plasticity that is dependent on the microenvironment stimulus. Specific niching patterns for cells with stem cell phenotype have been identified for certain tumour types. As microenvironment may play a crucial role in nurturing and sustaining aggressive cellular phenotypes, there may be considerable merit in imaging and targeting microenvironmental niches with radiation. The role of the above possible mechanisms in radiation resistance and biomarkers that may be linked to aggressive cellular phenotype and tumour milieu will be discussed with specific examples from solid tumours that are treated with radiation.

**SP-0058 Current status and future perspective of response adaptation**
**D. Zips<sup>1</sup>**
<sup>1</sup>*University Hospital Tübingen Eberhard Karls University Tübingen, Tübingen, Germany*

In my presentation I will introduce the rationale of the biological concept of delta imaging for individualized patient management. I will discuss supporting findings and preclinical proof-of-concept using PET/ fMRI and I will review current clinical evidence with examples in HN, rectal, prostate cancer.

**SP-0059 Response optimised treatment planning and guidance**
**B. Vanderstraeten<sup>1</sup>**
<sup>1</sup>*University Hospital Ghent, Radiotherapy - RTP, Gent, Belgium*

Biological imaging modalities like PET or fMRI aim to unravel tumor heterogeneity, e.g. by identifying the most radiation resistant parts of a tumor. As the total dose that can be delivered is limited by normal tissue toxicity, biological image-guided radiotherapy opts for dose modification based on pre-treatment imaging or per-treatment response assessment. The dichotomous nature of target contouring, where voxels are either “in” or “out” and hence intended to receive a homogeneous or no dose, is not in agreement with reality. Dose painting by numbers has been suggested to translate treatment response to dose modification by means of a voxel-based dose prescription.

Despite the present uncertainties about the applicability of dose painting and the need for accurate biological models, physicists and technologists should be prepared

for the challenges that per-treatment dose modification poses to treatment planning and delivery systems. This lecture will focus on the realization of individual dose modification in treatment planning, including different treatment modalities and techniques, treatment planning system requirements, the feasibility of dose painting in adaptive treatment schedules and automated planning. Practical examples for head and neck and prostate cancer will be shown.

The higher the intentional inhomogeneity of the dose distribution, the higher the risk of getting things wrong during treatment delivery because of set-up errors or changes in patient anatomy. Apart from treatment adaptation, it is important to minimize the uncertainties in delivery and account for residual uncertainties in planning. Using statistical models to predict tumor presence on a voxel level, the robustness against geometric errors can be improved. Because of the existing technical challenges, extensive collaboration between radiologists, radiation biologists, radiation oncologists and physicists is needed.

**OC-0060 Reference dosimetry of proton pencil beams based on dose-area product**
**C. Gomà<sup>1</sup>, S. Safai<sup>2</sup>, S. Vörös<sup>3</sup>**
<sup>1</sup>*University Hospitals Leuven, Department of Radiation Oncology, Leuven, Belgium*
<sup>2</sup>*Paul Scherrer Institute, Center for Proton Therapy, Villigen PSI, Switzerland*
<sup>3</sup>*Federal Institute of Metrology METAS, Ionising Radiation, Bern-Wabern, Switzerland*
**Purpose or Objective**

To study the feasibility of a novel approach to the reference dosimetry of proton pencil beams based on dose-area product (DAP<sub>w</sub>)—the integral of the absorbed dose to water (D<sub>w</sub>) over the plane perpendicular to the beam direction. The DAP<sub>w</sub> of a proton pencil beam is a quantity needed for beam modeling in most TPS. Currently, it is calculated indirectly through the determination of D<sub>w</sub> in a broad composite field together with the reciprocity theorem. This work investigates the direct determination of DAP<sub>w</sub> with reference dosimetry.

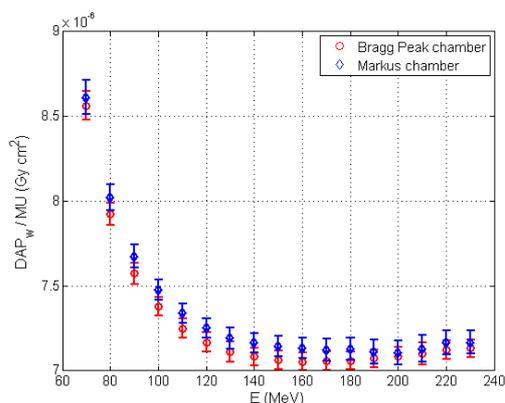

**Material and Methods**

The reciprocity theorem establishes an analytical relationship between (i) the DAP<sub>w</sub> of a single proton pencil beam and (ii) the D<sub>w</sub> at the center of a broad composite field generated by the superposition of proton pencil beams regularly-spaced at a distance of  $\delta x$  and  $\delta y$  (DAP<sub>w</sub> = D<sub>w</sub>  $\delta x \delta y$ ). The feasibility of reference dosimetry based on DAP<sub>w</sub> (DAP<sub>w</sub> = M<sub>Q</sub> · N<sub>DAP,w</sub> · k<sub>Q</sub>) was therefore assessed by comparison with the standard and well-established reference dosimetry in a composite 10x10 cm<sup>2</sup> field based on D<sub>w</sub> (D<sub>w</sub> = M<sub>Q</sub> · N<sub>D,w</sub> · k<sub>Q</sub>). First, we calibrated a PTW Bragg Peak chamber (BPC) and a PTW Markus chamber in a PSDL <sup>60</sup>Co beam, in terms of DAP<sub>w</sub> and D<sub>w</sub> respectively. Second, we calculated the beam quality correction factor (k<sub>Q</sub>) of the two ionization chambers using Monte Carlo simulation. Finally, we compared (i) the direct determination of DAP<sub>w</sub> of a single pencil beam using the BPC, and (ii) the indirect determination of DAP<sub>w</sub> (DAP<sub>w</sub> = D<sub>w</sub>  $\delta x \delta y$ ) using the Markus chamber to determine D<sub>w</sub> at the center of a broad composite field. The two approaches were compared for proton energies ranging from 70 to 230 MeV.

**Results**

The BPC was successfully calibrated in terms of DAP<sub>w</sub> in a <sup>60</sup>Co beam. The uncertainty of the calibration coefficient was estimated to be 0.2% larger than in the standard case, due to the uncertainty in the BPC sensitive area. Figure 1 shows that direct and indirect determination of DAP<sub>w</sub> were

found to agree within one standard uncertainty or better, for all proton energies.

**Figure 1:** Beam monitor chamber calibration curve in terms of  $DAP_w$  (at  $z_{ref} = 2$  cm) per MU, as a function of nominal proton energy, obtained with the Bragg Peak chamber (direct) and Markus chamber (indirect). The uncertainty bars correspond to one standard uncertainty.

#### Conclusion

This work proves the feasibility of the reference dosimetry of proton pencil beams based on  $DAP_w$ , as it agrees with the standard and well-established approach based on  $D_w$  within one standard uncertainty. Its main advantage is that it is not affected by the uncertainty in beam position, which results in an uncertainty in  $\delta x$  and  $\delta y$ . Its main drawback is the slightly larger uncertainty of the ionization chamber calibration coefficient. This drawback, however, could potentially pay off in the dosimetry of small photon fields, where perturbation factors of small detectors might result in a larger source of uncertainty.

**OC-0061 Development of a 3D plastic Scintillator detector for a fast verification of ocular proton beam**  
H. Ziri<sup>1</sup>, D. Robertson<sup>1</sup>, S. Beddar<sup>1</sup>  
<sup>1</sup>MD Anderson Cancer Center, Department of radiation physics, Houston, USA

#### Purpose or Objective

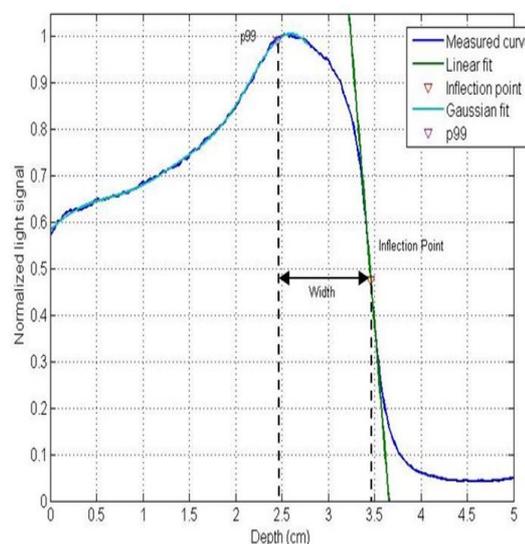

Scintillator detectors have been recently used for beam verification in radiation dosimetry. However, when irradiated with charged particles, scintillators undergo an ionization quenching effect that causes a decrease of the scintillation light emission with increasing linear energy transfer (LET). The goal of this project is to develop a tool for ocular proton beam quality assurance (QA) using a solid plastic scintillator without the need for quenching correction.

#### Material and Methods

**Figure:** Landmarks identification for range and SOBP width measurements

The measurements were done at the Proton Therapy Center-Houston (PTC-H). The detector system consists of a  $5 \times 5 \times 5$  cm<sup>3</sup> cube of a plastic scintillator, EJ-260, that converts the incident proton beam into visible light and a telecentric lens coupled to a CCD camera to image the emitted light distribution. Landmarks were determined directly on the quenched light-depth distribution to determine the range and spread-out Bragg peak (SOBP) width of the beam. A common behavior of having an inflexion point at the distal edge was noticed in the measured scintillation light profiles. The range was determined as the corresponding depth of that point. To identify the inflexion point, a linear function was fitted to the distal edge. Then, to determine the SOBP width, the assumption that quenching is negligible at the beginning of the SOBP was considered. A Gaussian fit was used to smooth the curve and get better estimation of the starting point of the SOBP. An empirical analysis showed that the

use of the 99% level of the proximal part (p99) of the normalized light curve, as the starting point of the SOBP seemed more appropriate to get accurate SOBP width measurement. The measured SOBP width corresponds then, to the distance between that identified point and the measured range.

**Figure:** Landmarks identification for range and SOBP width measurements

#### Results

The validity and the accuracy of this method was evaluated by comparison to ionization chamber measurements. The measured ranges were in good agreement with the ionization chamber measurements. The mean difference was within 0.05 cm and the standard deviation was within 2%. The measured SOBP widths, for a nominal range of 3.5 cm, were compared to the ionization chamber measured SOBP widths. The mean difference was within 0.06 cm and the standard deviation was less than 4%. SOBP width measurements were also in a good agreement with ionization chamber measurements.

#### Conclusion

Even though quenching decreases the emitted light with the increase of LET with depth, landmarks can still be identified for fast beam verification without the need for quenching correction. It has been shown that the developed approach works for different beam energies with a sufficient accuracy and reproducibility for clinical use. The accuracy of this approach is within 0.06 cm for range and SOBP width measurement for the ocular proton beam.

**OC-0062 Correcting for linear energy transfer dependent quenching in 3D dosimetry of proton therapy**

E.M. Høye<sup>1</sup>, M. Sadel<sup>2</sup>, L.P. Muren<sup>1</sup>, J.B.B. Petersen<sup>1</sup>, P. Skyt<sup>1</sup>, L.P. Kaplan<sup>2</sup>, J. Swakon<sup>3</sup>, L. Malinowski<sup>3</sup>, G. Mierzwińska<sup>3</sup>, M. Rydygier<sup>3</sup>, P. Balling<sup>2</sup>

<sup>1</sup>Aarhus University Hospital, Medical Physics, Aarhus C, Denmark

<sup>2</sup>Aarhus University, Department of Physics and Astronomy, Aarhus, Denmark

<sup>3</sup>Polish Academy of Sciences, Institute of Nuclear Physics, Krakow, Poland

#### Purpose or Objective

Three dimensional (3D) dosimetry allows for detailed measurements of dose distributions in photon-based radiotherapy, and has potential to become a useful tool for verification of proton therapy (PT). However, linear energy transfer (LET) dependent quenching of the signal in the Bragg peak results in an under-response of the dosimeter. In this study we investigate whether the LET

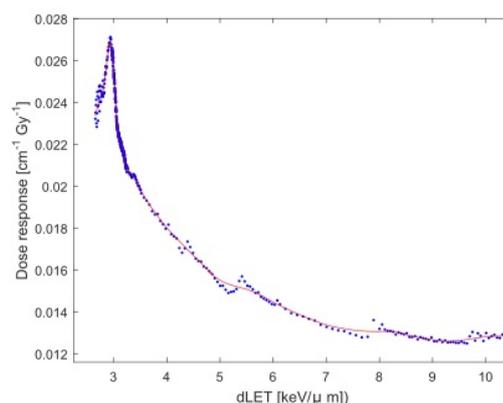

dependent quenching can be corrected by adjusting the measured 3D optical density (OD) distribution using a calibration model generated from a Monte Carlo (MC) simulation and a calibration dosimeter.

#### Material and Methods

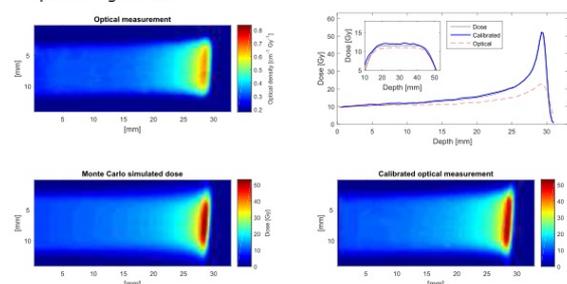

A radiochromic (leucomalachite green) silicone-based 3D dosimeter was irradiated with three spatially separated, unmodulated 60 MeV proton beams ( $\varnothing$  10 mm collimator), to plateau doses of 5, 10 and 20 Gy. Dosimeter read-out was performed prior to and after irradiation, in a Vista 10 optical CT scanner with 0.25 mm<sup>3</sup> voxel resolution, thus obtaining the change in OD caused by the radiation. MC simulation of 10<sup>8</sup> protons was performed in SHIELDHIT-12A, giving the dose and dose-averaged LET (dLET) distributions. A calibration model with respect to dose and dLET was generated from the 5 and 20 Gy Bragg peaks: Linear fits to OD as a function of dose were computed for all voxels within limited ranges in dLET. Only voxels within the central part of the beam ( $\varnothing$  5 mm) with doses above 1% of the maximum dose were used for the model. The slopes and intercepts from the linear fits were smoothed as a function of dLET (Fig. 1). Voxels in the 10 Gy Bragg peak were calibrated using these variables and compared to the dose distribution from the MC simulation (Fig. 2).

#### Results

Quenching results in a lower dose response in the Bragg peak of the proton beam (0.013 cm<sup>-1</sup> Gy<sup>-1</sup>) compared to the low-LET regions, such as the plateau (0.027 cm<sup>-1</sup> Gy<sup>-1</sup> at 2.94 keV/ $\mu$ m), see Fig. 1. The dose response increased to a sharp peak for dLET-values within the plateau region. The calibrated optical measurement was close to identical to the MC simulated dose in the central part of the beam. Less good results were obtained towards the edges of the beam (Fig. 2), which corresponded to areas where the MC beam model was suboptimal. Dose errors larger than 2 % of maximum dose (1.1 Gy) was found in 35 % of all calibrated voxels, while 3.5 % had dose errors larger than 5 % of maximum dose (2.7 Gy).

**Figure 1:** The dose response of the quenching model is shown as a function of dLET. The optical density was fitted to a linear expression, as a function of Monte Carlo simulated dose, for voxels within limited dLET ranges. The slope of the fit gives the dose response, and was smoothed (red line). These values, together with the smoothed intercept values were used as the quenching model.

**Figure 2:** Protons impinge on a curved dosimeter surface, travelling from left to right with the Bragg peak occurring close to 3 cm depth. The optical measurement shows LET-dependent quenching of the signal in the Bragg peak. The upper right panel shows a profile through the central part of the field, and the insert shows a transverse profile at 1 cm water equivalent depth. The black full line is the Monte Carlo simulated dose, the blue thick line is the calibrated optical measurement, and the red dashed line is the original optical measurement that has been normalised in the plateau region to the Monte Carlo simulated dose.

#### Conclusion

We present the first LET-corrected 3D dose measurements in a radiochromic dosimeter for proton therapy, showing that verification for single fields has been made possible. Acknowledgements: PL-Grid

#### OC-0063 Energy resolution and range reproducibility of a dedicated phantom for proton PBS daily QA

L. Placidi<sup>1</sup>, J. Hrbacek<sup>1</sup>, M. Togno<sup>2</sup>, D.C. Weber<sup>3</sup>, A.J. Lomax<sup>1</sup>

<sup>1</sup>Paul Scherrer Institute PSI, Medical physics, Villigen PSI, Switzerland

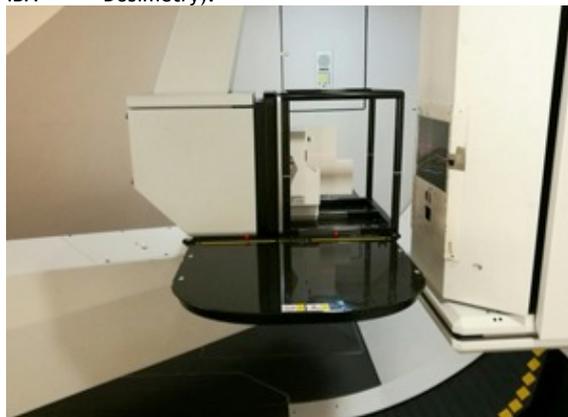

<sup>2</sup>IBA, Dosimetry GmbH, Schwarzenbruck, Germany

<sup>3</sup>Paul Scherrer Institute PSI, Radiation Oncology, Villigen PSI, Switzerland

#### Purpose or Objective

Wedge phantoms coupled with a CCD camera (Fig.1) were suggested as a simple mean to verify range consistency or reproducibility for a specific energy. The method is based on analysing of integral image created by a spot pattern that passed through a wedge. We have investigated the reproducibility and dependence of this method on setup errors (shift and tilt) for a commercially available phantom (Sphinx, IBA Dosimetry) and CCD camera (Lynx,

IBA Dosimetry).

### Material and Methods

The phantom includes 4 wedges of different thickness, allowing verification of the range for 4 energies within one integral image. Each wedge was irradiated with a line pattern (19 spots with 5mm separation) of suitable clinical energy (120,150,180 and 230MeV). In order to test reproducibility, the equipment was aligned to the isocenter using lasers, and delivery was repeated for 5 consecutive days, repeating delivery 4 times each day. Position of range (R) at distal fall-off (depth corresponding to the 80% in the distal part of the Bragg peak) was determined (myQA software, IBA Dosimetry) and inter- and intra-setup uncertainty calculated. Dependence of R on energy was performed delivering the same spots pattern but with energy variation in steps of  $\pm 0.2$  MeV for all the nominal energies, up to  $\pm 1.0$  MeV. Possible range uncertainties, caused by a daily setup error, were then simulated: inclination of the phantom ( $0.6^\circ$  and  $1^\circ$  slope), spot shift ( $\pm 0.5$  mm,  $\pm 1.0$  mm,  $\pm 2.0$  mm) and couch shift (2.0mm, 5.0mm and 10.0mm) simultaneously with an increased and fixed spot separation (10mm).

### Results

Inter and intra position setup shows a maximum in plane difference within 1mm. Reproducibility test results are shown in Fig. 2, in terms of mean ( $\mu$ ) and the standard deviation ( $\sigma$ ) of the R. Energy resolution was expressed as  $\gamma$  factor ( $\gamma = \sigma / \alpha$ , where  $\alpha$  is the slope of the range dependence on energy):  $\gamma$  defines what energy change would create the same effect as a 1 sigma outlier. Daily setup uncertainties results are also reported in Fig. 2 ( $\beta$  is the slope of the range dependence on the simulated daily setup error). An inclination of  $1^\circ$  leads to a maximum R variation of 0.2mm, 1.1mm, 0.5mm and 1.3mm for a 120MeV, 150MeV, 180MeV and 200MeV energy respectively. A slope of  $0.6^\circ$  leads to R variation less than 0.4 mm for all the energies. R biggest variation was 0.4 mm, only for a spot shift of +2.0mm for 150MeV and 200MeV energies. A spot separation of 15mm leads to R deviation of 0.6mm, 0.4mm, 0.6mm and 0.3mm for all the energies. A combination of 10mm couch shift and a 10mm spot separation lead to R deviation from the reference value of 1.4mm, 1.9mm, 1.2mm and 2 mm respectively, for the already mentioned correspondingly increasing energies.

Energy (MeV)	120	150	180	200
<b>Distal range reproducibility</b>				
$\mu$ (mm)	96.74	145.95	202.50	244.87
$\sigma$ (mm)	0.05	0.09	0.11	0.11
$\alpha$ (mm/MeV)	1.66	1.77	2.03	2.15
$\gamma$ (MeV)	0.03	0.05	0.05	0.05
<b>Distal range: daily setup error</b>				
$\beta$ - Inclination (mm/deg)	-0.02	-0.11	0.05	0.24
$\beta$ - Spot shift (mm/mm)	-0.06	-0.08	0.01	-0.07
$\beta$ - Couch shift + 10 mm spot separation (mm/mm)	0.08	-0.21	0.07	-0.28

### Conclusion

Inter position setup error can be easily improved by positioning the system also matching the laser with the beam and imaging system, achieving a sub-millimetre accuracy. Taking also into account different day-to-day setup errors, their influence on the range determination can be ignored.

### OC-0064 A Fano test for proton beams and the influence of nuclear interactions on ionization chamber factors

A. Lourenco<sup>1,2</sup>, H. Bouchard<sup>3</sup>, S. Galer<sup>2</sup>, G. Royle<sup>1</sup>, H. Palmans<sup>2,4</sup>

<sup>1</sup>University College London, Medical Physics and Biomedical Engineering, London, United Kingdom

<sup>2</sup>National Physical Laboratory, Division of Acoustics and Ionising Radiation, Teddington, United Kingdom

<sup>3</sup>Université de Montréal, Département de Physique, Montréal, Canada

<sup>4</sup>EBG MedAustron GmbH, Medical Physics Group, Wiener Neustadt, Austria

### Purpose or Objective

In this work, the accuracy of particle transport in the FLUKA Monte Carlo code for proton beams was evaluated by performing a Fano cavity test.

Ionization chamber perturbation factors were also computed for the PTW 34070 Bragg peak chamber, typically used for integral depth dose measurements in clinical proton beams, with particular attention to the influence of nuclear interactions.

### Material and Methods

To implement the Fano cavity test in FLUKA, a routine was written to generate a uniform, mono-directional proton source per unit of mass. Geometries were defined with homogeneous material interaction properties but varying mass densities. Simulations were performed for mono-energetic protons with initial energies of 60 MeV to 250 MeV. To study the influence of different subsets of secondary charged particle types, three simulations with different charged particle transport were performed for each proton energy considered; (i) all charged particles transported, (ii) alpha particles discarded and (iii) nuclear interactions discarded. Ionization chamber perturbation factors were also computed for the PTW 34070 Bragg peak chamber for proton beams of 60 MeV to 250 MeV using the same transport parameters that were needed to pass the Fano test.

### Results

FLUKA was found to pass the Fano cavity test to within 0.1%, using a stepsize of 0.01 cm for transport of all charged particles and cut-off energy for protons set to 10 keV. Ionization chamber simulation results show that the presence of the air cavity and the wall produces perturbation effects of the order of 0.2% and 0.8% away from unity, respectively. Results also show that proton beam perturbation factors are energy dependent and that nuclear interactions must be taken into account for accurate calculation of ionization chamber dose response.

## Conclusion

Ionization chamber perturbation factors can amount to 0.8% in high-energy proton beams and therefore need to be considered in dosimetry procedures. This work will feed into the development of data for future codes of practice for the dosimetry of proton beams.

## OC-0065 Ion recombination in scanned light-ion beams combining Boag's and Jaffé's theory

<sup>7</sup>EBG MedAustron GmbH, Medical Physics, Wiener Neustadt, Austria

<sup>8</sup>National Physical Laboratory, Acoustics and Ionising Radiation Division, Teddington, United Kingdom

## Purpose or Objective

As recommended in international dosimetry protocols (e.g. IAEA TRS-398) the response of ionisation chambers (ICs) has to be corrected for influence quantities. In this work, we investigate the ion recombination correction factor ( $k_s$ ) in scanned light-ion beams. Two contributing processes are distinguished: initial and volume recombination. Initial recombination occurs between ions created within the same track and depends on the ionisation density within the track. Volume recombination takes place between ions originating from different tracks and depends on the dose rate (DR). Numerous theories have been published to describe both mechanisms.

## Material and Methods

Measurements were performed in four scanned light-ion beams (proton, helium, carbon and oxygen), using two plane-parallel ICs (one serving as a monitor and the other as the IC under test). The saturation curve was measured at different DRs. Determining the saturation current ( $I_{sat}$ ) by linear extrapolation of the curve at high voltages,  $k_s$  was calculated by dividing  $I_{sat}$  by the current measured at the operating voltage (V). Due to the high DRs used with scanned beams and high LET-values,  $k_s$  results from a combination of initial and volume recombination:  $k_s = k_s^{ini} k_s^{vol}$ . Experimental results are compared to Jaffé's and Boag's theory for initial and volume recombination, respectively. Jaffé's theory predicts a logarithmic variation of  $k_s^{ini}$  as a function of  $1/V$ , whereas Boag's theory predicts a variation of  $k_s^{vol}$  as a function of  $1/V$  or  $1/V^2$ , depending on the radiation pulse duration compared to the ion collection time of the IC.

## Results

The figures present the theoretical (lines) and the experimental (symbols) variation of  $k_s$  as a function of  $1/V$ . Fig 1 shows results obtained in a 96 MeV pulsed PBS proton beam at three DRs and two depths (3.1 cm in black and at the peak in blue). Fig 2 shows results obtained at different DRs at a depth of 1.1 cm in a 115 MeV/n scanned carbon beam (black) and at the middle of a 6 cm SOBP carbon beam centered at 9 cm (blue). Similar graphs are obtained for other beams. Both figures show that initial recombination, which increases with LET, as expected, dominates at the highest voltages. For carbon ions, we can observe an inflection point when volume and initial recombination have similar magnitude.

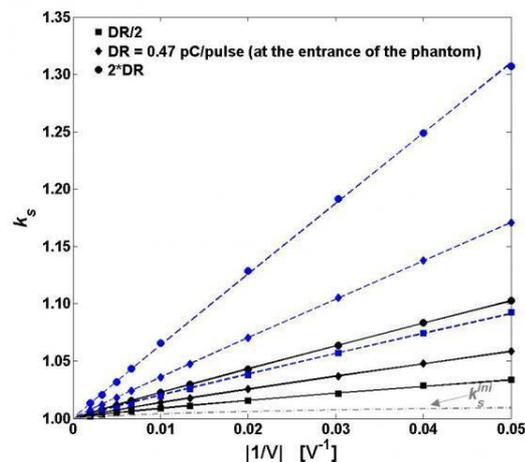

Figure 1. Results obtained in a 96.17 MeV pulsed PBS proton beam.

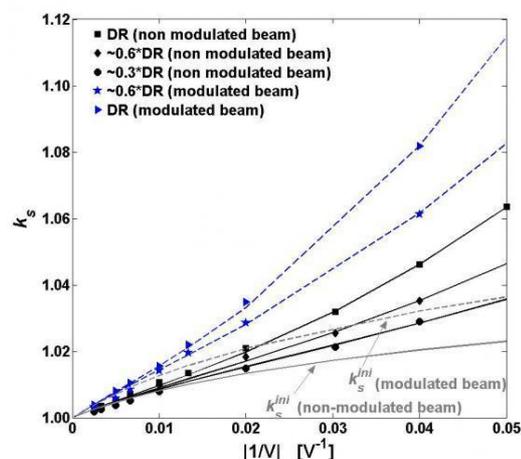

Figure 2. Results obtained in scanned carbon ion beams.

## Conclusion

Excellent agreement is found between experimental and theoretical ion recombination correction factors in scanned light-ion beams. Results confirm that  $k_s$  cannot be neglected. The solution to minimise  $k_s$  is to use the IC at high voltage. However, that brings a risk to observe charge multiplication in the IC. For the IC tested, it was found that a voltage of 300 V can be safely used. Due to the initial recombination contribution, the simple two-voltage method is not applicable to these scanned beams.

### OC-0066 Are quality improved CBCT images superior for measuring lung ventilation?

K.R. Jensen<sup>1</sup>, U. Bernchou<sup>1</sup>, O. Hansen<sup>1</sup>, C. Brink<sup>1</sup>  
<sup>1</sup>University of Southern Denmark, Institute of Clinical Research, Odense, Denmark

## Purpose or Objective

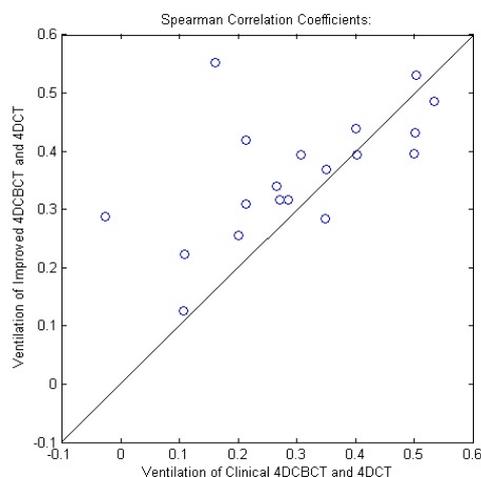

Changes in lung ventilation of lung cancer patients during radiotherapy may predict patient specific toxicities. Ventilation changes during a treatment course can be measured from frequently acquired 4D-Cone Beam CT (4D-CBCT), but as these images are of low quality, improvements in quality may increase the accuracy of the ventilation analysis.

### Material and Methods

This study is based on 4D-CBCT and 4D-CT scans of 19 non-small-cell lung cancer (NSCLC) patients subjected to curatively intended radiotherapy initiated between March 2012 and August 2014. Lung ventilation was measured as voxel-wise Jacobian determinants (JD) computed by deformable image registration between expiration phases and inspiration phases. All image registrations were carried out by the freeware tool elastix (elastix.isi.uu.nl). 4D-CT scans acquired before treatment were chosen as gold standard for ventilation. The clinical 4D-CBCT projection images of the first treatment fraction were improved by the procedure described in [PMB, 15, 5781, 2016], which corrected projections for image lag, detector scatter, body scatter, and beam hardening. Clinical and improved projection images were binned and FDK-reconstructed by software in the RTK-package (www.openrtk.org). All CBCT reconstructions were rigidly resampled into CT-space. Before deformable image registration a 1x1x1cm wide median filter was applied on all images. For each patient the clinical 4D-CBCT JDs and the improved 4D-CBCT JDs were voxel-wise compared to 4D-CT JDs by Spearman correlation and the resulting correlation coefficients were analysed by a paired t-test.

### Results

The clinical projection images were improved successfully and both versions of projection images were reconstructed to 4D-CBCT. Deformable registrations were carried out on clinical 4D-CBCT, improved 4D-CBCT, and 4D-CT. The sample mean for correlations between clinical 4D-CBCT and 4D-CT JDs was  $0.297 \pm 0.154$  while the sample mean for clinical 4D-CBCT and improved 4D-CBCT JDs was  $0.362 \pm 0.106$  ( $\pm 1$  SD). A paired t-test of the Fisher transform correlation values showed the difference to be statistically significant ( $p=0.047$ ).

### Conclusion

Ventilation computed from clinical 4D-CBCT and improved 4D-CBCT were compared to 4D-CT ventilation. The improved 4D-CBCT ventilation correlated better with 4DCT ventilation, suggesting that the improved 4D-CBCT are superior to clinical 4D-CBCT for measuring lung ventilation. Further improvements on measuring lung ventilation from 4D-CBCT may possibly be achieved by adding iterative reconstruction.

### OC-0067 4DCT imaging to assess radiomics feature stability: an investigation for thoracic cancer

<sup>1</sup>Maastricht University Medical Centre - GROW-School for Oncology and Developmental Biology, Department of Radiation Oncology - MAASTRO, Maastricht, The Netherlands

<sup>2</sup>Zuyderland Medical Centre, Department of Surgery, Heerlen, The Netherlands

<sup>3</sup>Zuyderland Medical Centre, Department of Nuclear Medicine, Heerlen, The Netherlands

### Purpose or Objective

For several tumour sites it was shown that quantitative radiomics features, derived from CT images, unravel valuable prognostic information. However, the large number of available features increases the risk of overfitting. Typically, test-retest scans allow to reduce this number by selecting a robust feature subset. However, these test-retest scans are not available for all tumour sites. Hence we hypothesized that different phases of respiratory-correlated 4D CT-scans (4DCT) can be used as alternative to test-retest imaging to select robust features. To test this hypothesis, we assessed the repeatability of 542 radiomics features in a test-retest and two 4DCT datasets of lung and oesophageal cancer patients.

### Material and Methods

The publically available RIDER dataset, consisting of test-retest CT-scans of 27 non-small cell lung cancer (NSCLC) patients, and 4DCT-scans of 22 NSCLC (4D-Lung) and 20 oesophageal cancer patients (4D-OES) were analysed. The 4DCT-scans contained 8 phases of the breathing cycle. The gross tumour volume (GTV) of the primary tumours were manually delineated. In total, 70 radiomics features describing the tumour shape, intensity and texture, and 472 wavelet-filtered features were calculated within the GTVs. A concordance correlation coefficient (CCC)  $\geq 0.85$  was used to identify robust features, either between the test-retest scans or over all phase pairs in the 4DCT scans.

### Results

Unfiltered features in general showed a higher robustness than wavelet-filtered features. In total 34/70 (49%) unfiltered features and 122/472 (26%) wavelet features were stable in both the test-retest dataset and the 4D-lung dataset. The four features selected previously to be prognostic in lung and head-and-neck cancer (Aerts et al 2014), had a minimum CCC  $> 0.95$  in both datasets. In the 4D-OES dataset 205/542 (38%) features showed a high robustness, of which 42 unfiltered and 99 wavelet-filtered features were also stable in the 4D-lung dataset. Due to the fact that the image acquisition settings and hardware were exactly the same in the 4D-lung and 4D-OES scans, this partial discordance suggests that the remaining stable features might be tumour site specific.

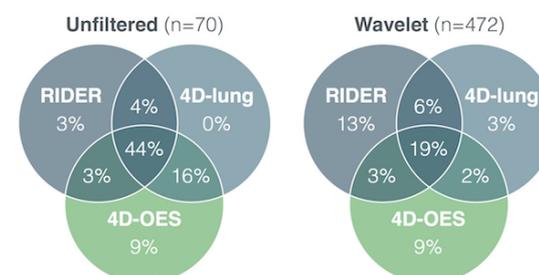

Figure 1. Venn chart visualizing the overlap of stable features with CCC  $> 0.85$  in the RIDER, 4D-lung and 4D-OES dataset.

Dataset	Category	Un-filtered	Wavelet filtered							Total	
			HHH	HHL	HLH	HLL	LHH	LHL	LLH		LLL

	GLRLM (11)	6	4	4	4	5	2	3	3	6	37
	GLSZM (11)	6	3	3	3	3	2	2	3	5	30
	Statistics (15)	11	6	5	10	8	6	8	5	8	67

**Table 1.** Total number of features per category with a minimum CCC>0.85 before and after wavelet filtering in all three datasets. Shape features are not calculated after wavelet filtering.

### Conclusion

We found a high agreement between radiomics feature stability based on 4DCT and test-retest data in lung cancer, meaning that 4DCT can be used as alternative to test-retest to eliminate unreliable features. For oesophageal cancer a subset of 205 stable CT radiomics features was identified, of which 64 (31%) were not stable in NSCLC. This underlines the need for tumour-specific feature selection prior to model building.

### OC-0068 Heterogeneous dose escalation in lung: How robust are high FDG-uptake volumes during radiotherapy?

A. Haraldsen<sup>1</sup>, C. Lutz<sup>2</sup>, L. Hoffmann<sup>2</sup>, A. Khalil<sup>3</sup>, D. Möller<sup>2</sup>

<sup>1</sup>Aarhus University Hospital, Department of Nuclear Medicine & PET Center, Aarhus C, Denmark

<sup>2</sup>Aarhus University Hospital, Department of Medical Physics, Aarhus C, Denmark

<sup>3</sup>Aarhus University Hospital, Department of Oncology, Aarhus C, Denmark

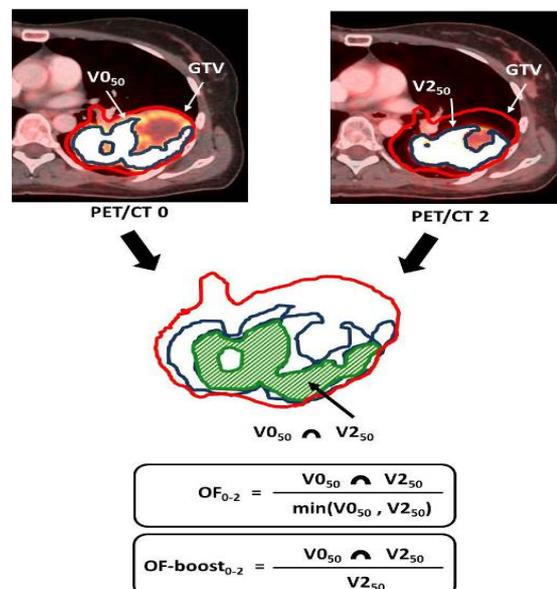

### Purpose or Objective

The Danish NARLAL 2 Trial (NCT02354274) compares 18F-fluorodeoxyglucose (FDG)-guided dose escalation to the current standard radiotherapy (RT) treatment (66Gy/33fx homogeneously). The dose is escalated heterogeneously delivering mean doses up to 95Gy/33fx to the high FDG uptake volumes of the primary tumour aiming to improve local control for patients with locally advanced Non-small Cell Lung Cancer (NSCLC). In this study, we investigated the robustness of these high FDG uptake regions within the Gross-Tumour-Volume (GTV) during the first weeks of RT and we calculated the influence of these changes on the dose coverage.

### Material and Methods

We evaluated three successive FDG-PET/CT scans performed on 20 patients. The baseline scan (PET/CT0) was dated 14 days prior to RT. The first and second scan during RT were performed on the same scanner at day 7 (PET/CT1) and 14 (PET/CT2). These two scans were rigidly registered to CT0 on the primary tumour. A sub-volume, defined by a threshold of 50% of the Standardized Uptake Value peak (SUV<sub>peak</sub>), was delineated within the GTV on each scan (V<sub>050</sub>, V<sub>150</sub> and V<sub>250</sub>). The overlap of the volumes was evaluated with the widely used overlap fraction (OF) and the OF-boost (see definitions in Fig. 1). The OF-boost specifies the fraction of respectively V<sub>150</sub> or V<sub>250</sub> that is included in the initial escalation volume, V<sub>050</sub>, and is thus more clinically relevant for this trial. The escalated dose plans were then recalculated on CT2 and the dose to V<sub>250</sub> was compared to the planned dose to V<sub>050</sub> on CT0 to estimate the effect of varying FDG uptake on the dose coverage.

**Figure 1**

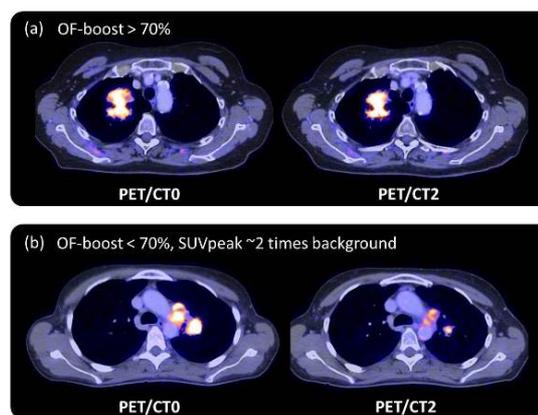

### Results

Median values for OF<sub>0-1</sub> and OF<sub>0-2</sub> were 0.79 [0.56;0.91] and 0.85 [0.58;0.95]. OF-boost<sub>0-1</sub> and OF-boost<sub>0-2</sub> yielded slightly lower median values of 0.77 [0.52-0.91] and 0.82 [0.58-0.92], respectively.

For 70% of the patients, we found an OF-boost>70% for all scans (Fig. 2 (a)). These patients showed only small or no dose decrements to V<sub>250</sub> (maximum 1,3 Gy), indicating that a 70% OF-boost is sufficient to maintain the initial escalation dose. In 30% of the patients, the OF-boost dropped below 70% (Fig. 2 (b)) and the mean dose to the high FDG uptake volumes decreased with up to 4 Gy. For these patients, we found that SUV<sub>peak</sub> declined to ~2 times background activity, rendering the definition of V<sub>150</sub> and V<sub>250</sub> questionable.

**Figure 2**

(a) PET/CT0 and PET/CT2 for a patient example with high degree of overlap, showing only minor changes in tumor size and tumor FDG uptake during first weeks of RT. (b) PET/CT0 and PET/CT2 for a patient example with lower degree of overlap, showing a significant decrease in tumor FDG uptake - SUV<sub>peak</sub> declined to ~2 times background activity.

### Conclusion

For the majority of the patients, the high FDG uptake sub-volume and the escalated dose level were maintained during RT. For 30% of the patients, the OF-boost decreased below 70% and a drop in dose coverage to the high FDG uptake volumes was observed. For these patients the definition of a 50% of SUV<sub>peak</sub> volume during RT was questionable due to low SUV<sub>peak</sub> values.

### OC-0069 Influence of PET radiomics implementation on reproducibility of tumor control prognostic models

M. Bogowicz<sup>1</sup>, R. Leijenaar<sup>2</sup>, S. Tanadini-Lang<sup>1</sup>, O. Riesterer<sup>1</sup>, M. Pruschy<sup>1</sup>, G. Studer<sup>1</sup>, M. Guckenberger<sup>1</sup>, P. Lambin<sup>2</sup>

<sup>1</sup>University Hospital Zurich and University of Zurich, Department of Radiation Oncology, Zurich, Switzerland  
<sup>2</sup>GROW - School for Oncology and Developmental Biology-Maastricht University Medical Centre, Department of Radiation Oncology MAASTRO clinic, Maastricht, The Netherlands

#### Purpose or Objective

Radiomics is a powerful tool for tumor characterization. However, the lack of the standardization in different radiomics implementations can be a cause of model irreproducibility. The aim of this study was to correlate local tumor control in head and neck squamous cell carcinoma (HNSCC) with post-radiochemotherapy (RCT) PET radiomics and test the obtained models against two independent radiomics implementations on a clinically relevant data set.

#### Material and Methods

HNSCC patients, who underwent a follow-up 18F-FDG PET scan 3 months post definitive RCT, were retrospectively included in the study (training cohort n=149, validation cohort=53). Tumors were semi-automatically segmented on the pre-treatment 18F-FDG PET using a gradient-based method and transferred to post-RCT scans. Radiomic features were extracted using two independent software implementations: in-house implementation from University Hospital Zurich (USZ) and Radiomics from MAASTRO. In total, 674 features, available in the both implementations and based on the same definitions, comprising: shape (n=8), intensity (n=16), texture (n=58) and wavelet transform (n=592) were compared using the intraclass correlation coefficient (ICC). Two separate models were built selecting features from either USZ or MAASTRO implementation. Redundant features were excluded in a principal component analysis. The best performing features based on univariable Cox regression were included in the multivariable analysis with backward selection of the variables using Akaike information criterion. The quality of models was assessed using the concordance index (CI). The performance of both models was tested on the training data using features from the other implementation as well as on the validation data using features obtained with both implementations. The performance was also evaluated on the patient level by the comparison of the patient ranking from two implementations using Pearson correlation.

#### Results

Only 71 PET radiomic features yielded ICC > 0.8 in the comparison between the two implementations. The wavelet features showed the biggest discrepancy. The features comprised in the two prognostic models were different between the two radiomics implementations. However, both models showed a good performance when corresponding features from the other implementation were used (Table 1). Both models performed equally well in the validation cohort for both radiomics implementations (CI: 0.67-0.71). However, features from different implementations resulted in altered patient ranking. In one of the models the ranks showed strong correlation ( $r_{\text{training}}=0.89$ ,  $r_{\text{validation}}=0.85$ ), whereas in the second the correlation was weak ( $r_{\text{training}}=0.62$ ,  $r_{\text{validation}}=0.45$ ) as more features characterized by low ICC were present.

Table 1. Performance of PET radiomics models for prediction of local tumor control and the stability of radiomic features between to radiomics implementations. CI – concordance index, ICC – intraclass correlation coefficient, MAASTRO and USZ two independent radiomics implementations.

Model developed using radiomic features from	Model radiomic features	ICC	CI training		CI validation	
			MAASTRO	USZ	MAASTRO	USZ
MAASTRO	HLL GLRLMLRUGE	0.20	0.81	0.72	0.69	0.67
	LHL GLCMsum_entropy	0.59				
	LHH GLCM_autocorrelation	0.03				
	LHL GLCMcluster_prominance	<0.01				
USZ	Histogramstandard_deviation	0.98	0.75	0.75	0.69	0.71
	GLRLMLGV	0.97				
	GLCMcluster_prominance	0.96				
	Histograminterquartile_range	0.94				
	LHL GLRLMHGRE	0.11				

#### Conclusion

The two post-RCT PET radiomic models for local tumor control preserved their prognostic power using independent radiomics implementation. However, the significant differences in patient rankings were observed.

### OC-0070 18F-FDG PET image biomarkers improve prediction of late radiation-induced xerostomia

L.V. Van Dijk<sup>1</sup>, W. Noordzij<sup>2</sup>, C.L. Brouwer<sup>1</sup>, J.G.M. Burgerhof<sup>3</sup>, J.A. Langendijk<sup>1</sup>, N.M. Sijtsema<sup>1</sup>, R.J.H.M. Steenbakkers<sup>1</sup>

<sup>1</sup>University of Groningen- University Medical Center Groningen, Radiation oncology, Groningen, The Netherlands

<sup>2</sup>University of Groningen- University Medical Center Groningen, Nuclear Medicine and Molecular Imaging, Groningen, The Netherlands

<sup>3</sup>University of Groningen- University Medical Center Groningen, Epidemiology, Groningen, The Netherlands

#### Purpose or Objective

Current prediction of radiation-induced xerostomia 12 months after radiotherapy ( $Xer_{12m}$ ) is based on mean parotid gland dose and baseline xerostomia scores. Our hypothesis is that the development of xerostomia is associated with patient-specific information from <sup>18</sup>F-FDG PET images that is quantified in PET image biomarkers (PET-IBMs). The purpose of this study is to improve prediction of  $Xer_{12m}$  with these PET-IBMs.

#### Material and Methods

<sup>18</sup>F-FDG PET images of 161 head and neck cancer patients were acquired before start of treatment. From these images, SUV-intensity (17) and textural (63) PET-IBMs of the parotid gland were extracted. In addition, XER-base, tumour, patient characteristics and mean doses to the parotid gland were considered. Patient-rated toxicity ( $Xer_{12m}$ ) was prospectively collected (EORTC QLQ-H&N35). PET-IBMs were selected using a forward step-wise variable selection procedure. The resulting logistic regression models with the selected PET-IBMs were compared with the reference model that was based on parotid gland dose and baseline xerostomia only. All models were internally validated by bootstrapping.

#### Results

Sixty (37%) patients developed moderate-to-severe  $Xer_{12m}$ . The 90<sup>th</sup> percentile of SUVs (P90) in the parotid gland of the intensity PET-IBMs was selected and was significantly associated with  $Xer_{12m}$  ( $p<0.001$ ). The P90 significantly improved model performance of the reference model in predicting  $Xer_{12m}$  (see Table 1: Likelihood-ratio test) from an AUC = 0.73 (reference model) to 0.77 (P90 added). Similar improvement was obtained from Long Run High Gray-level Emphasis 2 (LRHG2E) of the textural PET-IBMs (Table 1), which was significantly correlated with P90 ( $p=0.83$ ). The PET-IBMs P90 and LRHG2E both had high values with high SUVs present in the parotid gland. More specifically, P90 indicates the minimum value of the 90% highest SUV values and the LRHG2E indicated high SUV values that are spatially adjacent to each other (Figure). Both PET-IBMs were negatively associated with  $Xer_{12m}$ , suggesting that patients with low metabolic activity in the parotid glands were at risk of developing late xerostomia.

Since both P90 and LRHG2E have similar performance, P90 is preferred due to its calculation simplicity compared to LRHG2E.

#### Conclusion

Prediction of  $Xer_{12m}$  was significantly improved with 90<sup>th</sup> percentile of SUVs, indicating that low metabolic activity of the parotid gland was associated with the risk of developing xerostomia after radiotherapy. This study highlights the importance of incorporating patient-specific functional characteristics into NTCP model development.

#### OC-0071 Clustering of multi-parametric functional imaging: identifying high risk subvolumes in NSCLC tumours

A.J.G. Even<sup>1</sup>, M.D. La Fontaine<sup>2</sup>, B. Reymen<sup>1</sup>, M. Das<sup>3</sup>, D. De Ruyscher<sup>1</sup>, P. Lambin<sup>1</sup>, W. Van Elmpt<sup>1</sup>

<sup>1</sup>Maastricht University Medical Centre - GROW-School for Oncology and Developmental Biology, Department of Radiation Oncology - MAASTRO, Maastricht, The Netherlands

<sup>2</sup>Netherlands Cancer Institute, Department of Radiation Oncology, Amsterdam, The Netherlands

<sup>3</sup>Maastricht University Medical Centre, Department of Radiology, Maastricht, The Netherlands

#### Purpose or Objective

Tumours are heterogeneous. Characteristics such as metabolic activity, proliferation, cell death and vasculature vary throughout a tumour, influencing the sensitivity to (radio)therapy. Biomarkers predicting patient prognosis often neglect these subpopulation heterogeneities and rarely take spatial differences into account. This study aimed to identify tumour subregions with characteristic phenotypes and to correlate these subregions to treatment outcome using functional imaging for metabolic activity (FDG PET/CT), hypoxia (HX4 PET/CT), and tumour vasculature (DCE-CT).

#### Material and Methods

For 32 non-small cell lung cancer (NSCLC) patients, a planning FDG PET/CT, hypoxia PET/CT and DCE-CT scan were acquired before the start of radiotherapy. Kinetic analysis was performed on the DCE-CT to acquire parametric maps of blood volume (BV). HX4 PET/CT and DCE-CT scans were non-rigidly deformed to the planning (PET/CT). Similar voxels within the gross tumour volume (GTV) of the planning CT scan were grouped using a SLIC algorithm (Achanta, 2012) to create spatially independent 3D subregions (i.e. supervoxels), and to account for registration uncertainties. Inside these supervoxels, the median values of FDG SUV, HX4 SUV and BV were calculated, see Figure 1. Next, an unsupervised hierarchical clustering algorithm was used to group supervoxels of all patients. The number of clusters was based on the gap metric. Overall survival was assessed using Kaplan-Meier curves. Furthermore, patients were split into two cohorts based on median survival and individual supervoxels of all patients were compared.

#### Results

Supervoxels could be generated for 29 out of 32 patients with a small GTV volume hindering analysis on the other 3 patients. Unsupervised clustering of all supervoxels over all patients provided 4 independent groups. The red cluster (high BV, low/intermediate FDG, intermediate HX4) related to a high risk tumour type: patients presenting supervoxels in this cluster had significantly worse survival compared to patients that did not ( $p=0.037$ ; c-index Cox model=0.626), Figure 1. Figure 2 shows the supervoxels of all patients separated into survival larger than the median (=18 months) (green dots) or lower (red dots). Large values (e.g. outliers) in HX4 and FDG uptake corresponded to worse performing patients, while intermediate values (possibly corresponding to more homogeneous areas) were related to a good prognosis. The same was found for BV (not shown).

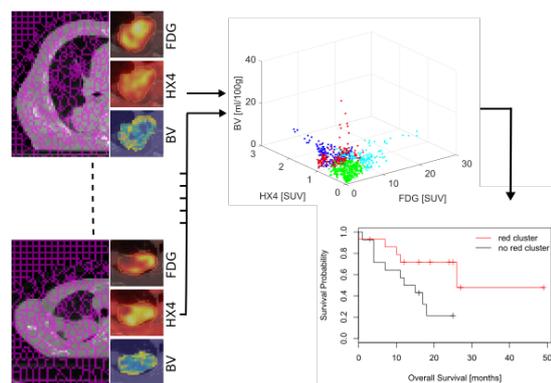

Figure 1. Workflow: supervoxels, clustering and Kaplan-Meier curves for red cluster.

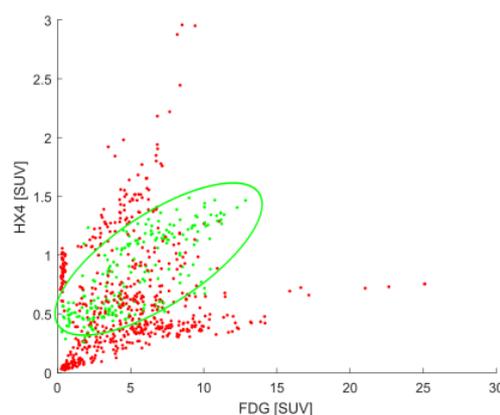

Figure 2. Supervoxels of patients with a survival larger (green) or lower (red) than the median overall survival.

#### Conclusion

We designed a methodology for the analysis of multi-parametric imaging data in NSCLC patients on sub-regional level. We showed that such an intra-tumour classification of heterogeneous subregions may allow to predict patient prognosis. This technique allows to gain further insight into the analysis of multi-parametric functional images.

#### Proffered Papers: Improvements in positioning and motion management

<sup>6</sup>Klinik und Poliklinik für Strahlentherapie und Radioonkologie, Radiology, München, Germany

### Purpose or Objective

Respiratory motion is a major concern in the treatment of lung tumors. Time resolved computed tomography (4D-CT) is the clinical standard to determine internal target volumes (ITVs). To overcome limitations of the 4D-CT (radiation dose, averaging of breathing cycles) the aim of this work is to develop a workflow for 4D-magnetic resonance imaging (4D-MRI) based target volume evaluation and determination.

### Material and Methods

4D-MRI (real-time, 157 volumes) with a temporal resolution of 0.5s and a spatial resolution of  $3.91 \times 3.91 \times 10 \text{ mm}^3$ , 4D-CT and breath-hold planning-CT (pCT) with clinical structures of lung tumor patients were utilized in this study. The diaphragm excursion in cranial-caudal direction was evaluated for the retrospective determination of the respiration phase on 4D-CT and 4D-MRI. The established workflow is outlined in fig. 1. The rigid registration from pCT to 4D-MRI and the corresponding propagation of gross tumor volume (GTV) and CT-based  $\text{ITV}_{\text{CT}}$  were performed using the *Image Processing Toolbox 9.2 (Matlab)*. The non-rigid registration and GTV propagation between the different 4D-MRI volumes was performed with the B-spline algorithm of *plastimatch* version 1.6.3.

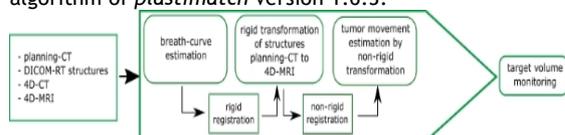

Fig 1: Schematic of the developed workflow: Computation of the target volume monitoring requires p-CT, DICOM-RT structures (GTV and ITV), 4D-CT and 4D-MRI. Reconstruction of the breathing-curve from 4D-CT and 4D-MRI enables a rigid registration of the p-CT to the 4D-MRI. By rigid transformation the GTV and the CT-based  $\text{ITV}_{\text{CT}}$  are transferred to the MRI. The estimation of the tumor movement is done with a non-rigid registration of 4D-MRI volumes and the propagation of the GTV structures.

### Results

The detection of the diaphragm is robust and facilitates a rigid registration of the p-CT to the most similar 4D-MRI volume. Based on non-rigid transformations of the GTV in-between the different volumes of the 4D-MRI, the movement of the tumor is determined and tracked ( $\text{GTV}_{\text{deformed}}$ ). The estimated breathing curve and two representative MRI images are shown in fig. 2. The algorithm highlights those voxels of the  $\text{GTV}_{\text{deformed}}$  in red which are not covered by the  $\text{ITV}_{\text{CT}}$ . The  $\text{ITV}_{\text{CT}}$  was too small for 34 out of 157 MRI volumes of the shown exemplary patient case. Maximally 7% of the  $\text{GTV}_{\text{deformed}}$  were not covered by the  $\text{ITV}_{\text{CT}}$ . An improved  $\text{ITV}_{\text{MR}}$  can be determined by the union of all  $\text{GTV}_{\text{deformed}}$ .

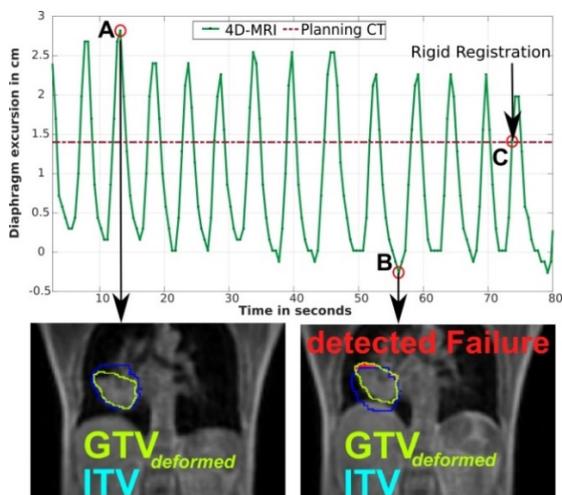

Fig 2: The estimated breathing curve is shown in the upper panel. The rigid registration from p-CT to 4D-MRI was performed using the 4D-MRI volumes of time point C. In the two shown MRI images the  $\text{ITV}_{\text{CT}}$  and the deformed GTV are marked for the two extreme values of the breathing curve. For the time point B the  $\text{GTV}_{\text{deformed}}$  is not covered by the  $\text{ITV}_{\text{CT}}$ .

### Conclusion

The feasibility of 4D-MRI based target volume evaluation and determination is demonstrated. The technique provides improved determination of a 4D-MRI based  $\text{ITV}_{\text{MR}}$ , which covers the GTV motion over several breathing cycles. The proposed technique can be used in MRI-guided radiotherapy workflows.

### OC-0073 Shoulder girdle impairment evaluation in breast cancer patients undergoing surgery and radiotherapy

D. Smaniotto<sup>1</sup>, D. Marchesano<sup>1</sup>, L. Boldrini<sup>1</sup>, V. Masiello<sup>1</sup>, M. Giraffa<sup>1</sup>, L. Maggi<sup>2</sup>, E. Amabile<sup>2</sup>, P.E. Ferrara<sup>2</sup>, F. Landi<sup>2</sup>, V. Valentini<sup>1</sup>, G. Mantini<sup>1</sup>

<sup>1</sup>Policlinico Universitario Agostino Gemelli- Catholic University, Radiation Oncology Department - Gemelli ART, Roma, Italy

<sup>2</sup>Policlinico Universitario Agostino Gemelli- Catholic University, Physical Medicine and Rehabilitation Unit, Roma, Italy

### Purpose or Objective

Aim of this study is to measure the incidence of pain and functional impairment of the ipsilateral shoulder girdle in patients who underwent surgery and radiotherapy (RT) for breast cancer, in order to elaborate preventive rehabilitation or treatments protocols contributing to an increase of patient quality of life.

### Material and Methods

Patients who underwent surgery and radiotherapy for breast cancer since 2009 and currently in follow up protocols were selected.

Exclusion criteria were the presence of moderate/severe arthrosis history and/or rheumatologic diseases. All the patients had complete physical and multi-dimensional exams during joint RT and physical medicine follow up visits.

The physical exam included the range of motion (ROM) evaluation through goniometric measurement of flexion, abduction, internal rotation and external rotation movements of the shoulder girdle.

Pain trigger points were identified and global performance status was assessed too.

The used scales were VAS (Visual Analogue Scale) for pain and depression, DASH (Disability of the arm, shoulder and hand) and the KI (Karnofsky Index).

Statistical analysis was realized with SPSS software v.14.

### Results

111 patients were selected: 94% of them underwent quadrantectomy while 6% had radical mastectomy. 60% of them had SLNB, while 40% underwent lymphadenectomy. 72% of them underwent standard adjuvant RT (5040 cGy/180 cGy on the breast and 1000 cGy/200 cGy boost and tumoral bed), while 28% had hypofractionated RT (4005 cGy/267 cGy).

Mean ages of the groups were 57.9 and 70.1 years respectively.

The ROM mean differences between the healthy and surgery side in the standard treatment group were  $7^{\circ}56'$  for shoulder flexion,  $13^{\circ}48'$  for abduction,  $1^{\circ}12'$  for external rotation and  $0^{\circ}6'$  for internal rotation. In the hypofractionated group the observed mean values were  $8^{\circ}52'$ ,  $11^{\circ}8'$ ,  $0^{\circ}35'$  and  $0^{\circ}14'$  respectively.

The standard RT group showed the following mean values: VAS pain 2.0, VAS depression 3.7, DASH 12.4 and KI 91.5%. For the hypofractionated group the following mean values were recorded: VAS pain 2.4, VAS depression 4.8, DASH 16.8 and KI 91.2%.

In the standard group, the considered trigger point percentages were 1.3 for neck, 13.8 for trapezium, 13.8 for scapula, 16.5 for pectoral muscle, 11.3 for arm and 5 for dorsal spine.

The corresponding values of the hypofractionated group were respectively 6.5, 29, 19.4, 6.5, 12.9, 6.5%. Results are summarized in table 1.

SCALES	Standard Radiotherapy	Hypofractionated Radiotherapy
	Mean Value $\pm$ DS	Mean Value $\pm$ DS
VAS scale for pain*	2,03 $\pm$ 3,07	2,42 $\pm$ 3,16
VAS scale for depression*	3,73 $\pm$ 3,28	4,87 $\pm$ 3,67
DASH SCORE (%)**	12,43 $\pm$ 18,27	16,87 $\pm$ 23,87
KARNOFSKY Index (%)***	91,5 $\pm$ 7,81	91,29 $\pm$ 9,22
<b>ROM - Range of Movement</b>	<b>Mean Value <math>\pm</math> DS</b>	<b>Mean Value <math>\pm</math> DS</b>
Shoulder flexion of surgery side	169°45' $\pm$ 18,79	163°42' $\pm$ 23,84
Shoulder flexion of healthy side	177°41' $\pm$ 8,57	172°34' $\pm$ 13,47
Shoulder abduction of surgery side	160°30' $\pm$ 29,15	152°44' $\pm$ 29,69

Trapezium	13.8	29
Scapula	13.8	19.4
Pectoral muscle	16.5	6.5
Arm	11.3	12.9
Dorsal Spine	5	6.5

\* VAS ( 0 = no pain or stress/depression, 10 = maximum pain or stress/depression)  
 \*\* DASH (0-20 = optimal 21-40 = discrete, 41-60 = good, 61-80 = sufficient, 81-100 = insufficient)  
 \*\*\* IF ( 100% = normal no complaints; no evidence of disease, 0% death)

### Conclusion

According to DASH score and trigger point evaluation, a better ROM can be appreciated in patients who underwent standard RT.

Pain is more common, both in terms of intensity and trigger point frequency (scapula and trapezium on top), in patients who underwent hypofractionated treatment. A slight arm functional impairment can also be recognized in this group.

These not statistically significant observations need to be further validated in more homogeneous and numerous samples in order to define an effective rehabilitation program.

### OC-0074 Analysis of diaphragm motion at various levels of abdominal compression by dynamic MRI

K.F. Cheng<sup>1</sup>, P.H. Fok<sup>1</sup>, J. Yuan<sup>2</sup>, O.L. Wong<sup>2</sup>, G. Chiu<sup>1</sup>  
<sup>1</sup>Hong Kong Sanatorium & Hospital, Department of Radiotherapy, Happy Valley, Hong Kong SAR China  
<sup>2</sup>Hong Kong Sanatorium & Hospital, Medical Physics and Research Department, Happy Valley, Hong Kong SAR China

### Purpose or Objective

To investigate the effectiveness of abdominal compression on diaphragm motion control.

### Material and Methods

15 healthy volunteers were recruited. Volunteers were positioned in Orfit stereotactic body radiation therapy (SBRT) solution which included a short SBRT base plate, a pressure system bridge, an adjustable screw and a pressure plate. The pressure plate was placed on the abdomen inferiorly to xiphoid process and rib cage to

apply abdominal compression force. Indexing numbers on the adjustable screw indicated the pressure that was applying to the volunteers. Four sets of MRI scans with four levels of abdominal compression were performed on each volunteer including, (i) free breathing (FB) representing no abdominal compression force applied (screw just touching pressure plate), (ii) high abdominal compression (HAC) representing the maximum abdominal compression force which the volunteer could tolerate, (iii) medium abdominal compression (MAC) representing 80% of HAC (80% of the screw reading difference between FB and HAC), (iv) low abdominal compression (LAC) representing 50% of HAC (50% of the screw reading difference between FB and HAC).

Examinations were done in a MR-Simulator (Siemens MAGNETOM RT Pro edition). Two six-channel radiofrequency coils were used to cover thorax and abdomen regions. A setup photo is shown in Fig.1. One dynamic MRI image (trueFISP sequence) was obtained at mid-coronal plane. The total acquisition time was about 14 seconds in a speed of 3 frames/s. The MR scan was repeated under the conditions of FB, HAC, MAC and LAC. Maximum diaphragm displacements were defined as the differences between the most superior and the most inferior diaphragm dome position in the dynamic MRI images. Maximum diaphragm displacements were compared among FB, HAC, MAC and LAC to investigate the effectiveness of abdominal compression on diaphragm motion control.

Fig 1. Abdominal compression setup with coils in MRI Sim.

### Results

One-way ANOVA was used to test the mean differences of maximum diaphragm displacement among the groups and the results are shown in table 1. The superior-inferior (SI) motion of diaphragm was decreased with increasing abdominal compression force. The mean of maximum right diaphragm displacement had significant differences in comparisons of HAC vs LAC, HAC vs FB, MAC vs FB (All  $p < 0.05$ ). Significant mean difference of maximum left diaphragm displacement was found in HAC vs. FB ( $p < 0.05$ ). The mean of maximum diaphragm displacement of right and left diaphragm was significantly reduced from 14.23 mm to 10.59 mm and from 13.64 mm to 10.34 mm respectively. 80% volunteers had less right diaphragm SI motion under HAC than FB. 73.3% volunteers had less left diaphragm SI motion under HAC than FB.

Table1. Mean of Max Displacement of right and left diaphragm under various abdominal compression levels.

Mean of Max Displacement - Rt Diaphragm (mm)				Mean of Max Displacement - Lt Diaphragm (mm)			
HAC	MAC	LAC	FB	HAC	MAC	LAC	FB
10.59 $\pm$ 3.17	11.18 $\pm$ 3.35	13.18 $\pm$ 4.39	14.23 $\pm$ 5.55	10.34 $\pm$ 5.57	11.32 $\pm$ 4.53	12.43 $\pm$ 5.04	13.64 $\pm$ 4.91

HAC=High Abdominal Compression, MAC=Medium Abdominal Compression, LAC=Low Abdominal Compression, FB=Free Breathing

**Conclusion** The performance of SBRT pressure bridge system is positive in reducing the diaphragm motion. However, because not all volunteers had reduced diaphragm motion under abdominal compression, screening is suggested for using the device to ensure patient can be benefited from it.

### OC-0075 Simple spatula improves the geometrical accuracy of a cranial mask for brain tumor radiotherapy

N. Wolffs<sup>1</sup>, R. De Jong<sup>1</sup>, L. Van Gorp<sup>1</sup>, K. Goudschaal<sup>1</sup>, N. Van Wieringen<sup>1</sup>, L. Stalpers<sup>1</sup>, A. Bel<sup>1</sup>

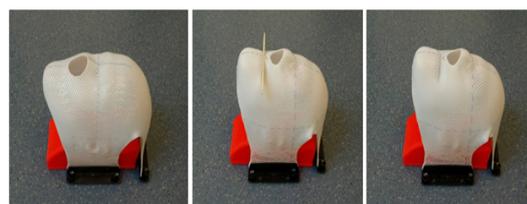

<sup>1</sup>Academic Medical Center, Department of radiation oncology, Amsterdam, The Netherlands

#### Purpose or Objective

The demands on accuracy in radiotherapy have increased especially in stereotactic treatments using IMRT or VMAT techniques where margins to the PTV are as small as 1 or 2 mm, but also for non-stereotactic treatments. Commercial systems providing better geometrical accuracy in patient positioning than conventional standard three-point masks, entail high costs. Although translations can be corrected with a couch shift, rotations cannot be corrected with a standard treatment couch and need to be prevented as much as possible. Therefore we aim to investigate whether the use of a dental fixation created with an inexpensive and simple wooden spatula, will improve accuracy in patient positioning.

#### Material and Methods

In 40 patients receiving non-stereotactic cranial radiotherapy, 144 conebeam CTs (CBCT) were acquired prior to treatment. Twenty patients had a standard three-point thermoplastic mask with a standard base (MacroMedics®, Waddinxveen, The Netherlands); next 20 patients had an identical mask and base, but with the addition of a dental fixation moulded by a wooden spatula, to create an extra point of fixation between the teeth rows. Patients were asked to bite gently on the wooden spatula during moulding of the mask to create an indentation in the mask for dental fixation. After cooling and hardening of the mask, the wooden spatula is removed. During the acquisition of the planning CT and all treatment fractions patients are instructed to bite gently on the indentation. All CBCTs were registered on bony anatomy of the skull. For patients with an online correction protocol, all data were included. For patients with extended NAL correction protocol, only the data of the first 'NAL'-phase were included. Thereby, the position inaccuracy was calculated on position errors before a position correction was applied. Individual systematic ( $\Sigma$ ) errors were calculated and analyzed with Levene test. Individual random errors ( $\sigma$ ) were calculated and analyzed with the Mann-Whitney test.

a

	Three-point mask with dental fixation and standard base					
	Translations mm			Rotations °		
	X (LR)	Y (CC)	Z (AP)	X (LR)	Y (CC)	Z (AP)
$\Sigma$ (group)	1.0	1.2	1.0	0.6 *	0.8	0.7
$\sigma$ (group)	0.8	0.9	0.6	0.5 *	0.6 *	0.6

\* (p=0.038), \* (p=0.017), \* (p=0.004)

#### Results

The table summarizes the group setup errors for both fixation systems. Most errors are smaller when using the three-point mask with dental fixation created with a simple wooden spatula compared to the three-point mask alone. Geometrical accuracy shows significant improvement in the systematic and random error for the rotation over the X axis and the random error for rotation over the Y axis.

#### Conclusion

Adding a dental fixation point to a standard three-point cranial mask by a simple wooden specula improves geometrical accuracy, particularly by reducing rotational errors. This may be of clinical importance, since rotational errors cannot be corrected by a standard treatment couch. Although the absolute errors are already small for the standard three-point mask, but given the small effort and the low additional costs of a simple wooden spatula, we decided to accept the mask with dental fixation as our standard for non-stereotactic brain tumor radiotherapy.

### OC-0076 Motion Capture Pillow shows potential to replace thermoplastic masks in H&N radiotherapy

S. Goldsworthy<sup>1,2</sup>, T. Dapper<sup>3</sup>, G. Griffiths<sup>3</sup>, A. Morgan<sup>1</sup>, S. McCormack<sup>1</sup>, S. Dogramadzi<sup>3</sup>

<sup>1</sup>Musgrove Park Hospital, Radiotherapy- The Beacon Centre, Taunton- Somerset, United Kingdom

<sup>2</sup>University of the West of England, Health and Applied Sciences, Bristol, United Kingdom

<sup>3</sup>University of the West of England, Bristol Robotics laboratory, Bristol, United Kingdom

#### Purpose or Objective

A key challenge to improve patient comfort is the common use of a thermoplastic mask for patients with head and neck cancers. Patients suffer from discomfort and the claustrophobic effect of the mask, or, as they lose soft tissue due to treatment and gain undesirable movement in the mask. A prototype system using a robotic Motion Capture Pillow (MCP) is investigated for proof-of-concept

and is pictorially presented for the potential replacement of thermoplastic masks.

#### Material and Methods

A radiographer nurtured a concept with robotics engineers and consulted with physicists regarding materials. A 3D head position tracking device - the MCP (Fig. 1) was designed and tested by robotics engineers in a limited user study. The pillow is a biologically-inspired sensing device based upon the deformation of the epidermal layers of the human skin. Deformation of MCP-head interaction is measured optically by tracking the movement of internal artificial papillae pins on the inside of the pillow skin (Fig. 1). These papillae pins create an image with a matrix of dots captured by a single camera inside the pillow. The head position image on the pillow has been matched with an absolute head position captured by an optical infrared system (Polaris NDI™) with a tracking tool attached to the person's mouth. The aim of the study was to validate accuracy of the MCP by measuring its resolution (smallest detectable input) and repeatability (the maximum deviation of output for the same input) (Fig. 2).

#### Results

Five basic movements of the head were detected 1. two translations across the MCP - laterally (Tx, x-axis) longitudinally (Ty, y axis) and one translation n vertical to the pillow (Tz, z axis) and 2. two rotations of the head: roll ( $\alpha$ ) and pitch ( $\beta$ ). A graphic user interface was created in Matlab™ to view and analyse the two sets of data - Polaris™ (Tx, Ty, Tz,  $\alpha$ ,  $\beta$ ) and MCP data. A minimum detectable deformation of the MCP in translation is 1mm, and in rotation is  $0.3^\circ$  ( $\alpha$ ) and  $0.6^\circ$  ( $\beta$ ). The repeatability test showed a maximum of one pixel output deviation for the same position.

#### Conclusion

The prototype MCP has been patented (1609040.9) and proof of concept has shown potential for consideration in clinical practice. The sensing resolution of the MCP can be improved by a larger number of dots per area or adaptations to the software algorithm. There is a small ambiguity between lateral translation and yaw rotations that can be resolved by an initial MCP calibration. The current challenge and future work is to develop a clinical system that will cause limited radiation attenuation, preserve some skin sparing, and is non-ferrous when considering magnetic resonance imaging. The preliminary prototype data calls for further investigations in the laboratory, including how to reduce jaw and cranium movement prior to being investigated in clinical practice.

#### OC-0077 Comparison of setup accuracy, intrafraction movement and comfort for two stereotactic masks

C. Meunier<sup>1</sup>, M. Pauvert<sup>1</sup>, V. Wergifosse<sup>1</sup>, M. Delree<sup>1</sup>, M. Wanet<sup>1</sup>, B. Bihin<sup>2,3,4</sup>, J.F. Daisne<sup>1,3</sup>

<sup>1</sup>CHU-UCL-Namur- site Sainte-Elisabeth, Radiation Oncology, NAMUR, Belgium

<sup>2</sup>University of Namur, Biology, NAMUR, Belgium

<sup>3</sup>Namur Research Institute for Life Sciences, NARILIS, NAMUR, Belgium

<sup>4</sup>CHU-UCL-Namur- site Godinne, Scientific Support Unit, YVOIR, Belgium

#### Purpose or Objective

Intracranial stereotactic radiosurgery (SRS) requires high precision for setup and during treatment. On Brainlab Novalis system, noninvasive repositioning with dedicated proprietary thermoplastic mask is as accurate as with the invasive ring. Macromedics developed a new full head mask dedicated to SRS, fully compatible with the Brainlab couch and localization system, named the Double Shell Positioning System (DSPS) with documented submillimetric and subdegree intrafraction accuracy. The aim is to prospectively compare both fixation systems in a

randomized trial for setup and intrafraction accuracy, as well as patient reported comfort.

#### Material and Methods

Study was approved by the Ethics Committee of CHU-UCL-Namur. All patients approved written informed consent. Sixty patients with various pathologies (metastases, vestibular schwannoma, meningioma or pituitary adenoma) had to be recruited. Randomization between Brainlab and DSPS masks was stratified according to disease and fractionation (one vs multiple fractions). For each treatment session, initial setup accuracy was measured and corrected with Brainlab exactrac system and 6 degrees of freedom (6DoF) values (tx, ty, tz, rx, ry, rz) were recorded in mm or degree and resultant vectors for translations were calculated. The same was made at the end of the session (intrafraction movement). Patient reported comfort with a Visual Analog Scale (VAS) at the end of confection time and for treatment (for fractionated treatments average value of all scores was considered). VAS went from 0 (most uncomfortable) to 10 (very comfortable). Comparisons for accuracy and comfort were made with mixed model linear regression (R 3.0.1, package nlme). Regarding accuracy, the variable was the mean movement (resultant vector) for each patient.

#### Results

We report the results for 58 patients, two patients are not treated yet. Among the 28 patients of the DSPS group, seven received a fractionated treatment (either 3 or 28 fractions). In the Brainlab group, it was the case for six of the 30 patients. Setup accuracy and intrafraction motion are recorded in Table 1. Initial setup accuracy was significantly better with the DSPS mask ( $P < 0.01$ ), particularly in the y direction (longitudinal) and around the x rotation (head tilt) where it showed less variability. There was no significant difference for intrafraction motion ( $P = 0.88$ ), both masks showing submillimeter and subdegree accuracy on average. During confection, both masks were rated as comfortable (average VAS scores 8.7 and 8.4 for DSPS and Brainlab,  $P = 0.53$ ). For treatment, DSPS was scored as more comfortable than Brainlab (average VAS scores 7.2 and 6.0,  $P = 0.04$ ).

Table 1: setup positioning and intra fraction accuracy for DSPS and Brainlab masks. Mean translation error (x, y and z directions) in mm, mean resultant vector in mm +/- SD and mean rotation error (around x, y and z rotation axes) in  $^\circ$ .

TIME	MASK	TRANSLATIONS (mm)			VECTOR (mm $\pm$ SD)	ROTATIONS ( $^\circ$ )		
		x	y	z		x	y	z
positioning	DSPS	-1.1	0.7	-0.6	2.5 $\pm$ 1.1	-0.3	0.9	0.8
	BRAINLAB	-1.8	2.3	-0.4	3.6 $\pm$ 1.8	-0.7	0.3	0.8
intrafraction	DSPS	-0.1	0.2	0.1	0.5 $\pm$ 0.2	0.0	-0.1	0.0
	BRAINLAB	-0.2	0.1	0.1	0.5 $\pm$ 0.3	0.0	0.0	-0.1

#### Conclusion

We could demonstrate that DSPS and Brainlab dedicated masks are both viable alternatives to invasive head frame for SRS, showing submillimeter and subdegree intrafraction motion. Initial setup accuracy was significantly better with DSPS, maybe due to the higher comfort reported by the patients.

#### Symposium with Proffered Papers: Novel approaches in gut matters

#### SP-0078 Best of both worlds: can novel pathways be targeted for reduced gut toxicity but improved tumour response?

M.M. Olcina<sup>1</sup>, R. Kim<sup>1</sup>, A.J. Giaccia<sup>1</sup>

<sup>1</sup>Stanford University, Department of Radiation Oncology, Stanford, USA

Radiotherapy is an effective treatment strategy for cancer, but a significant proportion of patients still

experience radiation-induced toxicity due to damage to normal tissue in the irradiation field. Increasing the therapeutic window of radiotherapy may be achieved by using molecularly targeted therapies against pathways that are altered in cancer. The complement system is an important pathway in immunity composed of soluble and cell surface proteins. Several members of this pathway are upregulated in cancer and complement inhibition is under investigation as a therapeutic strategy, including in combination with radiotherapy. Interestingly, our data suggests that in response to radiotherapy, expression of complement regulators CD55 and CD59 is decreased in normal colon. Importantly, these expression changes correlate with an increase in the C5b-9 complex (thought to be responsible for cell lysis) in irradiated colon *in vivo*. Furthermore, our results suggest that targeting the complement system (either genetically or pharmacologically) can result in increased survival of mice following radiotherapy, through protection of the gastrointestinal tract from radiation-induced toxicity. Together, these findings suggest that targeting the complement system could be a promising approach to reduced radiation-induced gastrointestinal toxicity thereby increasing the therapeutic window of radiotherapy.

**SP-0079 Bowel radiation injury: complexity of the pathophysiology and promises of cell and tissue engineering**

L. Moussa<sup>1</sup>, P. Weiss<sup>2</sup>, M. Benderitter<sup>1</sup>, C. Demarquay<sup>1</sup>, J. Guicheux<sup>2</sup>, G. Réthoré<sup>2</sup>, N. Mathieu<sup>1</sup>

<sup>1</sup>*Institut de Radioprotection et de Sûreté Nucléaire, SRBE, Fontenay-aux-Roses- Paris, France*

<sup>2</sup>*Institut National de la Santé et de la Recherche Médicale, LIOAD, Nantes, France*

Radiation therapy is crucial in the therapeutic arsenal to cure cancers; however, normal tissue situated in the irradiation field can be damaged by ionizing radiation, leading some specialists to define these specific gastrointestinal complications as “pelvic radiation disease”. This is particularly important as the number of patients suffering from this disease is increasing with increased life expectancy of patients treated for cancer. Mesenchymal Stromal Cells (MSCs) represent a promising strategy to treat radiation-induced intestinal damage. Indeed, we previously demonstrated in rats, mini-pigs then patients over-irradiated during radiotherapy for prostate cancer, that intravenous injection of MSCs reduces severe colorectal lesions. However, this effect seems temporary and repeated injections have been recommended. The beneficial effects of MSCs have been related to their capacity to engraft, survive and secrete bioactive factors in the host tissue. We need to optimize the efficacy of the injected cells, particularly, with regard to extending their life span in the irradiated tissue. Here, we propose to use a colonoscope to deliver MSCs embedded in a biocompatible hydrogel (Si-HPMC) directly into the colon. We demonstrated *in vivo* using a rat model of radiation-induced severe colonic damage that MSC+Si-HPMC improve colonic epithelial structure and function. These results could open up new perspectives in regenerative medicine in particular with the co-administration of MSC and ex-vivo expanded “mini-gut”.

**OC-0080 Normal tissue toxicity and in vivo dose-equivalence of synchrotron radiotherapy modalities**

L. Smyth<sup>1,2</sup>, J. Crosbie<sup>3,4</sup>, J. Ventura<sup>1</sup>, J. Donoghue<sup>1,3</sup>, S. Senthil<sup>4</sup>, P. Rogers<sup>1</sup>

<sup>1</sup>*University of Melbourne, Obstetrics & Gynaecology, Melbourne, Australia*

<sup>2</sup>*Epworth HealthCare, Radiation Oncology, Melbourne, Australia*

<sup>3</sup>*RMIT University, School of Science, Melbourne, Australia*

<sup>4</sup>*Alfred Hospital, William Buckland Radiotherapy Centre, Melbourne, Australia*

**Purpose or Objective**

Microbeam Radiotherapy (MRT) is a pre-clinical synchrotron radiotherapy modality characterised by fields of high intensity, parallel beams which form 25-50 micron ( $\mu\text{m}$ ) wide ‘peak dose’ regions spaced by 100 - 400 $\mu\text{m}$  ‘valley’ regions. The aim of this study was to assess the safety profile of MRT compared to high dose-rate broad-beam radiotherapy based on *in vivo* normal tissue toxicity.

**Material and Methods**

A dose-escalation study using MRT and high dose-rate synchrotron broad-beam radiotherapy (SBBR) was performed on C57BL/6 mice (male and female, 8-10 weeks old). Mice received either Total Body Irradiation (TBI) or Partial Body Irradiation to their entire abdomen (PBI). MRT was performed at the Australian Synchrotron with an array of microbeams 50  $\mu\text{m}$  wide and spaced by 400  $\mu\text{m}$ . SBBR was delivered at the Australian Synchrotron using a dose rate of 40 Gy/second. For TBI, the broad-beam doses were 4, 6, 8 and 10 Gy and the MRT peak doses were 48, 64, 96 and 144 Gy. For PBI, the broad-beam doses were 6, 9, 12 and 15 Gy and the MRT peak doses were 180, 270, 360 and 450 Gy. Five mice were irradiated per group. Mice were monitored twice per day for one month following irradiation for signs of weight loss and other gastrointestinal toxicities such as diarrhoea, and were euthanized according to strict intervention criteria.

**Results**

For TBI, all mice survived with no signs of diarrhoea up to peak MRT doses of 144 Gy. There was a dose-dependent increase in the incidence of sustained weight loss, with four out of five mice in the 144 Gy group showing at least 10% weight loss two weeks following irradiation. All mice in the 48 Gy and 64 Gy groups returned to within 5% of their pre-experimental weight eight days following irradiation. In the SBBR groups, 10 Gy led to irreversible weight loss and euthanasia for all mice within two weeks of irradiation. All mice in the 6 and 4 Gy SBBR groups returned to their pre-experimental weight within nine days of irradiation. For PBI, all mice in the 450 Gy group experienced 20% weight loss, severe diarrhoea and dehydration within six days of irradiation, consistent with gastrointestinal syndrome, and were euthanized. All mice in the 360 Gy MRT and 15 Gy SBBR groups also lost 20% of their pre-experimental body weight, showed signs of dehydration and were euthanized. All mice in the 270 and 180 Gy MRT groups and the 9 and 6 Gy SBBR groups survived, experiencing reversible weight loss and showing no signs of diarrhoea.

**Conclusion**

These are the first systematic dose-escalation toxicity data for MRT and high dose-rate SBBR for the gastrointestinal tract. The threshold for catastrophic acute gastro-intestinal toxicity lies between 270 and 360 Gy for MRT and between 10 and 15 Gy for high dose-rate synchrotron broad-beam radiotherapy when irradiating the entire abdomen. A comparison with toxicity data for conventional dose-rate broad beam radiotherapy is required to determine whether ultra-high dose-rates provide a normal tissue sparing effect.

**OC-0081 Patient Safety Is Improved With An Extensive Incident Learning System—9 Years Of Clinical Evidence**

C. Deufel<sup>1</sup>, L. McLemore<sup>1</sup>, L. Fong de los Santos<sup>1</sup>, K. Classic<sup>2</sup>, S. Park<sup>1</sup>, K. Furutani<sup>1</sup>

<sup>1</sup>*Mayo Clinic MN, Radiation Oncology, Rochester, USA*

<sup>2</sup>*Mayo Clinic MN, Radiation Safety, Rochester, USA*

### Purpose or Objective

Medical error rates are a leading cause of death in the United States. Health leaders have advocated for incident learning systems (ILS) to prevent errors, but there is limited evidence demonstrating that ILSs improve patient safety. Herein, we report a long term retrospective review of 2273 prospectively collected and analyzed incident learning system reports for the brachytherapy practice at a large academic institution for the years 2007-2015.

### Material and Methods

This nine-year ILS intervention extended reporting beyond the institutional pathway for near-misses. An ILS was established in 2007 for the entire department to report all standard operating procedures deviations, including low risk deviations that do not reach the patient but could indirectly impact patient care. A multidisciplinary committee continually measured risk to patients by assigning root causes and composite-risk-scores to all incidents. Primary outcomes were decreased dose risk and composite risk scores. Incidents were scored from 1 (low) to 5 (high) in five categories: likelihood of recurrence, likelihood of quality assurance failure, likelihood of non-dose related severity, likelihood of dose related severity or violation of radiation safety policy, and staff or patient time wasted. A composite-risk-score was calculated from the multiplicative product of the aforementioned scores (minimum score = 1<sup>5</sup>, maximum score = 5<sup>5</sup>). Secondary outcomes included safety culture metrics such as improved communication and written procedure quality. Risk scores were used to identify needed practice changes. Relevant incidents were communicated to all staff. Significance was tested using Chi-squared and Spearman statistical methods.

### Results

For 5258 brachytherapy procedures performed between January 1, 2007 and December 31, 2015, participation in the incident learning system increased remarkably between 2007 (0.12 submissions/procedures) to 2011 (1.58 submissions/procedures) and has remained stable since 2011. Since 2011, risk of dose error or radiation safety policy violation decreased by 60% ( $p < 0.001$ ), and frequency of composite-risk-scores greater than 50 (the ILS threshold for immediate action) decreased by 69% ( $p < 0.001$ ). Significant decreases were observed in incidents with root causes of poor communication (57% decrease,  $p < 0.001$ ) and poor quality of written procedures (56% decrease,  $p < 0.001$ ) as a result of practice improvement.

### Conclusion

Patient safety was significantly improved in brachytherapy through use of a comprehensive incident learning system that captured both low and high risk incidents. Incident learning systems may be effective in promoting a culture of safety and preventing medical error.

### OC-0082 Novel Valencia-type skin applicators: Dosimetry and implementation of a TG-43 hybrid technique

D. Baltas<sup>1</sup>, G. Anagnostopoulos<sup>2</sup>, M. Andrassy<sup>3</sup>

<sup>1</sup>Universitätsklinik Freiburg, Medical Physics - Radiation Oncology, Freiburg, Germany

<sup>2</sup>pi Medical Ltd, Medical Physics, Athens, Greece

<sup>3</sup>Eckert&Ziegler GmbH, Medical Physics, Berlin, Germany

### Purpose or Objective

To determine the relative dose rate distribution in water for the novel Bebig 20 mm (BVH-20) and 30 mm (BVH-30) skin applicators. Results for both skin applicators are also provided in the form of a hybrid TG-43 dosimetry technique. Furthermore, the radiation leakage around both skin applicators, as well as the impact of the geometrical uncertainties on the dose delivery are studied and reported.

### Material and Methods

MC simulations were performed using the MCNP5 v.1.6 code, which was benchmarked against dosimetry data for the Bebig Ir2.A85-2 <sup>192</sup>Ir source and the dose data for the two Elekta Valencia skin applicators. The dose distributions for both Bebig applicators in a water phantom were calculated. The dosimetric quantities derived according to a hybrid TG-43 dosimetry technique were incorporated in a TPS and the accuracy of the dose calculation in comparison to MC results was assessed. Furthermore the air-kerma rate in air was simulated in the vicinity of each skin applicator to assess the radiation leakage of both skin applicators. For the assessment of the geometrical uncertainties impact on the dose administered to the PTV, the tolerance limit values of all skin applicator parts and source offset positions were modelled and calculated. The dose percentage difference is shown with the aid of colormap figures.

### Results

Results from MC-simulations of both skin applicators are presented in form of figures, dose rate tables and with the aid of the quantities defined in the hybrid TG-43 dosimetry technique. Their output factors, flatness and penumbra are presented in Table 1. Their radiation shielding was adequate for their clinical employment with the 10% isokerma line in air confined within 1cm from the skin applicator shielding surface as illustrated in Figure 1. The TPS dose rate values calculated with the hybrid TG-43 technique were within 2% with the MC dose rate values in the dose flattened regions. The geometrical uncertainties impact on the PTV showed a 3% over-/underdosage at the prescription depth of  $d=0.3$ cm. The geometrical uncertainties impact on dosimetry are more profound at the applicator periphery projection in the high dose gradient regions outside of the PTV extension and could reach a value of up to 14% dose difference. Further work is currently performed for the experimental verification of the MC results.

Skin applicator type	Output factor (cGyh <sup>-1</sup> U <sup>-1</sup> )	Flatness (%)	Penumbra (mm)
BVH-20	0.2215 0.0063	+/- 1.8	2.0
BVH-30	0.1729 0.0049	+/- 2.0	2.2

**Table 1.** The output factors, flatness and penumbra of the novel Bebig skin applicators evaluated at the reference depth of  $d=0.3$ cm from the MC simulations

### Conclusion

The Bebig skin applicators are suitable for the treatment of skin lesions and their dosimetric data can be entered in the form of hybrid TG-43 dose datasets in the TPS, so as to enable 3D dose calculations. The user is advised to perform autoradiography prior to the clinical use because a potential source shift could result to the over-/underdosage of the PTV and the OARs.

### OC-0083 High-dose-rate surface brachytherapy for basal cell cancer

P. Wojcieszek<sup>1</sup>, M. Szlag<sup>2</sup>, A. Cholewka<sup>2</sup>, S. Kellas-Ślęczka<sup>1</sup>, A. Pruefer<sup>2</sup>, M. Fijałkowski<sup>1</sup>, B. Białas<sup>1</sup>

<sup>1</sup>MSC Memorial Cancer Center and Institute of Oncology Gliwice Branch, Brachytherapy, Gliwice, Poland

<sup>2</sup>MSC Memorial Cancer Center and Institute of Oncology Gliwice Branch, Radiotherapy Planning, Gliwice, Poland

### Purpose or Objective

To evaluate efficacy of high-dose-rate (HDR) surface brachytherapy with individual moulds and flaps in the treatment of basal cell cancer.

### Material and Methods

One hundred sixty two skin cancer patients were treated with HDR surface brachytherapy from 01.01.2008 to 31.12.2009 in our department. Patients with pathologically confirmed basal cell cancer were enrolled

2 and 3 respectively). Before treatment symptoms of itch (80% and 69%) and pain (67% and 58%) were present in a majority of cases in center 1 and 2, after treatment complaints were relieved completely or less severe in most patients (no or less itch 95%, no or less pain 95%). The scheme of 2x9Gy resulted in more and more severe complications, with 3x6Gy less complications were found, and using 2x6Gy even fewer and less severe complications were reported (major complication 24%, 16%, 6%  $p=0.046$ , minor complication 56%, 39%, 17%  $p<0.001$  for center 1, 2 and 3 respectively).

#### Conclusion

We conclude that the scheme using the lowest dose of radiation seems to have a similar good outcome on recurrences as well as a lower risk on mild as well as more severe side effects, like infections, chronic wounds and apparent pigmentation differences. Our results show that when using brachytherapy a BED of 30Gy is not needed and 19Gy can be sufficient. We recommend using a lower radiation scheme, i.e. 2x6Gy, to reduce adverse events and minimize stochastic effect of this treatment.

#### OC-0086 Perioperative interstitial high-dose-rate (HDR) brachytherapy for the treatment of recurrent keloids

P. Jiang<sup>1</sup>, M. Geenen<sup>2</sup>, F.A. Siebert<sup>1</sup>, R. Baumann<sup>1</sup>, P. Niehoff<sup>3</sup>, D. Druecke<sup>4</sup>, J. Dunst<sup>1</sup>

<sup>1</sup>UKSH- Campus Kiel, Department of Radiation Oncology, Kiel, Germany

<sup>2</sup>Lubinus Clinic, Department of Reconstructive Surgery, Kiel, Germany

<sup>3</sup>University Witten-Herdecke, Department of Radiation Oncology, Kiel, Germany

<sup>4</sup>UKSH- Campus Kiel, Department of Reconstructive Surgery, Kiel, Germany

#### Purpose or Objective

Perioperative radiotherapy of keloids can reduce the risk of recurrence. Due to the wide variety of concepts the optimal treatment regime remains unclear. We established in our clinic a protocol of perioperative interstitial HDR-Brachytherapy with 3 fractions of 6 Gy and achieved an excellent local control rate of 94%. (Jiang. et. al. 2015 IJROBP). We report now an update of our long-term results of this prospective study of perioperative interstitial brachytherapy. Here we include 29 patients with a median follow-up of 5 years.

#### Material and Methods

From 2009 to 2015, 29 patients with 37 recurrent keloids were treated with perioperative interstitial HDR-brachytherapy; 3 patients had been previously treated with adjuvant external beam radiotherapy and presented with recurrences in the pretreated area. After (re-) excision the keloids, a single plastic flexible brachytherapy tube for irradiation was placed subcutaneously before closing the wound. The target volume covered the scar in total length. CT-based treatment planning was used in selected cases, e.g. if two lesions in close proximity were to be treated or for lesions in difficult anatomic locations (e.g. helix of the ear). Brachytherapy was given in three fractions with a single dose of 6 Gy in 5mm tissue depth, with the exception of one patient with a keloid on the helix who received a single dose of 6 Gy to the whole tissue. The first fraction was given within 6 hours after surgery, the other two fractions on the first postoperative day. Follow-up visits were scheduled at 6 weeks, 3 months, 6 months, 1 year, and every year thereafter.

#### Results

No procedure-related complications (e.g. secondary infections) occurred. 23 patients had keloid-related symptoms prior to treatment like pain and pruritus; disappearance of symptoms was noticed in all patients after treatment. After a median follow-up of 49,7 months (range: 7,9 to 92,7 months), 3 keloid recurrences and 2

hypertrophied scars were observed. Pigmentary abnormalities were detected in 3 patients and additional 7 patients had a mild delay in the wound healing process.

#### Conclusion

Interstitial brachytherapy is able to deliver conformal radiation exactly in the scar with extremely low exposure of other normal tissues. It is suitable to most shapes and irregular surfaces. Brachytherapy is cost-effective and can be offered in the majority of radiotherapy centers. Our three-fraction treatment schedule reduces the treatment period to two days and is therefore convenient for the patients. A radiobiological analysis of more than 2500 patients from multiple centers found a low  $\alpha/B$ -value for local control of keloids (Flickinger et. al. 2011 IJROBP). The analysis recommended a treatment concept with few fractions and high doses per fraction delivered in a short period of time as early as possible after resection. Our results confirm it and suggest that brachytherapy may be advantageous in the management of high-risk keloids, even after failure of external beam radiotherapy.

#### PV-0087 Improvement of models for survival prediction through inclusion of patient-reported symptoms

C. Nieder<sup>1</sup>, T. Kämpe<sup>1</sup>, B. Mannsåker<sup>1</sup>, A. Dalhaug<sup>1</sup>, E. Haukland<sup>1</sup>

<sup>1</sup>Nordlandssykehuset HF, Dept. of Oncology and Palliative Medicine, Bodoe, Norway

#### Purpose or Objective

Widely used prognostic scores, e.g., for brain metastases and incurable lung cancer are based on disease- and patient-related factors such as extent of metastases, age and performance status (PS), which were available in the databases used to develop the scores. Few groups were able to include prospectively recorded patient-reported symptoms. In our department, all patients were assessed with the Edmonton Symptom Assessment System (ESAS, a questionnaire addressing 11 major symptoms and wellbeing on a numeric scale of 0-10) at the time of treatment planning since 2012. Therefore, we analyzed whether or not baseline symptom severity provides relevant prognostic information, which should be included during development of prognostic scores.

#### Material and Methods

A retrospective review of 112 patients treated with palliative radiotherapy (PRT) between 2012 and 2015 was performed. The patients scored their symptoms before PRT. ESAS items were dichotomized (below/above median). Uni- and multivariate analyses were performed to identify prognostic factors for survival, and from these a predictive model was developed.

#### Results

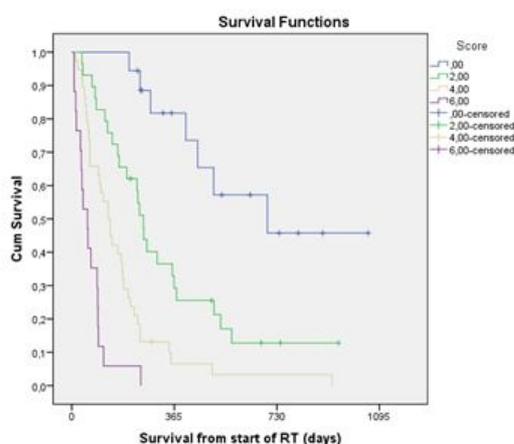

The most common tumor types were prostate (30%), breast (12%) and non-small cell lung cancer (26%), predominantly with distant metastases. Median survival was 8 months. Univariate analyses identified 12 factors that were associated with survival, including several ESAS items. Multivariate analysis confirmed the significance of 6 factors, from which a predictive model was developed. These were ESAS pain while not moving (median 3), ESAS appetite (median 5), ECOG PS, pleural effusion/pleural metastases, iv antibiotics during or within 2 weeks before PRT and no systemic cancer treatment. The table shows the prognostic score resulting from the multivariate model. One or two points were assigned, depending on the hazard ratio of each factor. Patients with a point sum of 0-1 had an estimated median survival of 23 months, a point sum of 2-3 8.4 months, a point sum of 4-5 4.2 months and a point sum of 6 or more 1.8 months ( $p=0.001$ ).

Calculation of the prognostic score

ECOG PS 2-4	2 points
No systemic treatment	2 points
Pleural effusion and/or metastases	2 points
On intravenous antibiotics during last 2 weeks	1 point
ESAS appetite worse than median	1 point
ESAS pain while not moving worse than median	1 point

#### Conclusion

The presence of pain while not moving and reduced appetite (below/above median) predicted significantly shorter survival. The score identified 4 groups with clearly different prognosis and should be examined in additional independent cohorts. Future research should include patient-reported symptoms because they were more important than primary tumor type, age and other baseline parameters.

#### PV-0088 Half body irradiation schedule in patients with multiple bone metastases: a phase I-II trial

<sup>7</sup>Policlinico Universitario "A. Gemelli"- Università Cattolica del Sacro Cuore, Department of Radiotherapy, Rome, Italy

#### Purpose or Objective

To evaluate the efficacy of an half-body irradiation (HBI) schedule on pain relief in multiple bone metastases cancer patients. The secondary aim was to evaluate the safety of this short course hypofractionated treatment.

#### Material and Methods

From August 2003 to February 2016, patients with widespread symptomatic bone metastases and no previous history of large field radiotherapy were enrolled. The pain score (pain evaluation obtained by multiplying severity × frequency) and the drug score (analgesic assumption evaluation obtained by multiplying severity×frequency) as

well as the visual analog scale (VAS) for pain were used to record and monitor pain. Data on pain status and dosage/frequency of analgesic consumption were recorded before treatment (baseline evaluation) and during follow-up. HBI encompassed the lower half body (pelvic bones, lumbo-sacral vertebrae and upper third of femurs). Prostate cancer metastases received 15 Gy/3Gy fraction along 5 days. Skeletal metastases due to other primary tumors received accelerated HBI (3 Gy fractions twice daily, 6-8 h apart, on 2 consecutive days, up to 12 Gy).

#### Results

258 patients (M/F 102/156; median age: 64; range 29-95) were enrolled and completed the treatment. After HBI, a significant reduction of pain, as evaluated by VAS, was recorded (pre- treatment versus post- treatment mean VAS: 5.4 versus 2.7, CI 2.2-3.2; p=0.0001). Moreover, 62 patients (24%) had complete pain relief and 64 patients (25%) showed more than a 30% VAS reduction. Overall response rate for pain was 53% (CI 0.95: 46.2% - 60.4%). In 182 patients (71%) Pain and Drug scores before and after treatment were valuable. Statistical analysis showed a significant reduction of Pain and Drug scores especially concerning patients with the highest scores before treatment (Chi squared test: p=0.001). In particular, 26 patients (14%) achieved a Drug Score's reduction and 40 patients (22%) discontinued analgesic therapy. Nineteen percent of all series exhibited no treatment related complications, and an additional 79% experienced only mild or moderate (transitory) toxicity. As a whole, Grade > 3 toxicity (severe) was seen in four patients (2%): haematologic G3 (1 pt) and gastro-intestinal G3 (2 pts). Only 1 Grade 4 haematologic toxicity was registered. 111 patients (43%) presented pain flare's phenomenon.

#### Conclusion

HBI is safe and effective, providing long lasting pain reduction in patients with multiple bone metastases.

#### PV-0089 Relation between pain control and bone mineral density change in bone metastases

H. Kobayashi<sup>1</sup>, H. Takagi<sup>1</sup>, K. Tanaka<sup>1</sup>, T. Matsuyama<sup>1</sup>, K. Yamazaki<sup>1</sup>, M. Matsuo<sup>2</sup>, T. Yanase<sup>1</sup>, M. Tanaka<sup>1</sup>  
<sup>1</sup>Ogaki Municipal Hospital, department of radiotherapy, Ogaki, Japan  
<sup>2</sup>Ogaki Municipal Hospital, department of nursing, Ogaki, Japan

#### Purpose or Objective

External beam radiation therapy is an effective technique for bone metastases. The main roles of radiotherapy are relief of pain and stabilizing metastatic bones. In achieving pain control in patients with bone metastases, pain relief is usually obtained in 70% of patients by using a variety of dose fraction schemes. However the role of radiotherapy in stabilizing is unclear. The purpose of this study is to investigate the relationship between the pain control effects of radiotherapy and bone mineral density change after the after the compression of radiotherapy

#### Material and Methods

Data from 102 patients who underwent radiation therapy because of lytic bone metastases lesions from January 2015 to December 2015 were retrospectively reviewed. Forty patients (sixty-two lesions) received computed tomography (CT) scans prior to initiation and at least twice after radiation therapy. The most common primary site was breast accounting for 14 (35%). Liver, lung, esophagus and rectal tumors accounted for 11 (27.5%), 8 (20%), 3 (7.5%), and 2 (5%) patients, respectively. Percent change in bone attenuation between pre-radiation therapy and post-radiation therapy were computed for irradiated metastatic bone (IMB) lesions and irradiated non-metastatic bone (INMB). Pain intensity was self-assessed by patients using a scale graduated from 0 to 10. Patients were asked for the scale at least once a week from the beginning of radiotherapy till 3 weeks after

compression of irradiation. Pain relief meant the achievement of the score 3 down in the scale.

### Results

The overall degree of response to radiotherapy was 51/62 (82.2%). The bone densities of both IMB and INMB dropped by about 10 % from immediate to one month after radiotherapy. The bone densities of IMB lesions increased after then. There are close relations between the pain control effects of radiotherapy and bone mineral density change. Overall, from 3 months onward, the bone densities of effective patients were significantly higher than its pre-radiotherapy value.

### Conclusion

Radiotherapy provide a meaningful supportive but not perfect prolong benefit to many patients with bone metastases. Mineralization effects of radiation therapy depend on the characteristic metastases, especially the effect of radiotherapy.

### PV-0090 The risk of myelopathy after reirradiation of the spinal cord.

M. Hiul Suppli<sup>1</sup>, P. Munck af Rosenchold<sup>1</sup>, H. Pappot<sup>1</sup>, S.A. Engelholm<sup>1</sup>

<sup>1</sup>Rigshospitalet, Department of Oncology, Copenhagen, Denmark

#### Purpose or Objective

Spinal re-irradiation has for a long time been considered unacceptable due to the risk of radiation induced myelopathy (RIM). Previous studies of of reirradiation have demonstrated the possibility of gait preservation with minimal risk of RIM. Recommendations regarding treatment dose, cumulative dose and time between treatments to estimate the risk of RIM based on previously reported data exist. However, these recommendations have been based on retrospective analysis of smaller cohorts of patients. Very limited data on the risk of vertebral fractures (VF) is presently available for fractionated palliative radiotherapy. In this study we investigate the risk of RIM and VF in a large cohort of consecutive patients treated multiple times with palliative radiotherapy of the spine.

#### Material and Methods

From the year 2010 until 2014 a total of 2387 patients received spinal irradiation with a palliative intent for metastatic spinal cord compression. All patients were reviewed for prior irradiation at either our facility or another radiotherapy department. We find that 249 patients had potentially overlapping fields on the spinal cord. After analysis of treatment plans, we find that 220 patients received re-irradiation of the spinal cord. Clinical and treatment data was obtained from the patients' records and RT planning system. Follow-up data was obtained with approval from the Danish board of health.

#### Results

Patients had metastatic disease from breast, prostate, lung, haematological or other cancers (22.7%, 21.8%, 21.4%, 3.2% and 30.9% respectively). Median time from 1st irradiation until 2nd irradiation was 306 days, range 15 days-33 years. Median number of days from 2nd irradiation until death was 91 days (range 1 days-5 years). Median cumulative dose was 57.8 Gy (EQD2, with  $\alpha/\beta=2$ ), range: 20.0-93.0Gy. Myelopathy or vertebral fracture likely related to re-irradiation was observed in fifteen patients. One patient developed myelopathy, for an additional five patients, myelopathy could not be ruled out from retrospective observations. Nine patients experienced a vertebral fracture within the treatment field, which resulted in neurological deficit for eight of these patients.

Patients characteristics: Re-irradiation of the spinal cord

		N	%	Mean
Gender	Female	92	36,9%	
	Male	157	63,1%	
Intent of first treatment	palliative	175	77,1%	
	curative	51	22,5%	
	Unknown	1	0,4%	
Diagnosis of myelopathy	No	212	96,4%	
	Yes	1	0,5%	
	Suspicion	5	2,3%	
	Unknown	2	0,9%	
Spinal fracture after re-irradiation	No fracture	210	95,5%	
	With neurological deficit	8	3,6%	
	Without neurological deficit	1	0,5%	
	Unknown	1	0,5%	
Size of spinal cord overlap in centimeters				6,6
Age at second treatment				64

220 cases of spinal re-irradiation, 2010-2014, Copenhagen, Denmark.

### Conclusion

Patients suffering from spinal metastases and impending spinal cord compression are often treated with radiation. Patients with neurological deterioration due to metastatic progression within a previously treated site of the spinal cord face the risk of either fulminant metastatic spinal cord compression or toxicity due to re-irradiation. Within our cohort the incidence of myelopathy remained low, but vertebral fractures were more prevalent. Patients with spinal metastases treated with repeated radiotherapy and potential long term survival should be considered for spinal instrumentation.

### PV-0091 Quantifying the Gap Between Radiotherapy in the Elderly and the Demand for Age-Agnostic Treatment.

T. Mee<sup>1</sup>, N.F. Kirkby<sup>1</sup>, K.J. Kirkby<sup>1</sup>, R. Jena<sup>2</sup>, A. Choudhury<sup>3</sup>

<sup>1</sup>University of Manchester, Division of Molecular & Clinical Cancer Sciences, Manchester, United Kingdom

<sup>2</sup>University of Cambridge, Department of Oncology, Cambridge, United Kingdom

<sup>3</sup>The Christie NHS Foundation Trust, Clinical Oncology, Manchester, United Kingdom

#### Purpose or Objective

Radiotherapy is prescribed less in the elderly compared to other age cohorts. However, current research suggests that there is little clinical evidence for this. In England, the demand for radiotherapy services is greater than capacity, so any increase in demand must be considered carefully. This can be done using population-based modelling systems. The potential effects of changing the prescription paradigm in the elderly needs to be modelled for a health care system at a local level to estimate the impact on demand for services, due to variations in local demographics and incidence rates.

#### Material and Methods

The Malthus model, an evidence-based tool for modelling radiotherapy demand, was used to calculate the demand for radiotherapy, broken down into age groups, for the whole of England for 2015. The simulation was completed in an age-agnostic manner. The simulation outputs were compared to the Radiotherapy Data Set, a dataset of delivered radiotherapy within the National Health Service

for England. Hence, the gap between delivered and theoretical maximum demand can be calculated. With the gap quantified, adjustments can be made to the delivered radiotherapy treatments in different age groups, or to access rates, to estimate the increase in demand for services.

### Results

Figure 1. shows the difference between modelled demand and delivered treatment. In the age bands there is a small fall-off in the number of fractions prescribed per incidence at the ages above 75 and a more marked drop-off above 80, shown in Table 1. However, the access rate appears to be declining steadily from an earlier age. If the average attendance per episode was to increase to a more steady decline of a few fractions per age band (80-84: 12.5#, 85+:10#) then demand would increase by 41,000 fractions per year. If access rate was to increase to account for a greater number of elderly being treated (80-84:32%, 85+:28%) then demand would increase by 44,000 fractions per year. If both the access rate and fractionation increased then demand would increase by 97,000 fractions per year. The effects on local populations will vary, considering Malthus predicts demand across England to vary between 19,000 fractions per million to 80,000 fractions per million.

Age Group	% # Demand actually delivered	Recorded attendance per episode	Access rate
65-69	95%	15.19	42%
70-74	94%	15.19	40%
75-79	86%	14.53	36%
80-84	52%	10.71	28%
85+	28%	7.48	20%

Table 1. Delivered fractionation as a percentage of evidence-based demand, actual attendance per episode and access rate for England, broken down by elderly age groups.

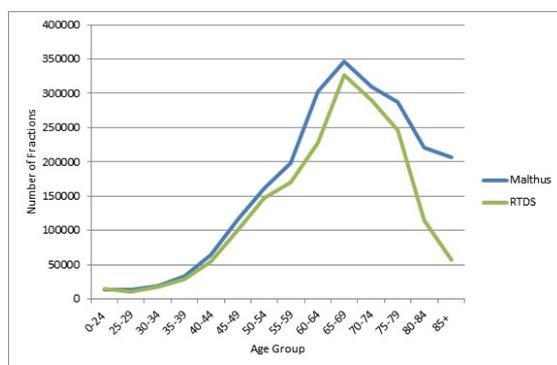

Figure 1. The difference between evidence-based fractions (Malthus) and actual delivered amounts (RTDS)

### Conclusion

Even with relatively minor increases to access rate and fractionation, the modelled fraction burden increases significantly enough to require extra investment in services. The numbers presented here are for England as a whole, however considerable regional differences are to be expected. A non-urban retirement area could expect a much greater increase in fraction burden with a change in the paradigm for treatment of the elderly, compared to inner-city hospitals that have a much younger population. Additionally, machine throughput would have to be studied closely as the elderly often take longer to treat due to patient factors such as decreased mobility.

### PV-0092 Criterion-Based Benchmarking approach of the appropriate use of radiotherapy in NSW-ACT, Australia

G. Gabriel<sup>1</sup>, G. Delaney<sup>1</sup>, M. Barton<sup>1</sup>

<sup>1</sup>Ingham Institute for Applied Medical Research, Collaboration for Cancer Outcomes Research and Evaluation CCORE and University of NSW, Liverpool-NSW, Australia

### Purpose or Objective

Planning for radiotherapy (RT) services requires information on the proportion of patients who should be given RT during their cancer journey. CCORE has previously estimated optimal rates of radiotherapy utilization (RTU) based on the development of decision-trees using evidence-based treatment guidelines and epidemiological data. Mackillop and colleagues in Ontario established a Criterion-Based Benchmarking (CBB) approach to estimate the proportion of cancer patients who should be treated with RT. Aims:

1. Calculate actual RTU rates for NSW-ACT patients
2. Identify benchmark communities
3. Calculate RTU rates for the benchmark communities
4. Compare actual and CBB RTU with the estimated optimal RTU rates

### Material and Methods

RT data were collected from all RT centers in NSW and ACT for Jan-2004 to Jun-2007 and were linked to Central Cancer Registry records. Road distance between patient residence and the nearest RT center was calculated. Cancer patients who lived nearer to RT center outside NSW or ACT were excluded. Non NSW-ACT residents who were treated in NSW or ACT were also excluded. Adjacent Local Government Areas (LGAs) with <500 patients in each LGA were merged to form larger geographical areas with number of patients equivalent approximately to the average number of patients in other LGAs. LGAs with public RT center that satisfy the following RT benchmarking criteria were selected, where:

1. Patients make no direct payment for RT
2. All RT is provided by site-specialized radiation oncologists in multi-disciplinary centers
3. Radiation oncologist receive a salary for their service
4. >75% of patients live within 30 km from the nearest RT, and
5. Patients waiting times were <4 weeks

### Results

Overall, 25.4% of patients received radiotherapy as part of their initial treatment (within 1-year of diagnosis) in the CBB LGAs compared to 22.1% in all LGAs. For patients diagnosed with cancer of breast, prostate, lung, rectum or cervix, the proportions of patients who received RT within 1-year were 60%, 22%, 40%, 26% and 53% in the CBB LGAs compared to 51%, 19%, 36%, 24% and 49% in all LGAs, respectively. The corresponding optimal RTU were 82%, 55%, 70%, 63% & 71%, respectively. Table-1 shows a comparison between our data and Ontario, Canada. Figure 1 shows RTU rates for all LGAs in NSW and ACT.

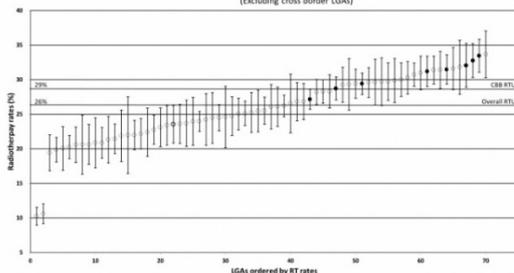

Table-1 Comparison of actual, benchmark & optimal RTU within 1 year of diagnosis between NSW-ACT, Australia (AU) and Ontario, Canada (CA)

Indicator	Breast		Lung		Prostate		Rectum		Cervix		All sites	
	AU	CA	AU	CA	AU	CA	AU	CA	AU	CA	AU	CA
	A Actual rate	51%	64%	36%	45%	19%	30%	24%	52%	49%	48%	22%
B Benchmark	60%	68%	40%	54%	22%	36%	26%	54%	53%	54%	25%	34%
C Estimated optimal	82%	57%	70%	45%	55%	32%	63%	70%	71%	63%	48%	-
D Shortfall between actual rate and CBB*	16%	6%	10%	17%	12%	18%	10%	4%	7%	11%	13%	11%
E Shortfall between actual rate and optimal**	38%	-12%	48%	2%	66%	8%	63%	26%	30%	24%	54%	-

\*: Shortfall between actual rate and CBB = (B-A)/B\*100

\*\* : Shortfall between actual rate and optimal = (C-A)/C\*100

Figure 1: Radiotherapy utilisation in NSW & ACT (2004-2006) by Local Government Areas (LGA) by Local Government Areas (LGA). Vertical bars represent 95% confidence interval (Excluding cross border LGAs)

## Conclusion

While RTU for the selected tumor sites were 7-16% higher in the CBB communities than in all communities, they are still 30-65% below the estimated optimal RTU and differed significantly from Canadian CBB. CBB is based on the assumption that there is perfect service delivery in some parts of the health service that can be used to benchmark the whole service. This approach may be applicable in well resourced service delivery model in Canada, but until the feasibility of the CBB is tested and proved applicable in different geographical regions, the CBB approach does not seem reproducible in other jurisdictions and may not be recommended for benchmarking RT services. We recommend the evidence-based approach of optimal RTU.

## PV-0093 Availability of radiotherapy in Africa: past and present of an unsolved problem

E.H. Zubizarreta<sup>1</sup>, A. Polo<sup>1</sup>

<sup>1</sup>IAEA, Radiation Oncology and Biology, Wien, Austria

### Purpose or Objective

To present data on availability of megavoltage (Mv) units (cobalt machines (Co) and linacs) in Africa from 1991 to 2015 and the additional resources needed to reach full capacity, including a cost analysis.

### Material and Methods

The list and income classification of countries were taken from the World Bank, Country and Lending Groups, 2017 fiscal year [1]. Data on population, number of cancer cases per country, and number of cancer cases for each cancer site was obtained from GLOBOCAN 2012 [2]. The number of radiotherapy courses needed to treat all patients with an indication for radiotherapy was calculated using the methodology from the Collaboration for Cancer Outcomes Research and Evaluation (CCORE) [3,4]. Data on availability of radiotherapy (RT) equipment was obtained from the IAEA Directory of Radiotherapy Centres (DIRAC) [5]. For the cost analysis we used an internally produced Excel sheet with data from December 2013. 51 countries were included in the analysis. Historical data was obtained from different published data [6,7,8,9]. Most of the other variables used for the calculations were taken from the GTRCC report [10].

### Results

The population in Africa is 1.07 billion, with a weighted GNI per capita of US\$ 2,086, and it is calculated that 438,000 cancer cases need radiotherapy annually. Mv units were 103 in 1991 (71 Co and 32 linacs), 155 in 1998 (93 Co

and 62 linacs), 277 in 2010 (88 Co and 189 linacs), 278 in 2013 (84 Co and 194 linacs), and 291 in 2015 (86 Co and 205 linacs), representing an increase of 283% in almost 25 years (fig 1). The proportion of Co units decreased from 69% to 30% in that period (fig 1). A total of 813 Mv units are required to treat 438,000 cancer patients needing RT. Only 149,000 can be treated with the installed capacity, which represents a coverage of 34% of the needs. Low income countries can only treat 4,800 cases, 3% of the needs.

The additional investment to bring full access is 2.12 billion US\$, which includes additional infrastructure, equipment, and training (fig2). The investment in 26 low income countries (LIC) represents 52% of the total, 40% for 16 lower middle income countries (L-MIC), and 8% for 9 upper middle income countries (U-MIC) (fig 2). The annual operating costs should jump from 182 to 571 million US\$, an increase of 214%, but the average cost per RT course would only from US\$ 1,226 to US\$ 1,306.

## Conclusion

Only 3 to 4 out of 10 cancer patients needing radiotherapy in Africa have access to treatment, but only 3 out of 100 can receive treatment in LIC, where the situation is dramatic. The additional investment required to bring full access is 2.12 billion US\$, half of it in LIC. If full capacity was obtained, operational costs will increase 214%. The cost per RT course will only increase 6%.

### SP-0094 Substantial and “for free” improvement of radiotherapy practice in high and low income countries

B. Heijmen<sup>1</sup>

<sup>1</sup>Erasmus MC Cancer Institute, Radiation Oncology, Rotterdam, The Netherlands

Radiotherapy is a highly technology driven medical field. Enormous amounts of money are spent on development and clinical use of advanced treatment units such as modern linear accelerators, robotic delivery systems, and units for particle therapy. Recently, evidence has been gathered pointing at massive and serious sub-optimal use of such equipment, related to problems with treatment plan generation. The current interactive trial-and-error planning approach, in which a planner iteratively tries to steer a treatment planning system towards an acceptable/optimal plan, results in variable and sub-optimal plan quality. A direct and painful consequence is that the expensive, and in principle highly potent treatment equipment is sub-optimally used. Much of the evidence for the planning problems has been provided in studies using fully automated treatment plan generation, instead of interactive trial-and-error planning. This lecture will discuss opportunities to “for free” substantially increase quality of radiotherapy practice in both high and low income countries by large-scale introduction of automated treatment plan generation.

## Award Lecture: Iridium Award Lecture

### SP-0095 Brachytherapy physics developments: Look back in anger, grateful, and with hope

J. Venselaar<sup>1</sup>

<sup>1</sup>Dr. Bernard Verbeeten Instituut, Tilburg, The Netherlands

Brachytherapy (BT) is by nature a strong tool in cancer treatment. Numerous textbooks and scientific articles include the statement that bringing the source of radiation directly into the tumour is a very direct and reliable approach. The result is a dose distribution that is tailored

to the target -although inhomogeneous on the inside- with a rapid dose fall-off in the direction of the surrounding normal tissue, which is mainly due to the inverse square law. This, we have to recognise, is not a belief, but simple and straightforward physics. Consequently, the resulting 'dosimetry' compares very favourably with other radiation therapy techniques. When applied to the selected patient groups the clinical results in terms of survival and toxicity are the best you (i.e., the patient) can get, as has been shown in many clinical and comparative studies. Notwithstanding these apparent benefits, the numbers of patients treated with BT show a persistent tendency to decline, while the use of other techniques such as IMRT, volumetric arc therapies, and -in near future- particle therapies increases. This happens especially for those cancer types for which BT has outstanding prospects, such as in cervical, prostate, and breast cancer. Evidence for the benefits linked to a given BT standard of care seems to be bluntly ignored, but it is unclear for what reasons: are these economical reasons (time consumption, reimbursement issues for the institution and the radiation oncologist), complexity of treatment (invasive procedures, high skills and QA demands), or lacking technical solutions compared to other techniques (tissue inhomogeneity correction in TPS, advanced imaging facilities for advanced IGBT, BT treatment verification)? It is very clear that in these areas BT still has to work hard to make the necessary huge steps forward. Many studies exploring this are on-going. And all of this is really feasible! Precisely in the fields mentioned here the GEC-ESTRO Brachytherapy group (started under the ESTRO-ESQUIRE project in 2001) made significant contributions over the years of its existence. A strong cooperation was developed in the entire radiation oncology community, including clinical and GEC committees, the physics committee of the ABS and the AAPM-BTSC, together with IAEA and the Euramet group of standard laboratories in Europe. The question is now whether or not time is allowed for these developments to reach the point of being fully introduced into clinical practice, while other and maybe at the first sight more 'sexy' radiation technology and possibly also other competing cancer treatment approaches are knocking on our doors. In all cases, it will be the patient who deserves her/his optimal treatment strategy. Title: free to John J. Osborne

#### SP-0096 Cognitive perspective in the radiation oncology physics domain

V. Valentini<sup>1</sup>

<sup>1</sup>Università Cattolica del Sacro Cuore - Policlinico A. Gemelli, Gemelli ART, Rome, Italy

Cognitive technology can learn a new problem domain, reason through the hypotheses, resolve ambiguity, evolve towards more accuracy, and interact in natural means. Some prototype showed this approach to be able to adapt and make sense of many data: "read" text, "see" images and "hear" natural speech with context; to interpret information, to organize it and to offer explanations of what it means, with rationale for the conclusions; to accumulate data and to derive insight at every interaction, indefinitely. The interest of this evolving technology in radiation oncology is very high. Radiotherapy is domain in medicine in which modeling the contents of the clinical choices permeates daily life. The opportunity to have a physic subdomain in radiation oncology and the interaction among all the professionals involved in this oncology field could represent a great opportunity to benefit of this approach. Possible implications of the cognitive approach in radiation

oncology, starting from the physic subdomain, will be explored.

#### SP-0097 Clinical approach to abscopal effects

P.C. Lara Jimenez<sup>1</sup>

<sup>1</sup>Hospital Universitario de Gran Canaria Dr. Negrin, Radiation Oncology, Las Palmas de Gran Canaria- Ca, Spain

SBRT is becoming a common approach to cancer treatment. By using this few, high dose per fraction schedules tumour responses are higher than predicted. Indirect cell death would account for this "extra cell kill" induced by high doses of radiotherapy. These indirect "non targeted" effects of radiotherapy could be related to vessel damage through radiation-induced endothelial apoptosis, but also, to an immune response to reject the tumour cells. In fact, SBRT is probably the most convenient, less toxic and more powerful way to "autovaccinate" patients eliciting antigen release from dying tumour cells. Endothelial damage, increased vessel's permeability, increased tumor infiltrating lymphocytes and "immune cell death" (ICD) types as necrosis or mitotic catastrophe that led to the release of calreticulin, ATP or HMBG-1, are mechanisms triggering the immune response. Later on, maturation of dendritic cells, APC-dependent antigen presentation to T cells in the nodes, microenvironment's modification and immune response against the tumour, through interferon  $\gamma$  release, are already demonstrated.

Besides this local effect, a distant immune-mediated non-targeted effect in tumor locations away from the radiotherapy treated disease, is called "abscopal effect". Radiation-induced T cell maturation against tumour antigens "make visible" other distant tumour focii to this specifically adapted cytotoxic lymphocytes (CTL). Abscopal effect after radiotherapy alone, is uncommonly observed in the clinical setting, probably due to the exhaustion of the immune response. The suppressor microenvironment surrounding the tumour focii, the CD8+ lymphocyte suppression and/or PD1/PDL-1 overexpression could be major mediators of tumour resistance to the immune attack. Abscopal effect could be raised to clinical relevance by reverting this scenario, through reinvigorating the patient's immune system. Immune checkpoint inhibitors (ICIs) are drugs that block the constitutive regulatory suppressor mechanisms designed to prevent "autoimmune attacks" from the immune system, to normal tissue. These mechanisms are constitutive either in lymphocytes (CTLA4/ PD-1/PDL-1) but also in tumour cells (PD-1/PDL-1). Then by "suppressing the suppressors" (using anti CTLA4, Anti PD-1 or anti PD-L1 antibodies) the immune system is free of the regulatory suppressive signals and results reinvigorated to respond to antigen stimuli. Therefore, SBRT autovaccination-mediated antigen presentation results in increased abscopal effect as the immune system is reinvigorated by the ICI-mediated activation. Preclinical and clinical evidence support this approach. Abscopal effect rate of presentation is increased when ICIs are combined with SBRT without increase in toxicity. ICIs toxicity is mainly related to autoimmune reactions as hypophysitis, colitis etc and should be carefully monitored. Dose reduction, halt drug administration, systemic corticosteroids or in severe cases, anti-TNF $\alpha$  therapy should be taken in to account. But still some questions remain to be solved, namely, the best SBRT schedule, the temporal integration of SBRT and ICIs and the combination of SBRT and more than one ICIs.

**SP-0098 What is the purpose of surgical metastasectomy and do we achieve it?**

T. Treasure<sup>1</sup>

<sup>1</sup>*UCL Cancer Institute, Clinical Operational Research Unit, London, United Kingdom*

Is the purpose palliation? Earlier detection of metastases, and selection for operations to remove them, systematically targets asymptomatic patients - who have no symptoms to palliate. There have been very many follow-up studies but none document symptomatic benefit. [Thorac Surg Clin 2016;26:79; Eur J Cardiothorac Surg 2016;50:792] Intervention is explicitly offered with curative intent.

Is cure often achieved? There has never been a study with any form of control group to test survival difference. On the other hand there have been multiple trials (16 RCTs to date) of increasing intensity of monitoring to find asymptomatic patients for metastasectomy with curative intent. A systematic review capably done by an international multidisciplinary team, including skills in oncology, surgical research, data analysis and guideline development, found no benefit but instead an excess of harm done. [Br J Surg 2016;103:1259] Metastasectomy appears to be an example of over diagnosis leading to harm by over treatment. [Ending Medical Reversal. Baltimore, Johns Hopkins University Press, 2015] Scholars of the history of medicine recognise that over time, disease states have been 'framed' and reframed as the sophistication of diagnostic methods escalated from clinical examination and morbid anatomy; through microscopy, bacteriology, clinical chemistry and haematology; and now to extraordinary advances in imaging. This has resulted in a new diagnostic frame 'oligometastatic cancer' which is operationally defined by excluding patients with more metastases than can be treated by surgical resection or ablative methods. [J R Soc Med 2012;105:242] This results in selection of patients at the less aggressive end of the spectrum of metastatic disease and hence naturally determined to be longer survivors. So benefits of metastasectomy may be an illusion. [JAMA Oncol 2015;1:787]

**SP-0099 What is the indication and what is the aim of clinical treatment: radiotherapy**

E. Lartigau<sup>1</sup>

<sup>1</sup>*Centre Oscar Lambret, Lille, France*

Oligometastatic disease is considered Today to be amenable to combined systemic and local treatment in order to increase local control, decrease tumor burden and potentially increase survival. Stereotactic body radiotherapy has been successfully used in the treatment of brain metastases for more than 3 decades and is now widely used for bone, lung and liver metastases. For example in our Department, the feasibility, efficacy, and toxicity of SBRT as been evaluated for treatment of unresectable hepatic or lung metastases regardless of their primary tumor site for patients with a history of aggressive systemic chemotherapy. Local control has been demonstrated as excellent (66.1% at 2 years) even if disease-free survival rates remains low (10%, 95% CI: 4-20%). SBRT is well tolerated with few toxicities and possible in aging patients. There is today a wide consensus on the local role of SBRT in oligometastatic disease. Current step is to optimize the combination with systemic treatments (chemotherapy and targeted agents). A new door has been more recently opened on the potential role of early SBRT together with immunotherapy in order to increase treatment response by neo antigens production following high dose RT, or by immune activation after low dose. Clinical studies are ongoing exploring this new path ways.

Abstract not received

**Symposium with Proffered Papers: Targeting tumour heterogeneity**

**SP-0101 Using heterogeneous brachytherapy dose distributions to target tumour cell heterogeneity**

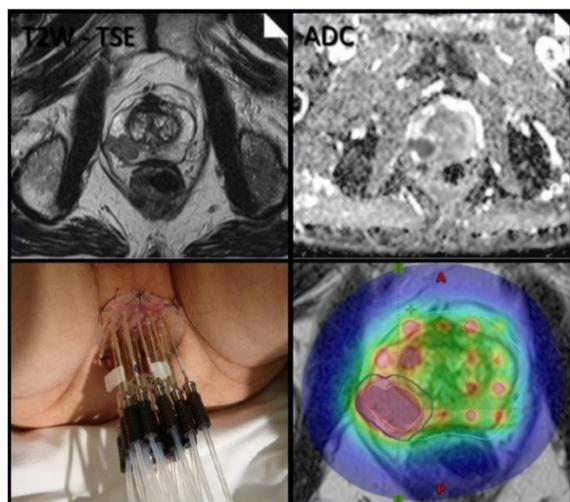

R. Alonzi<sup>1</sup>

<sup>1</sup>*Mount Vernon Hospital, Senior lecturer and consultant in clinical oncology, Northwood Middlesex, United Kingdom*

Some tumour characteristics, such as hypoxia, vascularity, cellular proliferation or clonogen density, can be mapped geographically using functional imaging techniques or by using systematic biopsies with subsequent immunohistochemistry or molecular characterisation. The ability to assimilate this functional information into the radiotherapy planning process poses a number of challenges, but the technology to achieve biological conformity is widely available and routinely used in most radiotherapy departments. The potential gains in therapeutic ratio from the precision targeting of areas of intrinsic resistance makes focused dose escalation an exciting field of study and will be the principal theme of this presentation.

Higher administered radiation doses can overcome intrinsic radio-resistance. However, dose escalation to the entire tumour volume may not always be possible. Increasing the tumour dose will inevitably increase the dose to the surrounding critical normal tissues leading to worse acute and late toxicity. Focused dose escalation is based upon the principle that areas of tumour with relative radio-resistance can be overcome by administering a higher biologically effective radiation dose (BED). This can be achieved either by giving a higher total dose or higher dose per fraction.

For focused dose escalation, brachytherapy offers some major advantages over external beam techniques. One of the key features of brachytherapy is that the irradiation only affects a very localised area around each radiation source as dose falls off rapidly, obeying the inverse square law. This feature has been exploited for many years and makes brachytherapy the most conformal of all radiotherapy techniques. As long as the sources are precisely placed within the tumour, there is minimal exposure to radiation of healthy tissues further away from the sources. This allows very high doses to be administered to the target volume. Also, patient set-up and tumour motion are less relevant because the radiation sources move with the tumour and therefore retain their correct position; this increases the confidence that the radiation has been delivered in accordance with the required plan. Brachytherapy plans are inhomogeneous by their very nature, with high dose regions surrounding each source and lower dose regions where there is maximum geometrical separation between sources. By carefully manipulating source positions and dwell times, the non-uniform dose distribution can be shaped to match a biological risk map. The brachytherapy implant technique may have to be adapted to accommodate this.

In this image a dominant intra-prostatic lesion (DIL) in the right posterolateral peripheral zone has been defined on both anatomical MRI sequences (top left) and on the diffusion weighted ADC map (top right). A dose-painting by contour method has been used to define the region for dose escalation. Treatment was performed using interstitial high dose-rate brachytherapy with 5mm catheter placement in the boost volume and 1cm spacing elsewhere (bottom left). The final dose distribution provides highly conformal dose escalation to the high risk region whilst delivering a standard dose to the remaining gland. In this plan, the dose escalation was designed to deliver 21 Gy to at least 95% of the boost PTV and 15 Gy to at least 95% of the remaining low-risk PTV.

**OC-0102 MRI assisted focal boost integrated with HDR monotherapy for low/intermediate risk prostate cancer**  
 L. Dalimonte<sup>1</sup>, J. Helou<sup>2</sup>, G. Morton<sup>2</sup>, H. Chung<sup>2</sup>, M. McGuffin<sup>1</sup>, A. Ravi<sup>3</sup>, A. Loblaw<sup>2</sup>

<sup>2</sup>Sunnybrook Health Sciences Centre University of Toronto, Radiation Oncology, Toronto, Canada

<sup>3</sup>Sunnybrook Health Sciences Centre University of Toronto, Medical Physics, Toronto, Canada

#### Purpose or Objective

There is growing evidence for the use of High Dose Rate (HDR) brachytherapy as monotherapy for the treated of low and intermediate risk prostate cancer patients. With the increasing availability of magnetic resonance imaging (MRI) there is an opportunity to further escalate dose to the dominant intraprostatic lesion (DIL). We report acute toxicity of this prospective Phase I/II trial.

#### Material and Methods

Eligible patients had low- and intermediate risk prostate cancer, IPSS < 16, were medically operable for HDR brachytherapy treatment and had an identified DIL on multiparametric MRI (mpMRI) prior to brachytherapy treatment. Patients were treated with 19 Gy delivered in one fraction to the whole prostate. A 0-5mm expansion was applied to the DIL to define the PTV DIL, with a DIL PTV D90 to receive > 23Gy based on previous experience. Toxicity was assessed using CTCAE v.4.0 at baseline, 6 weeks 3, 6, 9 and 12 months post brachytherapy.

#### Results

A total of 34 patients have undergone HDR monotherapy treatment with an integrated DIL boost with a median follow up of 6 months. The median age was 67 years (range 46-80). At presentation, median PSA was 6.1 ng/mL (2.5-16.4). Three, 26, and 6 patients had low, low intermediate and high intermediate risk disease. Baseline characteristics were PIRAD 5 (n=21) and PIRAD 4 (n=13),

mean prostate volume was 37.9 cc (range 18-54). No patients experienced acute or late Grade 2+ GI toxicity. The percentage of acute Grade 2 GU toxicity were as follows; retention 62%, frequency 18%, urinary tract pain 6%. One patient required catheterization (acute G3) for one day post treatment and has been catheter-free since. Urinary retention is the only late Grade 2 GU toxicity that has been reported (n=6).

#### Conclusion

The use of mpMRI to define and further escalate dose to the DIL using HDR monotherapy is achievable with minimal acute toxicities. Further long term follow is required to determine efficacy of treatment, and impact on quality of life and late toxicities.

#### SP-0103 The challenges of targeting tumour heterogeneity in the field of radiation oncology

P. Lambin<sup>1</sup>, L. Dubois<sup>2</sup>, A. Yaromina<sup>2</sup>

<sup>1</sup>MAASTRO Clinic, Maastricht, The Netherlands

<sup>2</sup>Maastricht University, Radiotherapy, Maastricht, The Netherlands

There is no doubt that tumours are heterogeneous at genetic, biological and pathophysiological level. Intra- and intertumoural heterogeneity, on one hand, can facilitate the development of new anti-cancer therapies such as immunotherapies (1), radiation dose-painting strategies (2), and can also have great implications for biomarker discovery. On the other hand, it can hinder anti-cancer therapy success due to the presence of a resistant clone. Overall tumour heterogeneity quantified at the genetic level, tissue level or imaging level (e.g. imaging of tumour hypoxia, or radiomics), is a negative prognostic factor (3,4,5). Tumour heterogeneity creates several challenges that need to be overcome to achieve disease cure. It is unlikely that a single anti-cancer therapy will work alone for several reasons. First, the target is likely heterogeneously expressed throughout a tumour and primarily (intrinsically) resistant (radio-, chemo- or immuno-resistant) tumour cells are likely to be present within a tumour cell population. One example is heterogeneous expression of epidermal growth factor receptor targeted to monoclonal antibody cetuximab. In addition heterogeneous distribution of functional blood vessels may hamper uniform drug delivery. Secondly, changes of molecular profile of cancer cells as a consequence of tumour progression and therapy mediated selection pressure may lead to acquired resistance and activation of counteracting mechanisms by cancer cells. Up-regulation of immune checkpoints or exhaustion markers is an example of acquired resistance to immunotherapies. Thirdly, therapy becomes ineffective if a target gradually disappears while therapy progresses such as tumour hypoxia during fractionated irradiation due to tumour reoxygenation. These barriers also emphasize the need for the development of clinical tools for patient selection and for novel preferentially non-invasive (imaging) or minimally invasive (blood based) biomarkers for tumour monitoring during therapy to enable treatment modification or adaptation. We believe that there is room for new treatment options exploiting tumour heterogeneity.

<sup>4</sup>Medical University of Vienna, Department of Nuclear Medicine, Vienna, Austria

<sup>5</sup>EBG Med Austron GmbH- Wr. Neustadt, Wr. Neustadt, Austria

**Purpose or Objective** To investigate the spatio-temporal stability of the tumor characteristics in cervix cancer patients undergoing radiotherapy with advanced imaging methods. More specifically, repetitive multiparametric MR-PET imaging prior, during and after the end of chemoradiotherapy was performed utilizing a hybrid scanner.

#### Material and Methods

Six patients with cervical cancer participated in this prospective study. All patients received chemoradiotherapy, with a total IMRT prescription dose of 45Gy (25x1.8Gy in 5days/week) followed by a MRI guided brachytherapy boost (4x7Gy). Patients underwent four PET/MR examinations performed on a Siemens Biograph mMR PET/MR at baseline (BL), in treatment week 2 (TP1) and 4 (TP2) of the IMRT schedule, and 3 months after end of treatment (FU). At all time-points T2w turbo spin echo, DWI, DCE T1w gradient echo with 35 repetitions and hypoxia PET scans with 18F-fluoromisonidazole (F-MISO) were acquired. ADC, K<sup>trans</sup> and iAUC maps were generated (cf. figure).

Representative BL images of the acquired modalities in acquisition plane of one patient. The GTV is delineated. a)T2w fused with PET b)DCE<sup>nmr</sup> c)ADC map d)K<sup>trans</sup> map e)iAUC map

All images were registered to neighboring time-points using RayStation (RaySearchLaboratories, Sweden) utilizing a hybrid deformable registration algorithm. Uterus, cervix, a reference structure for tumor to background ratio (TBR) calculation in gluteal muscle (GM) were delineated on all images. The GTV was defined on T2w images for the first 3 examinations. A sphere of 1cm diameter was created around the hottest voxel in the GTV of the PET to define the peak value. Datasets were assessed for tumor volume, enhancement kinetics (K<sup>trans</sup>,

iAUC), diffusivity (ADC) and F-MISO-avidity (TBR). The TBR was evaluated for the mean of the peak-sphere and the top 10% (TBR<sup>top10%</sup>) and the mean (TBR<sup>mean</sup>) of the TBR values in the whole GTV. Paired t-tests were performed to evaluate statistical significance.

#### Results

The mean volume of the GTV decreased from 62±42cm<sup>3</sup> (BL) to 50±35cm<sup>3</sup> (TP1) and 20±18cm<sup>3</sup> (TP2). The cervix volume at FU was 24±4cm<sup>3</sup>. The mean GTV ADCs (in x10<sup>-3</sup>mm<sup>2</sup>/s) were 0.98±0.10 at BL, and significantly increased during follow up investigations with 1.17±0.15 at TP1, 1.16±0.10 at TP2 and 1.25±0.12 at FU. No significant changes were found for the TBR<sup>peak</sup>. However, for the TBR<sup>mean</sup> as well as the TBR<sup>top10%</sup> the following drop was observed: from 1.81±0.14 (BL) to 1.52±0.10 (TP2) and 3.24±0.40 (TP1) to 2.40±0.39 (TP2), respectively. Intensity of T2w images, K<sup>trans</sup> and iAUC showed the same behavior: an increase at TP1 followed by a drop at TP2 as well as FU. The following changes reached statistical significance: T2w: BL-TP1(+20%), BL-TP2(-16%); iAUC: BL-FU(-29%); K<sup>trans</sup>: BL-FU(-55%), TP1-TP2(-32%).

#### Conclusion

First hybrid PET/MR results confirm previous results from serial MR and PET/CT, i.e. increasing ADC, K<sup>trans</sup> and iAUC in treatment week 2 correlates with morphological response. High FMISO uptake showed neither local stability nor persistency throughout the course of treatment. Final conclusions on quantitative PET/MR imaging for treatment response in cervix cancer requires a larger patient cohort.

#### Symposium: Innovations in ion beam therapy

#### SP-0106 Reducing range uncertainties: new approaches for stopping power determination and in-vivo range verification

K. Parodi<sup>1</sup>

<sup>1</sup>Ludwig Maximilians Universität München, Department of Medical Physics, München, Germany

Radiation therapy with protons and heavier ion beams is a rapidly emerging treatment modality which promises precise delivery of a biologically effective dose to the tumour, with optimal sparing of surrounding critical organs and healthy tissue. To this end, over the last years, technological advances in beam delivery have been accompanied by an increasing integration and usage of imaging in the entire chain of fractionated treatment, from pre-treatment identification and characterization of the tumour up to anatomical guidance for patient positioning at the treatment site.

Despite these recent technological advances, full clinical exploitation of the favorable ballistic properties of ion beams is still hampered by the yet unsolved problem of range uncertainties. To this end, new imaging approaches are being extensively investigated to tackle this issue at the stage of treatment planning or treatment delivery. In this contribution, special emphasis will be given to pre-treatment transmission imaging of multi-energy X-ray sources or energetic ion beams for refined assessment of the tissue stopping properties, as well as online/post-treatment detection of acoustic and nuclear-based emissions induced by ion interaction in tissue for in-vivo verification of the beam range. In particular, the main ongoing developments and initial pre-clinical or clinical experience will be critically reviewed, discussing the prospects of novel imaging methods for reducing range uncertainties in ion beam therapy.

#### SP-0107 Mechanisms and Models of Particle Relative Biological Effectiveness (RBE)

D.J. Carlson<sup>1</sup>

<sup>1</sup>Yale University School of Medicine, Therapeutic Radiology, New Haven- CT, USA

The physical pattern of energy deposition and the enhanced relative biological effectiveness (RBE) of charged particles compared to photons offer unique and not fully understood or exploited opportunities to improve the efficacy of radiation therapy. Variations in RBE within a pristine or spread out Bragg peak and between particle types may be exploited to enhance cell killing in target regions without a corresponding increase in damage to normal tissue structures. In addition, the decreased sensitivity of hypoxic tumors to photon-based therapies may be partially overcome through the use of more densely ionizing radiations. These and other differences between particle and photon beams may be used to generate biologically optimized treatments that reduce normal tissue complications. In this presentation, the biological basis of various models of RBE will be reviewed. In addition, the impact of the RBE of charged particles on measurable biological endpoints, treatment plan optimization, and the prediction or retrospective assessment of treatment outcomes will be examined. In particular, an AAPM task group was formed to critically examine the evidence for a spatially-variant RBE in proton therapy. Current knowledge of proton RBE variation with respect to proton energy, dose, and biological endpoint will be reviewed. The clinical relevance of these variations will be discussed. Recent work focused on improving simulations of radiation physics and biological response in proton, helium, and carbon ion therapy will also be presented. In addition to the physical advantages of protons and more massive ions over photons, the future application of biologically optimized treatment plans has the potential to provide higher levels of local tumor control and improved normal tissue sparing.

**SP-0108 New horizons in radiobiology: from Relative Biological Effectiveness to “new biology”**

M. Durante<sup>1</sup>

<sup>1</sup>University of Trento, Povo, Italy

The era of precision medicine has a strong impact on radiotherapy. Treatment planning is now moving from purely physical dose calculation toward biological optimization. Several studies on biomarkers and combined treatments are currently modifying the treatment plan and the design of clinical trials in oncology. In particle therapy, most of the discussion focus on the exploitation of the RBE, which is commonly done in heavy ion therapy and not yet in protontherapy. RBE assessment may improve plan optimization and prevent some side effects that seem to be related to the physical properties, both electromagnetic and nuclear, of protons. Charged particles can however elicit a gene response qualitatively different from that caused by X-ray exposure, and thus open new opportunities. The combination of particles and immunotherapy is particularly promising.

**Symposium: Imaging for therapeutic response / toxicity evaluation**

**SP-0109 Functional imaging as biomarker for toxicity response**

Y. Cao<sup>1</sup>

<sup>1</sup>University of Michigan, Radiation Oncology - Physics, Ann Arbor, USA

Population based models for radiation effects on normal tissue and organ function have played a role for minimizing risk of organ injury during treatment planning. However, precision individualized medicine requests to understand individual patient response and sensitivity to radiation doses. Quantitative functional imaging is a powerful tool to assess regional information, and understand local response to radiation doses, which is

complementary to molecular and genetic biomarkers if they exist.

Our recent studies in neurotoxicity reveal a few interesting findings. For example, a maximum dose effect in white matter fiber bundles is found using longitudinal diffusion tensor imaging and fiber tracking technique. Also, gEUD doses with large  $\alpha$ -values (e.g., 14 and 50) received in the brain are associated with late neurocognitive declines, suggesting a maximum dose effect on cognitive function. These results suggest that responses of brain tissue, critical structure, and cognitive function to radiation doses and dose distribution are more complex than we originally thought.

Liver is another organ that is sensitive to radiation. Recent studies show that liver function is a predominant predictor for overall survival for patients with intrahepatic cancer and cirrhosis regardless of intervention. Radiation effects on the liver function have been investigated and modeled using dynamic contrast enhanced MRI and HIDA SPECT. To safely treat intrahepatic cancers, both regional and global liver function measures are needed. Can a single test provide regional and global liver function measurements and allow for liver function management during therapy planning? Gadoxetic-acid is widely available liver-specific MRI contrast and is routinely used in clinical MRI. The routine clinical MRI scans with Gadoxetic-acid that are temporally sparse-sampled challenge quantification of liver function using the dual-input tow-compartment model. We have developed a robust algorithm to quantify regional and global liver function from dynamic gadoxetic-acid enhanced MRI. Using regional liver function maps created by our method, we can assess the dose-response of hepatic function in the individual patients, which can be used for optimizing the dose distribution in the liver and thereby minimizing risk of liver function failure. Also, the liver function distribution quantified by this method can be used for assessing liver function preserve by determining the liver functional volume (LFV) for support of clinical decision making for intrahepatic cancer therapy.

In this presentation, recent development of imaging and analysis techniques in brain and liver as well as implications of new findings using the techniques will be discussed.

**SP-0110 Imaging tumour response to neoadjuvant treatment in GI tumours**

G. Meijer<sup>1</sup>

<sup>1</sup>UMC Utrecht, Department of Radiation Oncology, Utrecht, The Netherlands

Trimodality treatments are often the preferred treatment option in the curative management of cancers in the gastrointestinal tract. Here a combined radiotherapy and chemotherapy regimen are administered prior to the surgical resection of the primary tumor and involved lymph nodes. Typically the primary aim of the neoadjuvant regimen is to downstage the tumor to facilitate negative resection margins at surgery. Interestingly, although these neoadjuvant treatment regimens are not optimized for obtaining local control, pathology reports regularly reveal a complete pathologic response (i.e. no viable tumor left in resection specimen) in particularly rectum and esophageal cancer patients. This opens the window to more tailored treatments where only patients are operated upon that really benefit from the surgery. However, this can only be accomplished if we have accurate means to predict the pathologic outcome prior to surgery. Many research groups have investigated the potential of pre-surgical clinical assessments (e.g. biopsies, endoscopies) to predict the outcome with moderate success. More recently, quantitative imaging techniques like FDG-PET, dynamic contrast enhanced (DCE) MRI, diffusion-weighted (DW) MRI, have shown more potential.

This presentation will give an overview of the work that has been up to now in these areas in particular in relation to the response assessment of neoadjuvant treatments of rectum and esophageal cancers. A special focus is given to the technical challenges that go along with quantitative MRI imaging in the thoracic and abdominal domain.

**SP-0111 Imaging biomarkers to predict and early assess the response to radiation therapy. Potential impact of studies in small animals**

B. Gallez<sup>1</sup>

<sup>1</sup>Louvain Drug Research Institute, Biomedical Magnetic Resonance, Brussels, Belgium

- Predictive markers (used before treatment planning) may help in defining which patient may benefit from a specific intervention in radiation therapy
- Early markers of treatment response may help in the management of patients by predicting the outcome of a specific therapeutic intervention and potential adaptation of the therapeutic strategy
- Examples of imaging biomarkers (MRI and PET) related to hypoxia-guided intervention will be presented (1-5)
- Validation of these markers is mandatory for translation into the clinical arena

**Symposium: Comprehensive motion management and immobilisation solutions in radiation therapy**

**SP-0112 Immobilising the patient to be as comfortable as possible. A general overview**

A. Osztavics MBA<sup>1</sup>, K. Kirchheiner- MSc- PhD<sup>1</sup>

<sup>1</sup>Medizinische Universität Wien Medical University of Vienna, General Hospital Vienna AKH Wien- Department of Radiation Oncology- Comprehensive Cancer Center, Vienna, Austria

**Purpose**

An individual tailored radiotherapy treatment with high accuracy represents daily clinical routine in most of the high-income countries worldwide. In the last two decades, technology has been rapidly progressing from 3D / intensity modulated radiotherapy (IMRT) to volumetric modulated arc therapy (VMAT) treatment techniques. With these developments it was possible to reduce the integral dose on normal tissue, increase the single / total dose to the planning target volume (PTV) and reduce the safety margins. Therefore, the reproducibility of the daily patient positioning has become of major importance. All

these high technical achievements have a natural limitation, which is the patients' compliance and cooperation in immobilization. Immobilization devices for comfortable and accurate reproducible patient positioning is indispensable in radiotherapy departments. Actual immobilisation devices have limitations regarding patients' comfort and substantial evidence in the literature shows the incidence of anxiety and distress among patients requiring immobilization during radiation therapy [1,2]. Radiation therapists (RTTs) are regularly in close personal contact with their patients and are aware of discomfort and worries, therefore playing a major role in reducing anxiety and distress. Adequate communication and training for correct use of the immobilization devices between RTTs and patients is likely to have positive impact for more precise treatment with the currently existing immobilisation devices.

**Conclusion**

There is still a great need to evaluate the accuracy and reproducibility of patient positioning in radiotherapy and moreover to create new immobilisation devices with greater comfort and higher tolerability for patients. This field of RTTs research will be ongoing in the next years and is supposed to show high impact on the precision and reliability of radiation therapy. Nevertheless, in order to achieve the full potential of immobilisation devices, the patients' close cooperation and compliance has to be regarded as integral part of any working process of RTTs and is based on adequate and comprehensive information and also emotional support.

**SP-0113 Added value of mechanical ventilation in the treatment of moving tumors with photon and proton therapies**

X. Geets<sup>1</sup>, G. Van Ooteghem<sup>1</sup>, E. Sterpin<sup>1</sup>

<sup>1</sup>UCL Cliniques Univ. St.Luc, Radiation Oncology, Brussels, Belgium

Breathing-related motion is a well-known and significant source of geometrical uncertainties in radiotherapy planning and delivery. For this reason, several respiratory-synchronized techniques have been proposed to mitigate the motion, such as 4D (robust) optimization, respiratory gating or tracking. However, all these techniques face the same issue: the motion model derived from the planning 4D-CT does not necessarily represent the actual motion at the time of treatment, because the depth and pattern of spontaneous breathing are known to vary markedly over time.

Consequently, an efficient motion management strategy should not only focus on the tumour motion itself, but also on the underlying mechanism of this motion, namely the breathing. In this regard, mechanically-assisted ventilation might offer new perspectives. Quite recently, some research groups have shown that mechanical ventilation can be easily performed on patients who are conscious and un sedated, without feedback to or participation from the patient. As a first application, it can be used to impose a completely regular pattern of breathing frequency and inflation volume on the patient for as long as required for patient positioning, image acquisition and treatment delivery. As long as the mechanical ventilation matches the metabolic rate of the patient and is tolerated well enough, a wide range of inflation frequencies and volumes could also be applied to suits the particular needs in delivering personalized RT.

On the other hand, JET ventilation may be used to fix the breathing, and thus reduce markedly the residual tumour motion.

This presentation will browse the various applications of mechanical ventilation for motion mitigation in photon and proton therapies of moving thoracic/upper abdomen tumours, and will discuss their advantages, potential drawbacks and pending issues.

**SP-0114 Motion of liver tumours using Active Breathing Control: keeping the margins small and the patient comfortable**

M.E. Mast<sup>1</sup>

<sup>1</sup>Haaglanden Medical Centre Antoniusshove, Radiation Therapy Department, Leidschendam, The Netherlands

In Stereotactic Body Radiation Therapy (SBRT) for liver metastases, treating the target volume as accurate as possible, is challenged by several factors. Movement of the liver due to breathing is the most prominent one. From literature it appeared that liver motion was largest in the cranio-caudal direction. To compensate for this movement a diversity of options is used. One of these options is performing a breath-hold technique. When using this technique the influence of respiration is strongly reduced and the Clinical Target Volume (CTV) - Planning Target Volume (PTV) margins can be decreased. Therefore, we copied our Active Breathing Control (ABC) technique for left-sided breast cancer patients to the liver SBRT, since we found that 98% of our breast cancer patients were able to undergo this technique successfully.

Liver SBRT delivery requires multiple breath-holds. The reproducibility of the diaphragm position for several consecutive breath-holds is one factor determining the CTV-PTV margin. We assessed this reproducibility of the ABC technique by making 10 consecutive CT-scans in breath-hold. Also, in order to compare with the broadly accepted Internal Target Volume (ITV) based technique to determine the PTV, we made a 4D-CTscan. For each patient individual margins were calculated for both the ABC technique and the ITV technique. The overall CTV-PTV margins are based on several uncertainties, such as patient set-up, reproducibility of the diaphragm position during breath-hold, physical inaccuracies, etc. We consistently found that the CTV-PTV margins in breath-hold were smaller compared to CTV-PTV margins based on the ITV technique.

Another advantage of the ABC technique is that the ConeBeamCT (CBCT), used in the position verification procedure, shows a sharper defined liver contour compared to the CBCT during free breathing. This enables a better volume match on the liver contour. Previous studies have shown that the entire liver contour is a representative surrogate for the liver tumour. Consequently, there was no need to use radio-opaque markers in the liver. This is another important advantage of application of ABC for liver SBRT.

We are the first radiotherapy department in the Netherlands that perform liver SBRT in combination with ABC. From January 2016 up until now we have treated 14 patients. All patients successfully used the ABC technique, and in all patients the liver contour could be used for the tumour match. All together, the use of ABC in liver SBRT is a feasible, patient friendly treatment technique as there is no need for invasive marker placement.

**Symposium with Proffered Papers: Novel approaches in brain matters**

**SP-0115 Response of adult neural stem cells to radiation-induced DNA damage**

L. Barazzuol<sup>1</sup>, L. Ju<sup>3</sup>, P.A. Jeggo<sup>3</sup>

<sup>1</sup>University Medical Center Groningen, Department of Radiation Oncology, Groningen, The Netherlands

<sup>2</sup>University Medical Center Groningen, Department of Cell Biology, Groningen, The Netherlands

<sup>3</sup>University of Sussex, Genome Damage and Stability Centre, Brighton, United Kingdom

Oncogenesis and aging often correlate with the accumulation of DNA damage and genetic mutations in long-lived adult stem and progenitor cells. Here, using the mouse brain as a model, we define the functional consequences and mechanisms by which adult neural stem cells (NSCs) and their progeny respond to radiation-induced DNA damage within the sub-ventricular zone (SVZ). Exploiting recent evidence showing regional differences within the SVZ, we spatially mapped apoptosis, DNA repair capacity and proliferation along the dorso-ventral axis of the SVZ of wild type and ataxia telangiectasia mutated mice in response to 2 Gy X-rays. We showed that progenitors and neuroblasts, in contrast to NSCs, undergo radiation-induced apoptosis. This differential response is cell type-dependent and is not the result of quiescence status, senescence induction or distinctions in DNA repair. Moreover, we showed that apoptosis together with proliferation arrest drive quiescent NSC activation allowing repopulation of the SVZ. In addition to the adult brain, we examined the DNA damage response of the neonatal SVZ at postnatal day 5, which is of importance for assessing their higher sensitivity to radiation-induced carcinogenesis. Radiation-induced apoptosis at P5 was overall higher than in the adult SVZ; however, the neonatal SVZ displays a lack of proliferation arrest such that repopulation occurs more rapidly from damaged progenitors and neuroblasts. We have demonstrated a spatially and temporally heterogeneous DNA damage response in adult NSCs and their progeny, thus providing new insight for development in radiotherapy and radiation protection.

**SP-0116 The cognitive defects of neonatally irradiated mice are accompanied by changes in adult neurogenesis**

S. Tapio<sup>1</sup>

<sup>1</sup>Helmholtz Zentrum Muenchen - German Research Center for Environmental Health, ISB Institute of Radiation Biology, Muenchen, Germany

Epidemiological studies on cancer survivors provide strong evidence for multifaceted damage to brain after ionizing radiation. Decreased neurogenesis and differentiation, alteration in neural structure and synaptic plasticity as well as increased oxidative stress and inflammation are suggested to contribute to adverse effects in the brain. In addition to neural stem cells, several brain-specific mature cell types including endothelial and glial cells are negatively affected by ionizing radiation. The radiation-induced changes in hippocampus using different mouse models irradiated with low to moderate doses of either total body or cranial exposure will be discussed. Not only the dose but also the age at exposure seems to play a significant role in the outcome. A better understanding of how irradiation impairs hippocampal neurogenesis at low and moderate doses is crucial to minimize normal tissue damage of therapeutic irradiation.

### OC-0117 Cisplatin sensitizes radioresistant mesenchymal stem cells

A. Rühle<sup>1</sup>, R. Lopez Perez<sup>1</sup>, K.J. Weber<sup>2</sup>, J. Debus<sup>1,2</sup>, P.E. Huber<sup>1,2</sup>, N.H. Nicolay<sup>1,2</sup>

<sup>1</sup>German Cancer Research Center, Radiation Oncology, Heidelberg, Germany

<sup>2</sup>University Hospital, Radiation Oncology, Heidelberg, Germany

#### Purpose or Objective

Mesenchymal stem cells (MSCs) have been shown to aid the regeneration of tissue damage induced by ionizing radiation or cisplatin. While these stem cells are relatively resistant to photon irradiation and cisplatin treatment alone, the influence of clinically relevant cisplatin-based chemo-radiation regimes on the survival and functional abilities of MSCs is unknown.

#### Material and Methods

The survival of human bone marrow-derived MSCs was assessed after pre-treatment with different doses of cisplatin, and the influence of cisplatin chemo-radiation on cellular morphology, adhesion and migratory abilities and differentiation potential was analyzed. Cell cycle distribution and apoptosis levels of MSCs were measured using flow cytometry, and DNA double strand break repair capacities were evaluated by immunofluorescence.

#### Results

Cisplatin pre-treatment resulted in a dose-dependent radiosensitization with sensitizer enhancement ratio values ranging between 1.07 and 1.30 depending on the cisplatin treatment dose. Cellular morphology, adhesion and migratory abilities were not significantly influenced by cisplatin chemo-radiation. MSC differentiation capability along the adipogenic and chondrogenic lineages was preserved after chemo-radiation, and the defining stem cell surface markers were stably expressed irrespective of treatment. Cisplatin pre-treatment resulted in an accumulation of MSCs in the radiosensitive G2/M phase of the cell cycle. Immunofluorescence analyses showed an increase in both initial and residual radiation-induced DNA double strand breaks following pre-treatment with cisplatin.

#### Conclusion

We could demonstrate for the first time that pre-treatment with cisplatin resulted in a dose-dependent sensitization of radioresistant MSCs, whereas the defining stem cell characteristics of the stem cells were largely preserved. A cisplatin-mediated G2/M phase arrest and an increase in residual radiation-induced DNA double strand breaks may at least be partly responsible for the radiosensitizing effect of cisplatin in MSCs.

### OC-0118 Mesenchymal stem cells are resistant to ionizing radiation irrespective of their tissue of origin

N.H. Nicolay<sup>1,2</sup>, A. Rühle<sup>2</sup>, O. Xia<sup>2</sup>, R. Lopez Perez<sup>2</sup>, J. Debus<sup>1,2</sup>, P.E. Huber<sup>1,2</sup>

<sup>1</sup>University Hospital, Radiation Oncology, Heidelberg, Germany

<sup>2</sup>German Cancer Research Center, Radiation Oncology, Heidelberg, Germany

#### Purpose or Objective

Mesenchymal stem cell-based therapies may provide a novel approach to treat radiation-induced organ damage. While mesenchymal stem cells (MSCs) required for those potential treatments can be harvested from various different tissues, the influence of ionizing radiation on the stem cells from diverse original tissues themselves is largely unknown.

#### Material and Methods

The radiation response of MSCs isolated from human bone marrow, adipose tissue and umbilical cord was investigated. Cellular survival, cell cycle effects and apoptosis were measured and compared to that of differentiated fibroblasts. The influence of irradiation on

the defining stem cell properties was assessed, and the radiation effects on MSC morphology, surface marker expression, adhesion and migration capabilities and the differentiation potential were measured.

Immunocytochemical analyses of DNA damage and repair foci were carried out to quantify the MSCs' ability for DNA double strand break repair.

#### Results

MSCs from different tissues were found to exhibit a relative radiation resistance comparable to that of differentiated fibroblasts. Irradiated MSCs demonstrated a prolonged arrest in G2 phase of the cell cycle, but were able to avoid induction of apoptosis even after treatment with high radiation doses. Surface marker expression, stem cell adhesion and migration capability were not generally reduced by irradiation, and MSCs also maintained their potential for adipogenic, osteogenic and chondrogenic differentiation. Analysis of DNA damage/repair foci demonstrated a swift and efficient repair of radiation-induced DNA double strand breaks in MSCs, providing an explanation for the observed radiation resistance of these stem cells.

#### Conclusion

These data demonstrate for the first time that MSCs from diverse human tissues exhibit comparable resistance to ionizing radiation and also largely maintain their defining stem cell characteristics independent of their original tissue. The observed radiation resistance of MSCs from different tissues will help to establish diverse stem cell sources for future MSC-based therapies against radiation-induced organ damage.

### OC-0119 Dermatan sulfate mitigates radiation-induced oral mucositis (mouse) - biological mechanisms

S. Gruber<sup>1</sup>, E. Bozsaky<sup>1</sup>, M. Arnold<sup>1</sup>, S. Pfaffinger<sup>1</sup>, S. Hetzendorfer<sup>1</sup>, V. Gernedl<sup>1</sup>, A. Rohorzka<sup>1</sup>, L. Kowald<sup>1</sup>, S. Morava<sup>1</sup>, J. Mayer<sup>1</sup>, P. Kuess<sup>1</sup>, W. Dörr<sup>1</sup>

<sup>1</sup>Medizinische Universität Wien Medical University of Vienna, Univ.Klinik f. Strahlentherapie, Vienna, Austria

**Purpose or Objective** Oral mucositis is the most frequent, dose limiting early adverse event of head-and-neck cancer radio(chemo)therapy. The present study quantified the mucoprotective effect of dermatan sulfate (DS) and characterised the underlying biological mechanisms. Irradiation- and DS-mediated changes of epithelial proliferation, cell junction formation, inflammation and hypoxia were investigated.

#### Material and Methods

The study comprises functional and mechanistic investigations. For the functional assessment of mucosal ulcer incidence and time course, mice were irradiated with 5x3 Gy/week over one (days 0-4) or two weeks (days 0-4, 7-11). Each protocol was concluded by graded top-up doses (day 7/14) to generate complete dose-effect curves. Daily doses of DS (4 mg/kg subcutaneously) were applied over varying time intervals during either the first or the second week of fractionation alone, or during both weeks, respectively. In the mechanistic analyses, groups of five mice per experimental arm were sacrificed every second day during the two week fractionated irradiation, the tongues were excised and subjected to histological / immunohistochemical processing.

#### Results

DS significantly increased the isoeffective doses for the induction of oral mucositis in almost all protocols. DS furthermore prolonged the latency to epithelial ulceration and reduced ulcer duration. Proliferation measurements did not show any substantial or systematic effect of DS. In contrast, the radiation-induced increase in the expression of the adherens junction proteins e-cadherin and  $\beta$ -catenin as well as the tight junction proteins claudin and occludin occurred significantly earlier and more pronounced with additional DS treatment. The expression of IL-1 $\beta$  and NF- $\kappa$ B as markers of inflammation was

dramatically increased during irradiation alone; while DS treatment significantly inhibited the radiation-induced increase of IL-1 $\beta$ , however, no systematic effect of DS on the expression of NF- $\kappa$ B was observed. The hypoxia markers HIF-1 $\alpha$  and GLUT-1 showed a progressive increase during irradiation alone that, however, was also not influenced by DS.

#### Conclusion

DS has a significant mucoprotective effect during daily fractionated radiotherapy. This is neither based on stimulation of epithelial proliferation nor on modulation of radiation-induced hypoxic changes. In contrast, increased expression of epithelial junctions and thereby strengthened epithelial anchorage and/or reduced or modulated inflammatory processes appear to be the biological mechanisms underlying the observed mucoprotective effect.

### Symposium: Brachytherapy pays

---

#### SP-0122 Introducing the Brachy-HERO initiative

L.T. Tan<sup>1</sup>

<sup>1</sup>Addenbrooke's Hospital - Oncology Centre University of Cambridge, Cambridge, United Kingdom

The ESTRO HERO project (Health Economics in Radiation Oncology) has the overall aim to develop a knowledge base and a model for health economic evaluation of radiation treatments at the level of individual European countries. The project deals with four dimensions organised in different work-packages: availability, resource needs, cost-accounting and economic evaluation.

This talk will introduce the Brachy-HERO project which seeks to extend the aims of the HERO project to the field of brachytherapy. Preliminary data on brachytherapy use and resource availability in Europe will be presented.

#### SP-0123 Review of health related quality of life measures with brachytherapy and application to QALY for economic evaluation

H. Kim<sup>1</sup>

<sup>1</sup>University of Pittsburgh Cancer Institute, Radiation Oncology, Pittsburgh- PA, USA

Patient reported outcome using health related quality of life (HRQOL) has become an increasingly important part of assessing therapeutic choices especially in cancer treatments.

The improvement in HRQOL is one of main economic benefits of treatment and it is incorporated in economic evaluation.

In this talk, the speaker will review the followings:

1. General overview of HRQOL
  - 1) Types of quality of life scales, 2) How the utility score for a particular health state is determined, 3) How utility values are applied to treatment effectiveness.
2. Utility values related to brachytherapy
3. Literature review of economic evaluation for various cancers treated with brachytherapy
  - 1) Partial breast irradiation brachytherapy, 2) Prostate HDR brachytherapy, 3) Gynecological HDR brachytherapy, 4) Eye plaque brachytherapy
4. Limitations of current utility values in brachytherapy

#### SP-0124 Optimal utilisation of brachytherapy in Europe - can it be measured?

J.M. Borras<sup>1</sup>

<sup>1</sup>Institut Català d'Oncologia, Cancer plan, L'Hospitalet de Llobregat, Spain

Most of the approaches applied in order to assess the need for radiotherapy have been focused on external radiotherapy. From this perspective, there is a gap in the

evaluation of the potential need for brachytherapy in European countries. Three approaches have been used for planning radiotherapy: expert opinion, benchmarking and evidence based assessment of the indications for treatment. Benchmarking is based on the selection of one territory with appropriate level of resources for therapy and accepted as a reference for the experts, which could be used as a comparison for the rest of territories. Usually, the reference territory has data from a population based cancer registry in order to make sure that all cancer patients are included in the comparison. Evidence based indications review the evidence, using clinical guidelines and primary evidence, in order to provide the optimal treatment percentage of cases that would receive radiotherapy, as shown by the CCORE model. Both approaches have advantages and problems that will be discussed with a focus on brachytherapy.

The epidemiological data required to assess the optimal use of brachytherapy is available for some countries in Europe but there are good estimates that allow to provide data for most countries in Europe, as it has been shown in the ESTRO-HERO project carried out recently for external radiotherapy. Data on incidence and stage at diagnosis for the most frequent tumour sites are available, from population based cancer registries. In addition to the epidemiological data, the potential indications for brachytherapy are also required. The consensus over the evidence for brachytherapy indications and the potential factors explaining the gap between optimal and actual use will be discussed, using prostate cancer as a case study.

The epidemiological approach proposed to assess the need for brachytherapy is aligned to the National cancer plan requirements and could be an useful input of data to assess the gap in the actual utilization of this therapeutic strategy.

#### OC-0124 Outcomes of concurrent chemo-radiotherapy in elderly patients with advanced bladder cancer

M. Christodoulou<sup>1</sup>, C. Hodgson<sup>1</sup>, A. Zeniou<sup>2</sup>, F. Slevin<sup>2</sup>, J. Kennedy<sup>1</sup>, P.J. Hoskin<sup>3</sup>, A. Henry<sup>2,4</sup>, A. Choudhury<sup>5</sup>

<sup>1</sup>The Christie NHS Foundation Trust, Clinical Oncology, Manchester, United Kingdom

<sup>2</sup>Leeds Teaching Hospitals NHS Trust- Bexley Wing- St. James's Institute of Oncology, Clinical Oncology, Leeds, United Kingdom

<sup>3</sup>Centre for Cancer Treatment- Mount Vernon Hospital, Clinical Oncology, London, United Kingdom

<sup>4</sup>The University of Leeds, Clinical Oncology, Leeds, United Kingdom

<sup>5</sup>The University of Manchester- Manchester Academic Health Science Centre- The Christie NHS Foundation Trust, Radiotherapy Related Research, Manchester, United Kingdom

There is little evidence to guide treatment in elderly patients with muscle invasive bladder cancer (MIBC). We aimed to assess the efficacy and tolerability of concurrent radical radiotherapy with gemcitabine radiosensitisation (GemX) in elderly patients with MIBC and correlate outcomes to those from the bladder carbogen and nicotinamide (BCON) phase III clinical trial.

#### Material and Methods

Data was retrospectively analysed from patients who received GemX between May 2010 and December 2014 from two oncology centres in the United Kingdom. Elderly was defined as aged  $\geq 75$  at the start of GemX. Following transurethral resection of bladder tumour, where appropriate, patients received neo-adjuvant platinum-based chemotherapy followed by radiotherapy (50-55 Gy/20 fractions) concurrently with weekly gemcitabine (100 mg/m<sup>2</sup>). A separate, elderly-specific analysis was performed in the BCON cohort. Overall survival (OS),

disease specific survival (DSS) and local progression free survival (LPFS) were evaluated using Kaplan-Meier methodology and Cox proportional hazards regression.

### Results

Out of 167 patients, 61 (36.5%) were elderly with a median age of 78 years (range 75-89). Elderly patients had worse performance status ( $p=0.02$ ) and co-morbidities ( $p=0.03$ ). A similar proportion of patients received planned dose radiotherapy in both groups ( $p=0.26$ ), although fewer elderly patients received all four cycles of concurrent chemotherapy ( $p=0.014$ ) due to toxicity. With a median follow-up time of 38 months for those alive; hazard ratios (HR) comparing younger and elderly for OS, DSS and LPFS were 1.04 (95% CI 1.00-1.08; log-rank  $p=0.068$ ), 1.00 (95% CI 0.95-1.04; log-rank  $p=0.916$ ) and 1.00 (95% CI 0.95-1.04; log-rank  $p=0.899$ ) respectively (Figure 1). Late grade 3/4 genitourinary (GU) or gastrointestinal (GI) toxicity was reported in three patients in the younger group and none in the elderly group. Age was not a significant prognostic factor in univariate analysis. In the CON arm of the BCON trial, elderly patients demonstrated similar LPFS (HR 1.03, 95% CI 0.99-1.06; log-rank  $p=0.145$ ), but worse OS (HR 1.05, 95% CI 1.02-1.08; log-rank  $p=0.002$ ) compared to their younger counterparts. Overall survival and LPFS in elderly patients were comparable between CON and GemX (HR 1.13, 95% CI 0.69-1.85; log-rank  $p=0.616$  and HR 0.85, 95% CI 0.41-1.74; log-rank  $p=0.659$  respectively) (Figure 2).

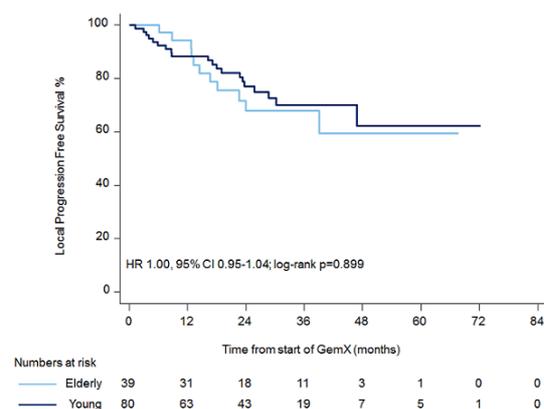

Figure 1. Kaplan-Meier curves for local progression free survival for elderly (light blue line) and younger (dark blue line) groups. Hazard ratio (HR), 95% confidence intervals (CI), log-rank p value and number of patients at risk against yearly intervals are shown. GemX, concurrent chemo-radiotherapy with gemcitabine radiosensitisation.

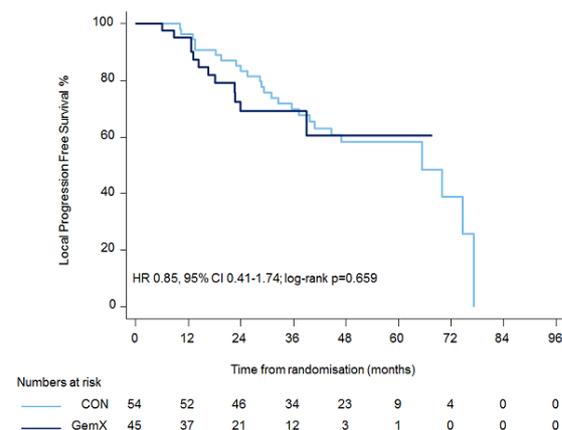

Figure 2. Kaplan-Meier curves for local progression free survival for elderly patients who received radiosensitisation with CON (light blue line) or GemX (dark blue line) (B). Hazard ratio (HR), 95% confidence intervals (CI), log-rank p value and number of patients at risk against yearly intervals are shown. CON, carbogen, oxygen and nicotinamide; GemX, concurrent chemo-radiotherapy with gemcitabine radiosensitisation.

### Conclusion

Radiosensitisation is safe and effective and should be considered for fit elderly patients with MIBC.

### Purpose or Objective

To conduct a central pathology review within a randomized clinical trial on salvage radiation therapy (RT) in the presence of biochemical recurrence after prostatectomy to assess whether this results in shifts of histopathological prognostic factors such as the Gleason Score.

### Material and Methods

A total of 350 patients were randomized and specimens of 279 (80%) of the patients were centrally reviewed by a dedicated genitourinary pathologist. The Gleason Score, tumor classification and resection margin status were reassessed and compared with the local pathology reports. Agreement was assessed using contingency tables and Cohen's Kappa. Additionally, the association between other histopathological features (e.g. largest diameter of carcinoma) with rising PSA (up to 6 months after salvage RT) was investigated.

### Results

There was good concordance between central pathology review and local pathologists for seminal vesicle invasion [pT3b: 91%;  $k=0.95$  (95% CI 0.89, 1.00)], for extraprostatic extension [pT3a/b: 94%;  $k=0.82$  (95% CI 0.75, 0.89)], and for positive surgical margin status [87%;  $k=0.7$  (95% CI 0.62, 0.79)]. Agreement was lower for Gleason score [78%;  $k=0.61$  (95% CI 0.52, 0.70)]. The median largest diameter of carcinoma was 16 mm (range, 3-38 mm). A total of 49 patients (18%) experienced a rising PSA after salvage RT. Largest diameter of carcinoma [odds ratio (OR): 2.04 (95% Confidence interval (CI): 1.30, 3.20);  $p=0.002$ ], resection margin status [OR: 0.36 (95% CI: 0.18, 0.72);  $p=0.004$ ]

and Gleason score [OR: 1.55 (95% CI: 1.00, 2.42);  $p = 0.05$ ] remained associated with rising PSA after salvage RT after backward selection.

#### Conclusion

The results of the central pathology analyses reveal concordant results for seminal vesicle invasion, extraprostatic extension, positive surgical margin but lower agreement for Gleason Score. Largest diameter of carcinoma was found to be a potential prognostic factor for rising PSA after salvage RT.

#### OC-0126 A gene expression assay to predict the risk of distant metastases in localized prostate cancer.

S. Jain<sup>1</sup>, C. Lyons<sup>1</sup>, S. Walker<sup>2</sup>, S. McQuaid<sup>1</sup>, S. Hynes<sup>3</sup>, D. Mitchell<sup>4</sup>, B. Pang<sup>5</sup>, G. Logan<sup>2</sup>, A. <sup>12</sup>Cardiff University, Wales Cancer Bank, Cardiff, United Kingdom

<sup>13</sup>Beaumont Hospital, Centre for Systems Medicine, Dublin, Ireland

#### Purpose or Objective

Approximately 20% of patients with organ confined prostate cancer (PCa) will develop disease recurrence following radical treatment (surgery or external beam radiotherapy (EBRT)). We hypothesized that a molecular subgroup of early PCa may have metastatic potential at presentation, resulting in disease recurrence.

#### Material and Methods

Using unsupervised hierarchical clustering of gene expression from a PCa dataset we identified a novel molecular subgroup with a transcriptional profile similar to metastatic disease. We developed a 70 gene expression assay to prospectively identify patients within the subgroup from formalin fixed and paraffin embedded tissue (FFPE). Initial assessment found the assay to be prognostic in three independent publicly available prostatectomy datasets. We therefore assessed the prognostic value of the assay in FFPE clinical samples collected from multiple international sites. FFPE tumor resections and tumor biopsy specimens were obtained from 322 surgical patients and 248 patients treated with EBRT. Regions of highest Gleason grade were identified for macrodissection, RNA extraction and gene expression analysis. Samples were dichotomized as metastatic biology assay positive or negative using a pre-specified cut-off. The association of assay results with biochemical failure (BF) and distant metastases (DM) was tested on multivariate (MVA).

#### Results

The assay was significantly associated with BF on MVA (HR 1.67 [1.16-2.38];  $p=0.0059$ ), (HR 2.26 [1.26-4.04];  $p=0.0062$ ) and DM on MVA (HR 3.39 [1.88-6.12];  $p=0.0001$ ), (HR 3.26 [1.27-8.30];  $p=0.0137$ ) for surgery and EBRT cohorts respectively. Importantly, in a combined model, the assay demonstrated additional information to the commonly used CAPRA clinical tool for prediction of DM, HR 2.72 [2.10-3.51];  $p<0.0001$ , and HR 2.72 [1.42-5.20];  $p=0.0026$  (Prostate Metastatic Assay combined with CAPRA-S and CAPRA respectively).

#### Conclusion

The metastatic biology assay predicts BF and DM in PCa patients treated with surgery or EBRT. The assay may help to select patients at risk of metastatic disease for additional treatment aimed at preventing disease recurrence.

#### OC-0127 Individualized prediction of nodal involvement based on Sentinel-node dissection of prostate cancer

A.C. Müller<sup>1</sup>, D. Zips<sup>1</sup>, A. Ernst<sup>1</sup>, R. Bares<sup>2</sup>, P. Martus<sup>3</sup>, D. Weckermann<sup>4</sup>, D. Schilling<sup>5</sup>, J. Bedke<sup>5</sup>, A. Stenzl<sup>5</sup>

<sup>1</sup>University Hospital Tübingen Eberhard Karls University Tübingen, Radiation Oncology, Tübingen, Germany

<sup>2</sup>University Hospital Tübingen Eberhard Karls University Tübingen, Nuclear Medicine and Clinical Molecular Imaging, Tübingen, Germany

<sup>3</sup>University Hospital Tübingen Eberhard Karls University Tübingen, Institute for Clinical Epidemiology and Applied Biometry, Tübingen, Germany

<sup>4</sup>Klinikum Augsburg, Urology, Augsburg, Germany

<sup>5</sup>University Hospital Tübingen Eberhard Karls University Tübingen, Urology, Tübingen, Germany

#### Purpose or Objective

The risk of nodal involvement in prostate cancer can be estimated by the Roach formula. However, this formula was criticized to overestimate nodal involvement and to be based on the lesser accurate standard lymph node dissection. The aim of this study was the development of a new formula overcoming these limitations and to individualize the decision of pelvic treatment using current surgical techniques. Therefore the prediction of nodal involvement was based on patients after sentinel node (SN) dissection which is comparable to extended node dissection.

**Material and Methods** Clinical data of 433 prostate cancer patients (>93.5% with MRI or CT staging) was used to develop a formula for prediction of nodal involvement which received SN dissection in the course of prostatectomy or staging before radiotherapy. Clinical parameters comprised TNM, Gleason score, percentage of biopsies, PSA level, d'Amico and NCCN risk grouping. The validation cohort included 414 patients of an academic hospital using the same SN-procedure, cross-sectional imaging was restricted to selected high risk patients.

#### Results

Available predictive nomograms (Briganti, Oldenburg), the Partin and Gancarczyk tables, the Roach formula and the MSKCC calculator were compared using ROC-curves. The best available nomogram was the Briganti nomogram (AUC=0.853+/-0.036 standard error). The formula was derived by logistic regression and test of relevant variables (cT-stage, PSA-level, Gleason score, positive cores) by ROC curves. The formula needs two variables: T-stage and percentage of positive cores. The formula is given in Fig.1 and can be easily applied by a spreadsheet analysis sheet. The developed formula reached an AUC of 0.863+/-0.034 standard error, which was comparable with the Briganti nomogram (AUC=0.853+/-0.036). The formula was validated by an additional data set of 414 patients. The AUC values were 0.665 for Briganti and 0.637 for our model.

**Fig. 1: Probability of nodal involvement (p), x1=cT-stage (see Tab.1), x2=percentage of positive cores**

$$p = \frac{1}{1 + e^{-(-7.978 + 1.022x_1 + 0.021x_2)}}$$

**Tab. 1: Definition of variable x1**

cT-stage	Variable x1
cT1c	1
cT2a	2
cT2b	3
cT2c	4
cT3a	5
cT3b	6
cT4a	7

### Conclusion

We developed a new formula based on SN-dissection needing only two parameters in contrast to other nomograms. The new formula is based on SN dissection which is comparable to extended node dissection. The prediction accuracy of the new formula was comparable to the best nomogram i.e. the Briganti nomogram. In general, accuracy of nomograms including the new formula was improved when T-stage was based on MRI.

### OC-0128 Patient-reported outcome in the prostate HYPRO trial: gastrointestinal toxicity

W. Heemsbergen<sup>1</sup>, R. Wortel<sup>2</sup>, F. Pos<sup>1</sup>, R. Smeenk<sup>3</sup>, S. Krol<sup>4</sup>, S. Aluwini<sup>2</sup>, M. Witte<sup>1</sup>, B. Heijmen<sup>2</sup>, L. Incrocci<sup>2</sup>  
<sup>1</sup>Netherlands Cancer Institute, Radiation Oncology, Amsterdam, The Netherlands  
<sup>2</sup>Erasmus MC Cancer Institute, Radiation Oncology, Rotterdam, The Netherlands  
<sup>3</sup>Radboud University Medical Center, Radiation Oncology, Nijmegen, The Netherlands  
<sup>4</sup>Leiden University Medical Center, Clinical Oncology, Leiden, The Netherlands

### Purpose or Objective

The phase 3 HYPRO trial, randomizing to 19x3.4 Gy hypofractionation (HF) or 39x2 Gy standard fractionation (SF), recently reported that the hypothesized non-inferiority of the HF schedule was not proven for late Grade  $\geq 2$  gastrointestinal (GI) toxicity, neither was there a significant difference observed for GI Grade  $\geq 2$  and Grade  $\geq 3$  with 5y follow-up. The aim of this analysis was to compare dose parameters and patient-reported late GI symptoms between SF and HF, and between hospitals of treatment.

### Material and Methods

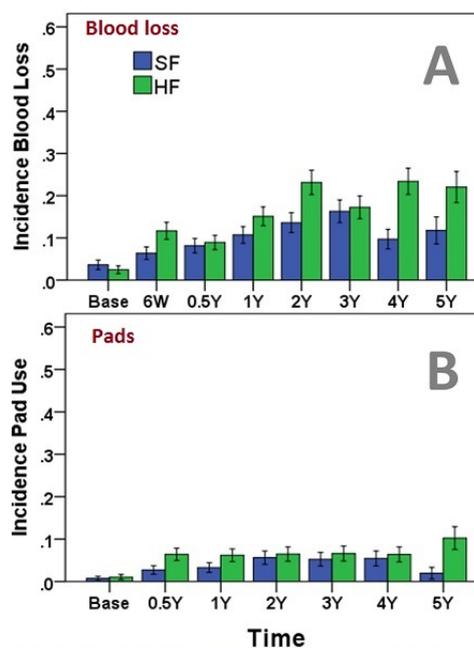

Patients with localized prostate cancer from four hospitals applying Image-Guided IMRT protocols and recruiting >70 patients were analyzed. Patients (n=578; 284 SF, 294 HF) with  $\geq 1$  follow-up symptom questionnaire were eligible (n=2442). Protocol dose constraints were: mean dose anal canal <58 Gy and rectal volume <50% receiving  $\geq 65$  Gy, using a 0 mm margin towards rectum for the boost. Local guidelines were applied for delineation, dose (in)homogeneity, margins (5-8 mm), and further optimization. One hospital applied a rectal balloon and another hospital delineated the prostate on MRI. Incidences of GI symptoms for the period 0.5y-5y post-RT were compared between treatment arms and hospitals. Medication prescription was evaluated as well. Anorectal dose parameters (EQD2) were calculated with  $\alpha/\beta=3$  Gy. The effect of hospital and treatment on the incidence of complaints was estimated in a multivariate model including follow-up time. Treatment groups were well balanced within hospitals and over time.

### Results

Mean anorectal dose and surface > 70 Gy (S70) were 29.0 Gy vs 29.5 Gy (p=0.4) and 14.2% vs 12.6% (p<0.01), for HF and SF, respectively. Differences between hospitals varied between 24.7 Gy-33.2 Gy (average mean dose) and 10.4%-16.1% (average S70), and were significant (p<0.01). Patient-reported GI symptoms of blood loss (p<0.001) and use of pads (p<0.01) were significantly higher in the HF group (FIG 1); pain with stools, abdominal cramps, and diarrhea were not increased and mucus loss was non-significantly increased (p=0.07). Significant differences between hospitals were observed for all complaints, except rectal pain (FIG 2). In general, the hospital with rectal balloon (D) and hospital with MRI delineation (A) showed favorable dose parameters and symptom patterns compared to the other hospitals. Patients treated with a rectal balloon reported relatively low symptom rates but at the same time, prescribed medication for GI complaints was reported more frequently as well (14% doctor's reported versus  $\approx$ 4% for the other hospitals).

### Conclusion

We conclude that the HF schedule was associated with slightly larger rectal high-dose volumes assuming an  $\alpha/\beta$  of 3 Gy, and a significantly higher risk of rectal bleeding and use of pads. Furthermore, we found that variation in local treatment protocols had a significant impact on rectal dose and toxicity risks, despite the use of similar techniques and identical dose prescriptions.

**FIG 1. Incidences per treatment group (1SE)**

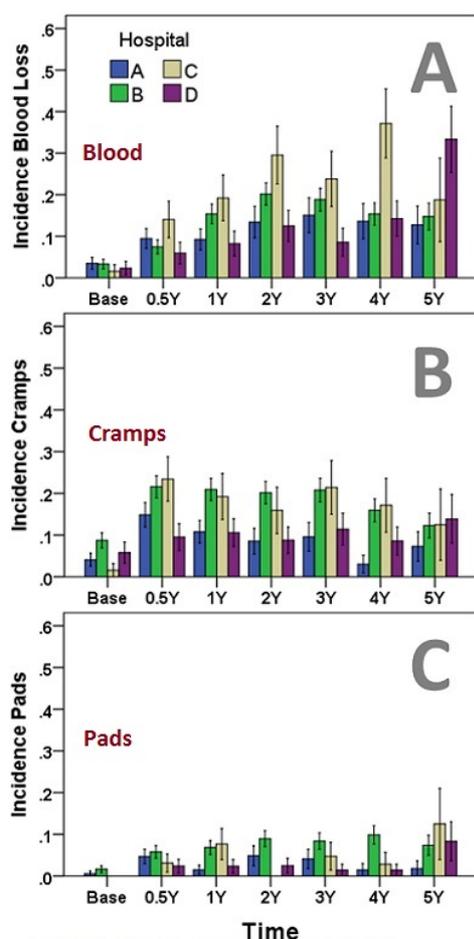

FIG 2. Incidences per hospital (1SE)

**OC-0129 5-year safety, efficacy & quality of life outcomes from multi-center SBRT trial for prostate cancer**

R. Meier<sup>1</sup>, I. Kaplan<sup>2</sup>

<sup>1</sup>Swedish Cancer Institute, Swedish Radiosurgery Center, Seattle, USA

<sup>2</sup>Beth Israel Deaconess Medical Center, Radiation Oncology, Boston, USA

**Purpose or Objective**

Single-institution studies suggest SBRT is a cost-effective alternative to external-beam RT for prostate cancer. We hypothesized that dose-escalated SBRT could be safely administered across multiple institutions, and that in low-risk (LR) patients, dose escalation would improve 5-year disease-free survival (DFS) rates compared to historic controls. We now also report 5-year quality of life (QOL) outcomes.

**Material and Methods**

21 centers enrolled 309 evaluable patients with biopsy-proven prostate adenocarcinoma: 172 with low-risk, and 137 with intermediate-risk (IR) disease. All patients were treated with a non-coplanar robotic SBRT platform using real-time tracking of implanted fiducials. The prostate was prescribed 40 Gy in 5 fractions of 8 Gy. Toxicities were assessed using CTCAE v3 criteria, and biochemical failure using the nadir+2 definition. Study populations yielded 90% power of identifying excessive (>10%) rates of grade 3+ GU or GI toxicities, and in the LR group, 80% power of showing improvement in DFS over a historic comparison control rate of 93%.

QOL for urinary, bowel and sexual function were assessed using the Expanded Prostate Cancer Index Composite (EPIC-26) questionnaire. Outcomes were analyzed with a

longitudinal analytic approach using generalized estimating equations; the dependent variable was change in scores from baseline. Post-SBRT domain score differences were considered clinically relevant if they exceeded ½ standard deviation of pre-treatment scores.

**Results**

Median follow-up was 61 months. Two LR patients (1.7%) and two IR patients (1.5%) experienced grade 3 toxicities, far below the 10% toxicity rate deemed excessive (P<0.001 for both cohorts). There were no grade 4-5 toxicities. All grade 3 toxicities were GU and occurred between 11 and 51 months after treatment. For the entire group, actuarial 5-year overall survival was 95.6%, and DFS was 97.1%. In LR patients, the 5-year DFS was 97.3%, which was superior to 93% DFS from historic controls (p=0.014). 5-year DFS was 97.1% for IR patients.

Patient-reported QOL outcomes are described in the table below. Clinically relevant declines in urinary irritative scores from were observed at 1 and 12 months after treatment, with subsequent return to baseline. A fall in bowel QOL was seen at 1 month only. The gradual decline in sexual QOL did not reach clinical relevance.

Pt-Reported QOL	Mean Scores	EPIC							
		Baseline	1 mo	6 mo	1 yr	2 yr	3 yr	4 yr	5 yr
Follow-up interval:	Baseline	1 mo	6 mo	1 yr	2 yr	3 yr	4 yr	5 yr	
# responses:	298	294	210	263	265	223	191	163	
Incontinence:	93.5	89.3	90.8	87.7	88.9	89.2	87.6	88.5	
Irritative:	87.6	75.0*	84.8	80.9*	87.2	89.7	89.0	90.3	
Bowel:	94.8	83.4*	92.1	90.8	92.2	93.0	92.3	92.5	
Sexual:	56.2	53.7	51.1	43.8	47.8	47.6	45.8	43.1	

\*=clinically relevant

**Conclusion**

Dose-escalated prostate SBRT can be safely administered across multiple institutions. In LR patients, 5-year DFS rates are superior to historical EBRT control rates. In IR patients, 5-year DFS also appears favorable. Declines in GI and GU QOL are transient. SBRT is a suitable option for low- and intermediate-risk prostate cancer.

<sup>11</sup>Hopitaux Universitaires de Genève, Radiation Oncology, Genève, Switzerland

<sup>12</sup>Centre Georges-François Leclerc, Radiation Oncology, Dijon, France

<sup>13</sup>Centre Hospitalier Universitaire Vaudois, Radiation Oncology, Lausanne, Switzerland

**Purpose or Objective**

Adult prostatic sarcomas (PS) are rare. While surgery is considered the standard approach, the role of other therapies is not completely established. We report data on a large population of adult, non-metastatic PS patients (pts).

### Material and Methods

This is a multicentric Rare Cancer Network (www.rarecancer.net) retrospective study launched in February 2016. Demographic, therapeutic and outcome data of 48 adult PS pts treated in 13 European and American Institutions were collected in a common database and then analysed. Median age was 64.5 years (range: 22 - 87). Curative surgery was delivered in 35 pts (prostatectomy = 19, cystoprostatectomy = 16), usually with lymphadenectomy (n = 24). Curative radiotherapy (RT) was delivered in 24 pts, as neoadjuvant (n = 2), postoperative (n = 17), or as definitive treatment (n = 5). Ten pts received neoadjuvant (n = 3) or adjuvant (n = 7) chemotherapy. None of the patients received hormonal therapy.

### Results

Median follow-up was 67 months. Five-year local control (LC), overall survival (OS), cancer-specific survival, disease-free survival, and metastases-free survival rates were 48.9%, 45.2%, 52.4%, 29.7%, and 31.2%, respectively. Irradiated patients presented better 5-year LC (63.8% vs 38.8%,  $p = 0.2$ ) but its impact was not confirmed in the 35 pts receiving curative surgery. In the subgroup of pT3-T4 patients treated with curative surgery, RT significantly improved the 5-year LC (45.7% vs 0%,  $p = 0.007$ ) and OS (48% vs 0%,  $p = 0.014$ ) rates. cT4 pts presented a significantly lower 5-year OS (60.1% vs 29.5%,  $p = 0.001$ ) and LC (70.2% vs 11.4%,  $p < 0.001$ ) rates. Histologic type did not significantly influence the LC and OS, but pts presenting a prostatic stromal sarcoma, a rhabdomyosarcoma, or a sarcomatoid carcinoma showed a trend toward a worse outcome (5-year LC [31.9% vs 59.2%] and OS [28% vs 70%]).

### Conclusion

Adult PS has a bad prognosis. More advanced diseases present lower LC and OS rates. Curative RT should be considered part of the multidisciplinary approach to PS.

## Poster Viewing : Session 3: Treatment planning

### PV-0131 MR-only prostate external radiotherapy treatment planning - a multi-center/multi-vendor validation

E. Persson<sup>1</sup>, C. Gustafsson<sup>1,2</sup>, F. Nordström<sup>3</sup>, M. Sohlín<sup>3</sup>, A. Gunnlaugsson<sup>4</sup>, K. Petruson<sup>5</sup>, N. Rintelä<sup>6</sup>, K. <sup>7</sup>Umeå University, Radiation Sciences, Umeå, Sweden

<sup>8</sup>Uppsala University, Immunology- Genetics and Pathology, Uppsala, Sweden

<sup>9</sup>Spectronic, Medical, Helsingborg, Sweden

### Purpose or Objective

An important prerequisite for MRI only radiotherapy is the generation of a synthetic CT (sCT) from MRI-data. This study aims to validate the use of MriPlanner™, a software for MR to sCT conversion, for 170 prostate cancer patients. Performed within the Swedish consortium Gentle Radiotherapy, this multi-center study enables a large-scale validation of calculated synthetic CTs for multiple vendors. This is a presentation of the full results of the MR-Only Prostate External Radiotherapy (MR-OPERA) study.

### Material and Methods

The four participating centers had MriPlanner™ (Spectronic Medical AB, Helsingborg, Sweden) installed as a cloud based service. The software makes use of an atlas-based generation method, called the statistical decomposition algorithm, which generates sCTs from T2-weighted MR-images. Study participation did not affect treatment prescription, and the patients followed the routine clinical workflow.

A T2-weighted MRI, covering the external body contour, was added to the clinical MRI scan protocol. The MR-image was sent from the MR-scanner workstation to the MriPlanner™ platform. The generated sCT was automatically returned to the treatment planning system. A total of four different MR-scanners from two vendors and two magnetic field strengths were included in the study. For each patient, a CT-treatment plan was created and approved according to clinical practice. The generated sCT was rigidly registered to the CT, the structures transferred, and the clinical treatment plan was recalculated on the sCT. Separate external contours were generated based on the sCT and CT images respectively. The dose distributions from the CT-plan and the sCT-plan were compared based on a set of DVH-parameters and with gamma evaluation. Treatment techniques included VMAT, IMRT and conventional treatment using two commercially available treatment planning systems.

### Results

The overall (multi-center/multi-vendor) mean difference between sCT and CT dose distribution were  $0.23\% \pm 0.42\%$  for PTV mean,  $0.04\% \pm 0.27\%$  for bladder mean and  $0.16\% \pm 0.42\%$  for rectum mean (1 s.d). Gamma evaluation showed a mean pass rate of  $99.12\% \pm 0.63\%$  in the complete body volume and  $99.97\% \pm 0.13\%$  in the PTV volume using a 2%/2mm global gamma criteria (1 s.d). The four centers showed similar results. All evaluated DVH-criteria were shown to be equivalent at a 95% confidence interval using a two one-sided test of equivalence for paired samples.

### Conclusion

The results of the MR-OPERA study showed that an MRI only workflow using the MriPlanner was dosimetrically accurate for a variety of vendors, field strengths and treatment techniques. Minimal differences were observed between sCT and CT dose distributions, and in comparison to other uncertainties in radiotherapy, they can be considered negligible. The proposed method will allow for a straightforward implementation of an MRI only workflow for external prostate radiotherapy at most clinics.

### PV-0132 Comparison of planned versus simulated delivered dose in IMRT for endometrial cancer

I. White<sup>1</sup>, D. McQuaid<sup>1</sup>, A. Dunlop<sup>1</sup>, N. Hopkins<sup>1</sup>, M. Caputo<sup>1</sup>, S. Mason<sup>1</sup>, S. Lalondrelle<sup>1</sup>

<sup>1</sup>The Institute of Cancer Research and The Royal Marsden NHS Foundation Trust, Radiotherapy, Sutton, United Kingdom

### Purpose or Objective

To quantify the planned versus the delivered radiation dose using deformable image registration of cone beam CT (CBCT), in patients treated with IMRT for endometrial cancer.

### Material and Methods

1. Post-hysterectomy patients treated with adjuvant IMRT (4500cGy in 25 fractions) for endometrial cancer were retrospectively dose tracked using CBCT on a commercial treatment planning system (RayStation v5, Raysearch Laboratories).

2. CBCTs were acquired days 1-4 and then weekly except when error >5mm.

3. Rigid registration between the planning CT and each CBCT was performed based on treatment position.

4. CBCT electron density values were established.

5. CTV for the vaginal vault and upper vagina (CTVv), bladder and rectum were manually contoured on each image set.

6. Dose was computed on each CBCT and then deformed to the planning CT by a computed deformable registration.

7. For the purpose of summation of simulated dose, because patients did not receive daily CBCTs, the allocated dose for adjacent CBCTs where an interval of more than one fraction occurred was calculated by interpolation.

8. The planned dose to the CTVv, rectum and bladder was compared to the simulated delivered dose using paired t-test with Bonferroni correction.

9. The deformation vector field (DVF) for each voxel within a 1mm internal annulus of the CTVv contour was used to calculate mean and standard deviation (SD) displacement in left-right (LR), anteroposterior (AP) and superoinferior (SI) directions.

### Results

A total of 169 CBCTs from 17 patients were analysed. There were statistically significant differences in the planned and delivered dose to the target CTVv (Table 1), with clinically significant under dosing of CTVv D95% in 2 patients (4068cGy and 4135cGy, target 4275cGy). In these patients there was substantial reduction in rectal volume during treatment compared to the reference CT (mean rectal volume relative to baseline 51.1% and 58.1%). This resulted in posterior displacement of the CTVv (Fig 1). A further 4 patients had clinically significant under dosing of CTVv D50%. As a group there was no statistically significant difference in delivered dose to the organs at risk (OARs), but individually some patients showed marked differences. Bladder and rectal volume varied during treatment. The range of maximal % change was 9- 260% for bladder and 32-249% for rectum. Grand mean  $\pm$  SD (range) (cm) for displacement of the DVF within the CTVv annular structure were LR  $0.04 \pm 0.28$  (-2.11-2.27), AP  $0.19 \pm 0.54$  (-2.99- 2.92) and SI  $-0.15 \pm 0.26$  (-2.17-2.00).

Table 1. Paired t-test comparing planned versus simulated delivered dose in IMRT for endometrial cancer

Dose Constraint	Mean Difference	Standard Deviation	p-value
CTVv D95% (target >4275cGy)	56.18 cGy	90.51	0.02
CTVv D99% (target >4050cGy)	50.41 cGy	108.88	0.07
CTVv D50% (target 4455-4545cGy)	65.71 cGy	69.85	0.01
CTVv D5% (target <4725cGy)	82.47 cGy	64.69	<0.01
CTVv D2% (target <4815cGy)	83.82 cGy	62.39	<0.01
Rectum V4500cGy	2.26 %	7.85	0.25
Rectum V3000cGy	1.74 %	5.72	0.23
Bladder Mean Dose	-17.71 %	63.57	0.27

### Conclusion

Simulation of delivered dose using deformable registration reveals significant differences in the planned and delivered dose. Target and OAR motion may not be accounted for with standard margins. Changes in rectal volume can lead to significant under dosing to target and AP margins of over 2cm may be required in some patients

as demonstrated by the DVF displacement.

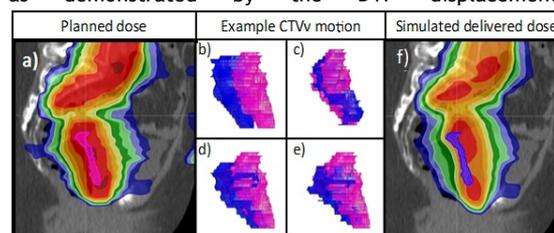

Fig 1: Sagittal images of one patient with significant under dosing of CTVv showing (a) Planned dose with the CTVv annotated in pink, (b-e) CTVv geometry at treatment CBCTs (blue) compared with CTVv geometry at planning CT (pink) for weeks 1-4 respectively, and (f) Simulated delivered dose, with CTVv annotated in blue. Dose distribution (a and f): red 95%, orange 90%, yellow 80%, green 70%, and blue 55%.

### PV-0133 Re-irradiation of pelvic recurrence of rectal cancer: Developing an adaptive plan selection strategy

L. Nyvang<sup>1</sup>, C.S. Byskov<sup>1</sup>, M.G. Guren<sup>2</sup>, L.P. Muren<sup>1</sup>, K.L.G. Spindler<sup>3</sup>

<sup>1</sup>Aarhus University Hospital, Dept. of Medical Physics, Aarhus, Denmark

<sup>2</sup>Oslo University Hospital, Dept. of Oncology and K.G. Jebsen Colorectal Cancer Research Centre, Oslo, Norway

<sup>3</sup>Aarhus University Hospital, Dept. of Oncology, Aarhus, Denmark

### Purpose or Objective

Radiotherapy (RT) of rectal cancer is challenged by potentially large inter-fractional changes in internal anatomy, of the tumour site as well as surrounding normal tissues. Adaptive RT strategies have so far not been applied clinically for rectal cancer. The aim of this study was to develop an adaptive plan selection strategy based on assessment of CBCTs in patients receiving RT for recurrent rectal cancer, and to show its clinical feasibility as well as its normal tissue sparing potential.

### Material and Methods

Five patients previously treated with pre-operative chemo-RT followed by surgery for rectal adenocarcinoma, received pelvic re-irradiation according to a re-irradiation protocol comprising - 40.8 Gy delivered in 34 fractions with two fractions per day and concomitant capecitabine. Daily CBCTs were acquired prior to each fraction with a Varian Truebeam accelerator. A plan selection strategy with a library of three plans was investigated, with the target volume in Plans A, B and C covering the CTV with a margin of 5 mm, 10 mm and 15 mm, respectively (Plan C is close to the current non-adaptive plan). The CBCT of each fraction was matched on the CTV of the planning CT and analysed in order to determine which plan would cover the CTV at the specific treatment fraction. The 'effective PTV' (PTVeff), a weighted mean of the volumes treated throughout the treatment course using the plan selections, was calculated for each patient in order to quantify the potential reduction of the treated volume compared to the standard non-adaptive PTV.

### Results

Evaluations of all CBCTs were possible for all five patients. For three patients, the CTV was included in Plan A in all 34 CBCTs. For one patient (patient 5), Plan A could have been used in 25 fractions and Plan B in the remaining nine fractions. One patient (patient 4) was more challenging than the others due to a systematic change in the position of the CTV resulting in Plan B to be chosen for all fractions. In this case a re-scan and a new treatment plan would have accounted for the systematic change. Overall, a considerable potential for reduction of the treated volumes is evident from table 1.

PTV and plan selection volumes

Patient ID	V <sub>ctv</sub> [cm <sup>3</sup> ]	V <sub>ptv</sub> [cm <sup>3</sup> ]	V <sub>ctv+5mm</sub> [cm <sup>3</sup> ]	V <sub>ctv+10mm</sub> [cm <sup>3</sup> ]	V <sub>ctv+15mm</sub> [cm <sup>3</sup> ]	V <sub>ptvref</sub> [cm <sup>3</sup> ]	PTV reduction [%]
1	23.9	226.8	66.4	127.6	214.8	66.4	70.7
2	539.07	1400.4	837.7	1105.9	1433.9	837.7	40.2
3	15.68	149.7	41.7	80.4	141.5	41.7	72.1
4	141.2	607.6	276.2	421.8	614.4	421.8	30.6
5	59.4	311.7	126.7	211.4	337.6	149.1	52.2

Table 1

### Conclusion

The CTV and/or surrogate target structures in recurrent rectal cancer are visible on all CBCTs from our on-board imaging system, enabling volumetric image-guided adaptive strategies. A 5 mm margin was found to be sufficient to account for the deformations of the target in the majority of treatment fractions; there is therefore a considerable potential for reduction of the treated (normal tissue) volume compared to current wide margins.

### PV-0134 Isotoxic stereotactic radiotherapy for central pelvic recurrence in gynecological cancer

M. Llewelyn<sup>1</sup>, A. Taylor<sup>1</sup>

<sup>1</sup>The Institute of Cancer Research and The Royal Marsden NHS Foundation Trust, Clinical Oncology, Sutton, United Kingdom

### Purpose or Objective

Radical radiotherapy is the treatment of choice for central pelvic recurrence in gynaecological cancer. Following whole pelvic radiotherapy, a high dose boost is given to macroscopic disease. When brachytherapy is not feasible, local control with EBRT alone is only 30-50%. Stereotactic radiotherapy offers potential for dose escalation to improve outcomes. Cumulative OAR dose tolerances are internationally established for intrauterine brachytherapy, and similar principles can be applied with SBRT. This can be delivered with Cyberknife or linear accelerator VMAT, and the GTV-PTV margin depends on whether real-time motion tracking of tumour is utilised. The aims were to compare dose escalation options with the two stereotactic techniques and the impact of variable GTV-PTV margins.

### Material and Methods

The scans of 10 patients with central pelvic recurrence were used for comparison of techniques, delivering EBRT 45 Gy in 25 fractions to pelvis followed by a SBRT boost. Cumulative dose limits for bowel, bladder and rectum were developed using GEC-ESTRO guidelines. Cyberknife and VMAT SBRT plans were produced: initially 20 Gy in 5 fractions with GTV-PTV margins of 3mm, 5mm and 7mm. Plans were normalized for 95% coverage by prescription isodose and D<sub>max</sub> 125-140%. Dose was then escalated or de-escalated in 2.5 Gy increments until the OAR dose limits were exceeded. The highest dose level meeting OAR criteria was compared between techniques for each GTV-PTV margin, with assessment of boost dose and total cumulative dose including the phase one EBRT (EQD2-10).

### Results

With 20 Gy in 5 fractions and 5mm margin, mean GTV dose with Cyberknife was 23.0 Gy (total 72 Gy) and VMAT-SBRT 24.3 Gy (74.1 Gy). Conformity index was 1.1 vs 1.2 and dose drop off Cyberknife 5.0, VMAT 4.5. Using isotoxic planning to OAR tolerances, CK 3mm was 23.8 Gy (total 73.3 Gy), VMAT 3mm using equivalent prescription 25.7 Gy (76.5 Gy) and highest deliverable with VMAT 3mm 28.7 Gy (81.6 Gy). With 5mm margin, CK 21.6 Gy (69.8 Gy), VMAT 5mm equivalent dose 22.6 Gy (71.3 Gy) and highest deliverable 26.1 Gy (77.2 Gy), while a 7mm margin with VMAT is 24.0 Gy (73.6 Gy).

### Conclusion

SBRT can significantly increase total dose to GTV compared to conventional radiotherapy techniques. With an isotoxic approach VMAT-SBRT can deliver higher doses to GTV than Cyberknife, even when a larger GTV-PTV margin is used to allow for the lack of real time tracking.

We plan to proceed with a clinical trial to evaluate long-term outcomes.

### PV-0135 Short tangential arcs in VMAT based breast and chest wall radiotherapy planning

A. Munshi<sup>1</sup>, B. Sarkar<sup>1</sup>, S. Roy<sup>1</sup>, T. Ganesh<sup>1</sup>, B.K. Mohanti<sup>1</sup>

<sup>1</sup>Fortis Memorial Research institute, Radiation Oncology, Haryana, India

### Purpose or Objective

The study aimed to analyze partial tangential arc Volumetric Modulated Arc Therapy (VMAT) treatment planning and delivery, including analyzing the cardiac and contralateral breast doses resulting from this technique.

### Material and Methods

A total of 104 consecutively treated breast cancer (conservation as well as mastectomy) patients were taken for this dosimetric study. All patients were planned using partial arc volumetric modulated arc therapy (VMAT) in the Monaco treatment planning system (TPS) using two partial arc beams. All patients were divided into seven different categories: 1) All the patients in the study (OVERALL), 2) Left sided whole breast and chest wall patients (LWBCW), 3) Left chest wall patients (LCW), 4) Left whole breast patients (LWB), 5) Right sided whole breast and chest wall patients (RWBCW), 6) Right chest wall (RCW) patients, and 7) Right whole breast (RWB) patients. We evaluated each treatment plan for PTV coverage and doses to OARs. SPSSversion 16.0 software was used for statistical analysis.

### Results

There were 62 left sided and 42 right sided breast cancer patients in the overall analysis. The percentage of PTV volume receiving 95% of the prescription dose (PTV V95%, mean±SD) varied in the range of 91.2±5.2% to 94.8±2.1 with mean dose of 92.4±5.2% for all cases. The (mean ±SD) cardiac dose for all the patients was 289±23 cGy. The (mean±SD) cardiac doses were higher for left sided patients (424±33.8 cGy) as compared to right sided patients (123.9 ± 80 cGy) (p<0.001). Cardiac mean doses were higher with arc angles > 30 degrees versus 30 degrees (324.5±247.1 cGy versus 234.4±188.4 cGy) (p=0.001). Similarly contralateral breast mean dose was higher with arc angles > 30 degrees versus 30 degrees (126±115 cGy vs 88.6±76.1 cGy) (p =0.001). However cardiac V20Gy, V30Gy and V40Gy did not exhibit any statistical difference between the two groups (p= 0.26, 0.057 and 0.054 respectively).

### Conclusion

This is the first large study of its kind that assesses the dosimetric outcome of tangential partial arc VMAT treatments in a large group of mastectomy and breast conservation patients. Our study demonstrates the efficacy of this technique in dose coverage of PTV as well as in minimizing dose to OARs. Further, based on our results, we conclude that the arc length for the bi-tangential arcs should be 30° since it helps to achieve the most optimal balance between target coverage and acceptable OAR doses.

### PV-0136 Linear energy transfer in normal tissues in spot scanning proton therapy of prostate cancer

J. Pedersen<sup>1</sup>, J. BB Petersen<sup>1</sup>, C. H. Stokkevåg<sup>2</sup>, K. S. Ytre-Hauge<sup>3</sup>, O. Casares -Magaz<sup>1</sup>, N. Mendenhall<sup>4</sup>, L. P. Muren<sup>1</sup>

<sup>1</sup>Aarhus University Hospital, Department of Medical Physics, Aarhus C, Denmark

<sup>2</sup>Haukeland University Hospital, Department of Oncology and Medical Physics, Bergen, Norway

<sup>3</sup>University of Bergen, Department of Physics and Technology, Bergen, Norway

<sup>4</sup>University of Florida Proton Therapy Institute, Department of Radiation Oncology, Gainesville- FL, USA

### Purpose or Objective

Clinical treatment planning of proton therapy assumes that the *relative biological effectiveness* (RBE) of protons is uniformly 10% higher than photons. However, the energy deposition of protons is considerably different from photons resulting in an increased *linear energy transfer* (LET) at the distal end and laterally of the proton beam Bragg Peak. In addition, the distal end of proton beams is often located in or very close to normal tissues / organs at risk. This gives rise to concern of an increase in the biological effects of the normal tissues. We are currently initiating a normal tissue complication probability modelling project on outcomes following proton therapy of prostate cancer. As a first step, we have in this study investigated the dose-averaged LET<sub>d</sub> distributions in the normal tissues (rectum and bladder) for spot scanning proton therapy of prostate cancer using the two most common field arrangements for these patients.

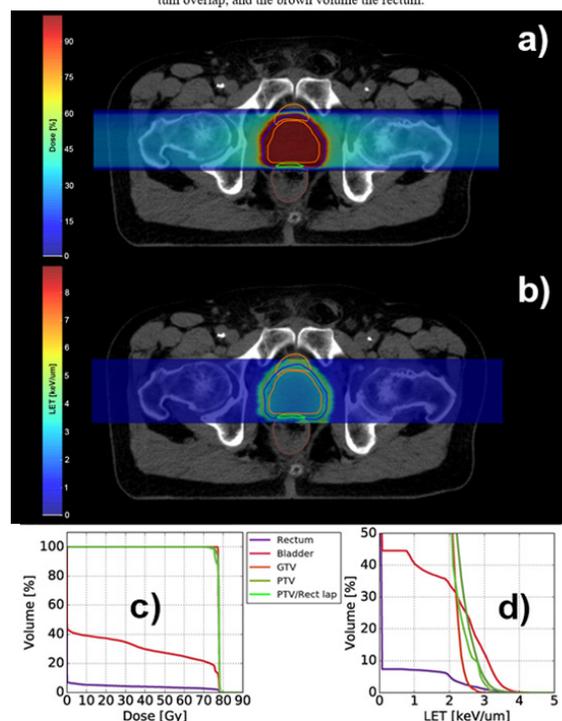

### Material and Methods

Spot scanning proton therapy plans (3 mm spot size with 1 mm spacing) were created in the treatment planning system PyTRiP on CT scans of seven prostate cancer patients (without rectal balloons or spacers). The CTV included the prostate gland, while CTV-to-PTV margins of 4 mm axially and 6 mm in the superior and inferior directions were used. The PTV was planned to receive a dose of 78 Gy (RBE). Treatment plans with two opposing lateral fields (90°/270°) and with two lateral oblique fields (70°/290°) were created for all cases. Dose and LET<sub>d</sub> distributions were calculated in PyTRiP for all plans and visualised as dose and LET<sub>d</sub> volume histograms (DVHs/LET<sub>d</sub>-VHs).

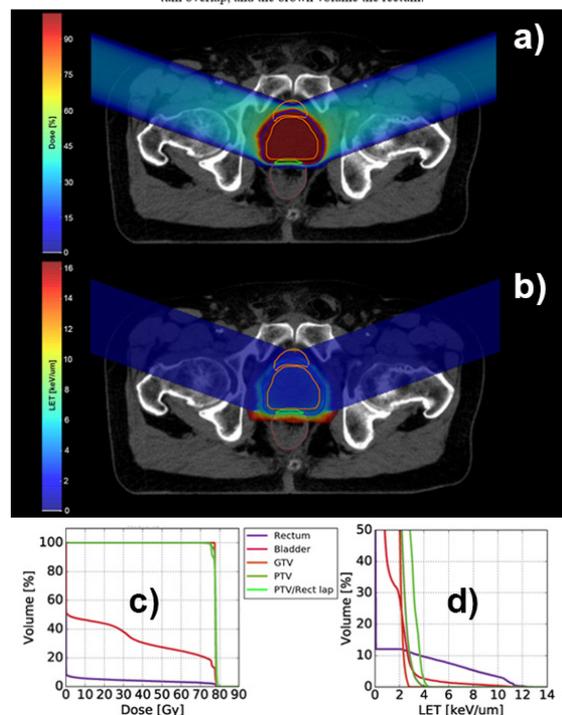

### Results

The LET<sub>d</sub> distribution patterns for both the lateral opposing and the lateral oblique fields were overall similar for the seven patients. For the two lateral opposing fields the median (range) of the mean LET<sub>d</sub> in the prostate was 2.1 keV/μm (2.0-2.2 keV/μm) while somewhat higher LET<sub>d</sub> was found in the high-dose areas outside of the prostate (Fig. 1). For the rectum, 6% (median; range 4-13%) of the volume had an LET<sub>d</sub> higher than the mean LET<sub>d</sub> in the prostate, compared to 27% (median; range: 8-36%) for the bladder. For the lateral oblique fields the mean LET<sub>d</sub> in the prostate was 2.1 keV/μm (2.0-2.1 keV/μm) while the LET<sub>d</sub> more than doubled compared to the plans with lateral opposing fields (Fig. 2). For the rectum, 15% (median; range 12-24%) of the volume had an LET<sub>d</sub> higher than the mean LET<sub>d</sub> in the prostate, compared to 23% (median; range: 2-35%) for the bladder.

**Figure 1:** Dose and LET<sub>d</sub> distributions and their dose- and LET<sub>d</sub> volume histograms for the same patient in the case of lateral opposing fields. a) Dose distribution, b) LET distribution, c) DVH curves, and d) LET<sub>d</sub>-VH curves. In a) and b) the small orange volume is the bladder, the large orange volume the GTV, the blue volume the PTV, the green volume the PTV/rectum overlap, and the brown volume the rectum.

**Figure 2:** Dose and LET<sub>d</sub> distributions and their dose- and LET<sub>d</sub> volume histograms for the same patient in the case of lateral oblique fields. a) Dose distribution, b) LET distribution, c) DVH curves, and d) LET<sub>d</sub>-VH curves. In a) and b) the small orange volume is the bladder, the large orange volume the GTV, the green volume the PTV/rectum overlap, and the brown volume the rectum.

### Conclusion

High LET<sub>d</sub> volumes outside the target were seen in both rectum and bladder when treating with spot scanning proton therapy. In particular, the rectum was subject to high LET<sub>d</sub> volumes when irradiated with lateral oblique fields compared to lateral opposed fields.

**PV-0137 Validation of fast motion-including dose reconstruction for proton scanning therapy in the liver**  
 E. Colvill<sup>1</sup>, J. Petersen<sup>1</sup>, M. Høyer<sup>1</sup>, E. Worm<sup>1</sup>, R. Hansen<sup>1</sup>, P. Poulsen<sup>1</sup>  
<sup>1</sup>Aarhus University Hospital, Radiation Oncology, Aarhus C, Denmark

#### Purpose or Objective

The large respiratory motion present during liver treatments means that the interplay effect could be of great concern for hypofractionated proton scanning therapy. A method has been developed to use recorded 3D motion to calculate the dose delivered to moving targets in scanning proton therapy using a commercial treatment planning system (TPS). In this study, we validate the method for the application in liver where tumor motion and other anatomical changes are large.

#### Material and Methods

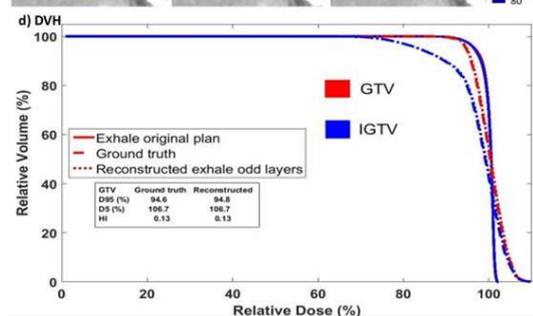

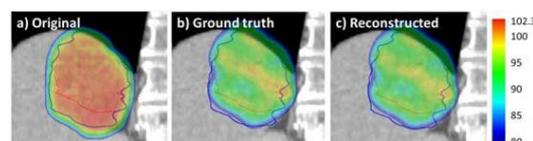

The fast dose reconstruction utilizes an in-house computer program to manipulate dicom plans exported from the TPS and incorporates the motion by shifting each proton spot to its position as seen in tumor's eye view. Depth motion and SSD variations are modeled by modifying the beam energy. The motion-included plans are imported and recalculated in the TPS in the original CT scan. To validate the accuracy of the dose reconstruction the 4DCTs of 13 liver patients treated with photon SBRT were used. For each patient, an IGTV was created from exhale and inhale GTVs. A plan was created on both inhale and exhale phases using three-field single-field-optimization with 6mm spot spacing and mean IGTV coverage of 56.25Gy in three fractions. Four dose reconstruction plans were created for each patient to represent potential interplay effects, two from each of the original inhale and exhale plans; One plan with all odd layers shifted to the opposite phase and one with all even layers shifted. These were imported and calculated on the original CT phase. Corresponding ground truth doses were created by splitting the original plans into sub-plans with odd and even layers, calculating one sub-plan in the original CT phase and the other in the opposite phase, and then summing the two dose maps. The reconstructed plans were compared to the ground truth plans to assess the accuracy of the fast dose reconstruction and the original to the ground truth plans to assess the magnitude of interplay effects. The comparisons included D5, D95 and the homogeneity index (HI=(D2-D98)/D50) for the GTV and the root-mean-square (RMS) dose errors for dose points above 70% and 90% cutoff levels.

#### Results

To date validation on two patients (8 plans) has been completed. Figure 1 shows the results for one plan. The mean and range of errors of the fast dose reconstruction GTV D5, D95 and RMS errors above 70% dose and above 90% dose are shown in Table 1 along with the interplay effect results for comparison. The mean and range of the HI for the original, ground truth and reconstructed plans were 0.07(0.05-0.08), 0.19(0.13-0.28) and 0.19 (0.13-0.28) respectively.

#### Conclusion

Validation of a method of fast dose reconstruction to assess the dosimetric impact of tumor motion on scanning proton therapy for liver SBRT treatments was performed. The results show that the dose reconstruction can utilize a single phase of a 4DCT with dose calculation errors that are much smaller than the dose distortion created by the interplay effect itself.

	Dose reconstruction errors [relative to ground truth] mean(range)	Interplay effect [ground truth vs original plan] mean(range)
<b>GTV</b>		
D5 (%)	-0.1(-0.9-0.4)	5.1(3.3-8.1)
D95 (%)	-0.6(-4.1-2.5)	-5.6(-10.25--1.99)
<b>RMS</b>		
Doses >70%	2.2(1.0-3.8)	12.5(10.7-14.3)
Doses >90%	1.6(0.8-2.6)	10.0(8.5-12.3)

**PV-0138 Pencil beam scanning treatments in free-breathing lung cancer patients - is 5 mm motion a limit?**

A. Jakobi<sup>1</sup>, R. Perrin<sup>2</sup>, A. Knopf<sup>2,3</sup>, C. Richter<sup>1,4,5,6</sup>

<sup>1</sup>OncoRay - Center for Radiation Research in Oncology, High Precision Radiotherapy, Dresden, Germany

<sup>3</sup>University of Groningen - University Medical Center Groningen, Department of Radiation Oncology, Groningen, The Netherlands

<sup>4</sup>German Cancer Consortium Dresden and German Cancer Research Center Heidelberg, DKTK, Dresden, Germany

<sup>5</sup>Faculty of Medicine and University Hospital Carl Gustav Carus - Technische Universität Dresden, Department of Radiation Oncology, Dresden, Germany

<sup>6</sup>Helmholtz-Zentrum Dresden - Rossendorf, Institute of Radiooncology, Dresden, Germany

#### Purpose or Objective

To evaluate the dose degradation when treating lung cancer patients with proton pencil beam scanning during free-breathing. We assess if treatments without rescanning are feasible in order to avoid prolonged treatment time, especially for slow scanning facilities.

#### Material and Methods

For 40 lung cancer patients, 4DCT imaging was used to generate 4D dynamic dose distributions of 3D treatment plans with 3 pencil beam scanning fields optimised with the single field uniform dose technique. Simulations included the use of random breathing states of the patient at start of irradiation resulting in multiple possible 4D dynamic dose distributions per fraction. Complete treatment was assumed to consist of 33 fractions of probabilistically chosen single fractions. Treatments were assumed to be delivered with an IBA universal nozzle without rescanning (1.5ms between spots, 2s between energy layers, spot sigma 4mm at highest energy). Tumour motion amplitude was the maximum displacement in tumour centre-of-mass assessed by the 4DCT. Evaluation was done by looking at under- and overdosage in the target structure. In addition, changes in the dose distribution due to changes in motion and anatomy during treatment were analysed using a repeated 4DCT for 4D dynamic dose calculation in one patient case.

## Results

Almost 50% of the patients had tumour motion amplitudes of less than 5mm. For these patients, the simulated dose degradation per fraction was much smaller than for patients with larger motion amplitudes, with 2% versus 12% average absolute reduction of the V95 ( $p < 0.01$ ), and an average increase in absolute V107 of 2% vs 9% ( $p < 0.01$ ). In no patient case studied was the minimum dose in the target degraded to below 80% of the prescribed dose, and rarely increased above 120%. Simulating a 33-fraction treatment, the mean reduction of the V95 was below 1% for patients with motion amplitudes below 5mm, while for patients with larger motion, V95 was degraded on average by 4% with worst case scenarios of 4% versus 19% ( $p < 0.01$ ), cf. Fig. 1. V107 had an average increase of about 0% and 1% (n.s.), with worst case values of 5% and 15%. The additional analysis of one patient case with a repeated CT revealed a large increase of tumour motion by about 5mm during treatment, resulting in a large dose degradation and partial miss of the target ( $V95 < 70\%$ ), cf. Fig. 2.

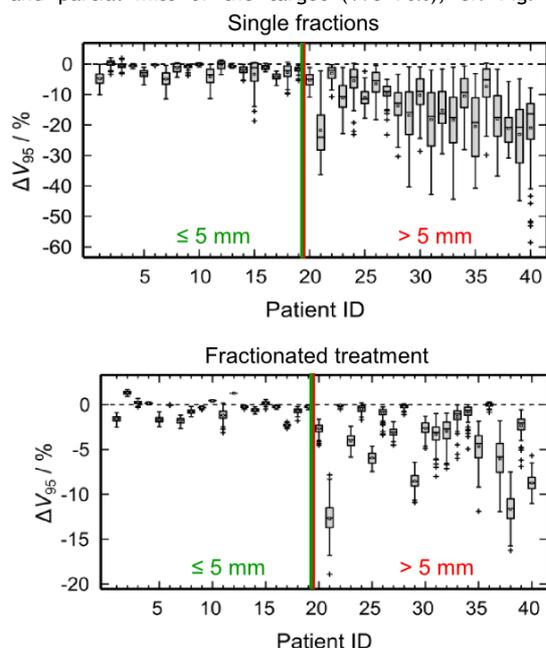

Figure 1: Dose degradation in terms of V<sub>95</sub> difference between the 4D dynamic dose distribution and the planned 3D dose.

Change in DVH of target due to tumour motion change

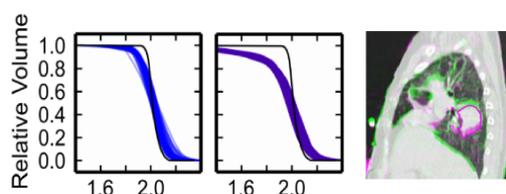

Figure 2: PTV DVH band change of 4D dynamic dose calculated with the original 4D-CT (left) and the sequential 4D-CT (middle) for the patient with a change in tumour motion by 5 mm (8.8 mm to 13.8 mm) as shown in overlay of exhalation position (right).

## Conclusion

Motion amplitude is an indicator of dose degradation caused by the interplay effect. Fractionation reduces the dose degradation to such an amount that rescanning might be unnecessary for patients with a small tumour motion less than 5mm. Patients with larger tumour motion should not be treated without any kind of motion mitigation technique (e.g. rescanning, gating or breath hold) to prevent tumour underdosage persisting through to the end

of fractionated treatment. Furthermore, the tumour motion needs to be assessed during treatment for all patients to quickly react to possible changes in motion which might require a treatment adaptation.

## Proffered Papers: Lung

### OC-0139 Induction of pulmonary hypertension may explain early mortality after thoracic radiotherapy

P. Van Luijk<sup>1</sup>, T.M. Gorter<sup>2</sup>, T.P. Willems<sup>3</sup>, R.P. Coppes<sup>1</sup>, J. Widder<sup>1</sup>, J.A. Langendijk<sup>1</sup>

<sup>1</sup>University Medical Center Groningen, Department of Radiation Oncology, Groningen, The Netherlands

<sup>2</sup>University Medical Center Groningen, Department of Cardiology, Groningen, The Netherlands

<sup>3</sup>University Medical Center Groningen, Department of Radiology, Groningen, The Netherlands

#### Purpose or Objective

Studies of primary or postoperative radiotherapy for thoracic tumours, such as for lung and oesophageal cancer) suggest increased early post-treatment mortality with escalated dose (e.g. RTOG0617, INT0123). This increase in mortality is largely unexplained and is not due to currently-recognized cardiac and pulmonary toxicities. We have previously shown in rats that thoracic irradiation can also lead to pulmonary hypertension (PH) secondary to endothelial cell loss and pulmonary vascular remodelling (1). PH is a progressive and lethal disease that might explain the early mortality after thoracic radiotherapy. However, since detection of PH requires specialized diagnostics, PH has not been assessed in RT patients so far. Therefore, the main objective of this first-in-human translational study was to test the hypothesis that thoracic radiotherapy can induce PH.

#### Material and Methods

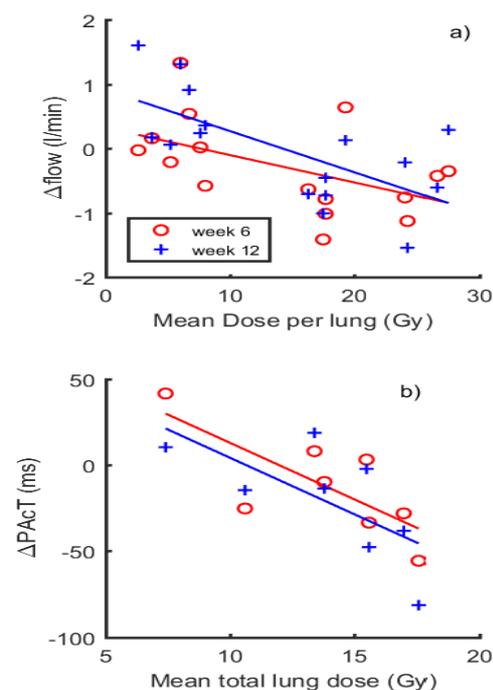

Patients with locally advanced NSCLC undergoing standard concurrent chemoradiotherapy (60 Gy in 5 weeks) were included in this prospective cohort study (clinicaltrials.gov; NCT02377934). Since PH typically decreases pulmonary arterial blood flow (PAF) and acceleration time (PACT), these were measured using cardiac MRI before and at 6 and 12 weeks after radiotherapy. To establish treatment dependence, changes in PAF and PACT were tested for correlation with mean dose to the lungs.

#### Results

PAF was reduced by 0.5-0.6 l/min in individual (left/right) lungs receiving >15 Gy. The reduction in PAF was significantly correlated with mean radiation dose to that lung ( $p=0.04$  and  $p<0.01$  at 6 and 12 weeks after radiotherapy, respectively). In addition, in patients receiving >15 Gy mean dose to their total lung volume, PACT was decreased by 30-40 ms, and this reduction in PACT again was correlated with dose ( $p=0.03$  and  $p=0.07$  at 6 weeks and 12 weeks after radiotherapy respectively). Both hemodynamic changes are strong indicators for PH. Therefore, these results indicate that PH occurs in patients treated with thoracic radiotherapy.

#### Conclusion

In line with our preclinical data we found that thoracic radiotherapy may induce pulmonary hypertension, which might in turn explain observed early mortality in patients treated with thoracic radiotherapy. Additional investigations are needed to characterise the incidence and clinical impact of radiotherapy-induced PH and to develop prevention and treatment strategies to ameliorate its consequences in terms of quality of life and survival of these patients.

#### OC-0140 Updating QUANTEC and clinically adjusted QUANTEC models for pneumonitis at external validation

A. Van Der Schaaf<sup>1</sup>, J. Lodeweges<sup>1</sup>, A. Niezink<sup>1</sup>, J. Langendijk<sup>1</sup>, J. Widder<sup>1</sup>

<sup>1</sup>UMCG University Medical Center Groningen, Radiation Oncology, Groningen, The Netherlands

#### Purpose or Objective

To externally validate and eventually recalibrate and update the original QUANTEC pneumonitis (QP) model (Marks et al, IJROBP 2010) and the QUANTEC model adjusted for clinical risk factors (AQP; Appelt et al, Acta Oncol 2014) in a cohort treated with 3D-CRT, IMRT, or VMAT, combined in 90% with chemotherapy.

#### Material and Methods

The external validation cohort was composed of n=220 patients with lung cancer (NSCLC, SCLC) stages (II-III) with complete dosimetric and prospectively scored pneumonitis data (G2 or higher), treated from 2013 to 2016 within the framework of a prospective data registration program (clinicaltrials.gov NCT02421718). Model performance was tested for discrimination (area under the curve, AUC), (pseudo-)explained variance (Nagelkerke's R<sup>2</sup>), and calibration (Hosmer-Lemeshow test, HL-test), before and after intercept and slope recalibration. Then, updating was performed by first refitting the coefficients from the AQP-model to our data, then stepwise manually removing unnecessary variables, followed by adding new potential variables. The procedure was then repeated automatically using Akaike and Bayes Information Criteria (AIC, BIC), respectively. Resulting models were in turn internally validated to correct AUC and R<sup>2</sup> for optimism using bootstrapping with backward elimination based on AIC.

#### Results

After recalibration of intercept and slope, the QP-model predicting pneumonitis based exclusively on mean lung dose (MLD) performed well (AUC=0.77; R<sup>2</sup>=0.21; HL-test: p=0.38), while without recalibration the model would not fit our data (HL-test: p<0.001). The AQP-model needed recalibration of the intercept only, but discriminated worse and explained less variance (AUC=0.72; R<sup>2</sup>=0.16)

compared with the recalibrated QP-model. This suggested the need to add different factors to improve discrimination. Using restrictive (BIC) analysis, the final model contained smoking status (current vs former&never) and MLD (AUC=0.78; R<sup>2</sup>=0.23). At less restrictive analysis (AIC), age, total-lung-volume, V5 and V30 of the heart, sequential chemotherapy, and MLD might be useful; in addition, MLD may be replaced by ipsilateral-lung V20 and total-lung V5. At internal validation, this latter model rendered AUC=0.80 and R<sup>2</sup>=0.28, however with much higher correction for optimism, implying potentially decreased generalizability to other cohorts.

#### Conclusion

Intending external validation, both the QP and the AQP-models needed recalibration (of slope and intercept, and of intercept only, respectively), which might be explained by employment of modern RT techniques and 90% administration of chemoradiotherapy in our cohort. A conservatively improved pneumonitis model employing modern chemoradiotherapy-techniques includes MLD and current-smoking status (Figure).

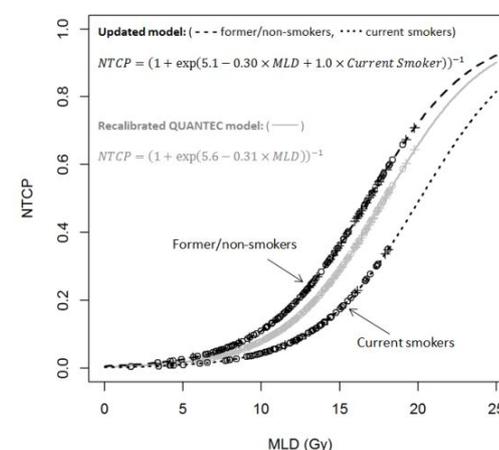

Figure: Recalibrated QUANTEC model (grey solid line) compared with the updated pneumonitis model (black lines, dashed=former/non-smokers, dotted=current smokers); NTCP=probability of pneumonitis (G2 or higher); MLD=mean lung dose (Gy); +/-o=patients with/without pneumonitis

#### OC-0141 Validation of dose-sensitive heart regions affecting survival in SABR lung cancer patients

A. McWilliam<sup>1</sup>, J. Kennedy<sup>2</sup>, C. Faivre-Finn<sup>1</sup>, M. Van Herk<sup>1</sup>

<sup>1</sup>The University of Manchester, Division of Molecular and Clinical Cancer Science- Faculty of Biology- Medicine and Health, Manchester, United Kingdom

<sup>2</sup>The Christie NHS Foundation Trust, Department of Informatics, Manchester, United Kingdom

#### Purpose or Objective

Recent advances in radiotherapy allow an increasing proportion of lung cancer patients to be treated with curative intent. However, evidence is emerging that dose to critical organs may be influencing patient survival. The authors recently presented their work identify a dose sensitive sub-region located in the base of the heart where excess dose resulted in worse patient survival (McWilliam IJROBP 96(2S):S48-S49). This work aims to determine whether the same effect was observed in patients treated with Stereotactic Ablative Radiotherapy (SABR), thereby validating our previous results.

#### Material and Methods

The previous work used 1101 non-small cell lung cancer patients treated with 55Gy in 20 fractions. Validation was performed in 89 SABR patients treated with 60Gy in 5 fractions. For both groups, CT scans and dose distributions

were deformable registered to a reference patient, focusing on the lungs with bone masked. Mean dose distributions were created for patients alive or dead at a set time-point, censored for follow-up. Dose differences were tested for significance with permutation testing.

The most significant area defined an anatomical region of interest and individual patient doses collected. A multivariate analysis investigated the importance of this region in patient survival, including tumour size. Cox-regression survival curves were plotted with patients split to those receiving less than or more than the same biologically equivalent dose that optimally split survival in the 20 fraction patients ( $\alpha/\beta = 2$ ).

### Results

For 20 fraction patients, from 6 months, a significant difference was seen in the dose difference between patients alive and dead ( $p < 0.001$ ). The most significant area was in the base of the heart near the origin of the coronary arteries, median dose of 16.3Gy (BED 10.3Gy). Multivariate analysis showed that tumour size was highly significant for patient survival ( $p < 0.001$ ) as was dose received by the anatomical region ( $p = 0.029$ ), HR 1.21 (1.02-1.44), highlighting the importance of dose received by this region. Cox-regression survival curves were plotted with patients split by those receiving more than or less than 8.5Gy, log-rank  $p < 0.001$ , figure 1A, controlled for tumour size ( $p < 0.001$ ) and age ( $p = 0.11$ ).

A cox-regression with the SABR patients split at 6.3Gy (translated BED from the 20 fraction patients) was plotted, figure 1B. A highly significant difference in survival (log-rank  $p = 0.016$ ) was seen where patients receiving more than 6.3Gy showed worse survival. Tumour size was not significant in the SABR group.

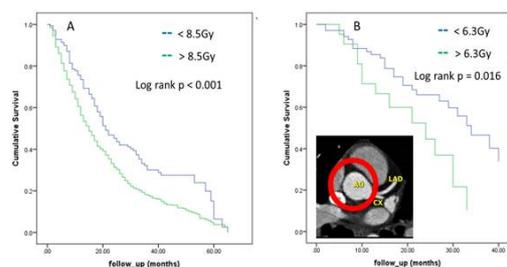

Figure 1. (A) Cox-regression for the 1101 20 fraction NSCLC patients receiving greater than or less than 8.5Gy to the identified base of the heart region.

Tumour size and patient age are included as continuous covariates, log-rank  $p < 0.001$ . (B) Validation cohort of 89 5 fraction SABR patients split on region dose greater than or less than 6.3Gy (BED 10.3Gy to match the 20 fraction patient dose). A log-rank of  $p = 0.016$  was calculated. The identified anatomical region in the base of the heart is included.

### Conclusion

Dose to a specific region in the base of the heart predicts for early death in lung cancer patients treated with 55Gy in 20 fractions, as well as for SABR patients treated to 60Gy in 5 fractions. The effect was seen for the same BED ( $a/b = 2$ Gy). In the future, we will extend the SABR group and initialise cardiac imaging studies to identify a clinical cause for this effect.

### OC-0142 Incidental dose to cardiac subvolumes does not improve prediction of radiation pneumonitis in NSCLC

R. Wijsman<sup>1</sup>, F. Dankers<sup>1</sup>, E. Troost<sup>2</sup>, A. Hoffmann<sup>2</sup>, J. Bussink<sup>1</sup>

<sup>1</sup>Radboud University Medical Center, Radiation oncology, Nijmegen, The Netherlands

<sup>2</sup>Institute of radiooncology, Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany

### Purpose or Objective

Conflicting results have been reported for the combined effect of heart and lung irradiation on the development of radiation pneumonitis (RP). The reported studies based on 3D-conformal radiotherapy considered the whole heart as an organ-at-risk, thereby not distinguishing between dose to the cardiac ventricles and atria. We assessed whether inclusion of incidental dose to these cardiac subvolumes improved the prediction of Grade  $\geq 3$  RP.

### Material and Methods

We retrospectively assessed 188 consecutive patients with stage III non-small cell lung cancer (NSCLC) having undergone (chemo-)radiotherapy ( $\geq 60$  Gy) using intensity-modulated radiation therapy (until 2011) or volumetric-modulated arc therapy (starting in 2011). Most patients ( $n = 182$ ) received 66 Gy in 33 (once-daily) fractions to the primary tumour and involved hilar/mediastinal lymph nodes based on FDG-PET/CT. The lungs and heart (ventricles and atria separately in 156 patients that received a contrast enhanced planning CT) were re-contoured to generate accurate dose-volume histogram (DVH) data. RP was assessed using the Radiation Therapy Oncology Group scoring criteria for pulmonary toxicity. Since high multicollinearity was observed between the DVH parameters, those with the highest Spearman correlation coefficient ( $R_s$ ) were selected for the modelling procedure. Using a bootstrap approach, clinical parameters [age, gender, performance, smoking status, forced expiratory volume in 1 second, and cardiac comorbidity (i.e., medical history of myocardial infarction, heart failure, valvular heart disease, cardiac arrhythmias and/or hypertension)] and DVH parameters of lungs and heart (assessing atria and ventricles separately and combined) were evaluated for RP prediction.

### Results

Twenty-six patients (13.8%) developed RP (median follow-up 18.4 months). Only the median lung dose (MLD) differed between groups (15.3 Gy vs 13.7 Gy for the RP and non-RP group, respectively;  $p = 0.004$ ). Most  $R_s$  of the lung DVH parameters exceeded those of the heart DVH parameters and only some lung DVH parameters were significantly correlated with RP [See Figure 1; highest  $R_s$  for MLD (0.21;  $p < 0.01$ )]. Only cardiac comorbidity was borderline associated with RP ( $p = 0.066$ ) on univariate logistic regression analysis. After bootstrap modelling, heart DVH parameters were seldom included in the model predicting Grade  $\geq 3$  RP. The optimal model consisted of: MLD (Odds ratio (OR) 1.28 per Gy increase;  $p = 0.03$ ) and cardiac comorbidity (OR 2.45 in case of cardiac comorbidity;  $p = 0.04$ ). The area under the receiver operator characteristic curve was 0.71, with good calibration of the model.

Figure 1 Correlation between the dose-volume histogram parameters and radiation pneumonitis.

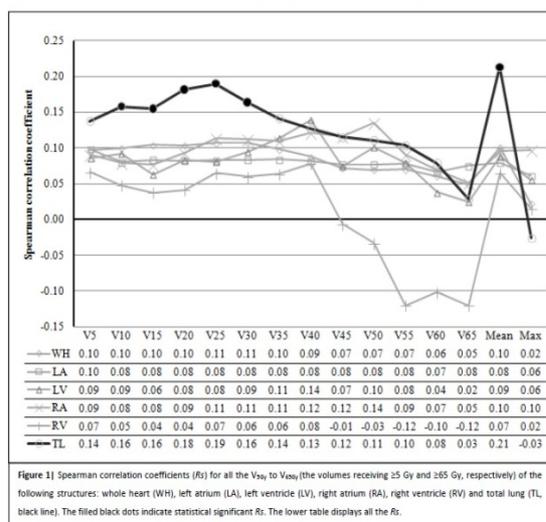

Figure 1) Spearman correlation coefficients (Rs) for all the V50 to V90 (the volumes receiving 25 Gy and &gt;=65 Gy, respectively) of the following structures: whole heart (WH), left atrium (LA), left ventricle (LV), right atrium (RA), right ventricle (RV) and total lung (TL, black line). The filled black dots indicate statistical significant Rs. The lower table displays all the Rs.

### Conclusion

Incidental dose to the cardiac atria and ventricles did not improve RP risk prediction in our cohort of stage III NSCLC patients as the DVH parameters for lung outperformed those for the heart. The multivariable model containing the variables cardiac comorbidity and MLD is the optimal model for RP prediction in this cohort.

### OC-0143 Adaptive radiotherapy reduces pneumonitis without increasing the risk of failure in lung cancer

A.A. Khalil<sup>1</sup>, M.M. Knap<sup>1</sup>, M.T. Petersen<sup>1</sup>, M. Kandi<sup>1</sup>, H.H. Schmidt<sup>1</sup>, D.S. Møller<sup>2</sup>, L. Hoffman<sup>2</sup>

<sup>1</sup>Aarhus University Hospital, Department of Oncology, Aarhus C, Denmark

<sup>2</sup>Aarhus University Hospital, Department of Medical Physics, Aarhus C, Denmark

### Purpose or Objective

Radiation pneumonitis (RP) remains the most significant dose-limiting factor in lung radiotherapy (RT). Sparing the volume of the irradiated lung has always been an aim of oncologist but this was hindered by the fear of increasing the local and regional failures. In April 2013 an adaptive strategy with daily online tumour match was introduced in locally advanced lung cancer patients (pts) treated with curative intended RT. The aim of this study was to evaluate the impact of introducing the adaptive strategy on RP as well as on the incidence of failure.

### Material and Methods

Hundred and eight consecutive lung cancer pts receiving RT with an adaptive strategy (ART) using smaller planning target volume (PTV) margins were analysed. A matching control group of 102 consecutive pts (noART) treated prior to April 2013 with bone match and larger margins were analysed. The normal tissue constraints were similar in both groups. RP was scored using CTCAE 4.03. Pts were followed up with CT-scans every third month in both groups and failures were proven histologically. Data analysed included patient and tumour characteristics, chemotherapy given as well as radiation dose. All time analysis was calculated from the RT start date. Kaplan Meier survival analysis was used to estimate the RP and recurrence risk and groups were compared using chi square test. All statistical tests were 2 sided and p<0.05 was considered significant.

### Results

Median follow-up time was 20 months (range 2-56). The gross tumour volume (GTV) was not different between the groups (p=0.8). The PTV was significantly smaller in the ART group as compared to the noART group (p <0.0001). That was accompanied by a significant reduction in mean

lung dose (MLD) from a mean of 13.8 Gy in noART group to 12.4 Gy in ART (p=0.004). The heart dose was not significantly different between the groups (Table 1). Recurrence at tumour site was 32% and 36% in ART and noART, respectively. The incidence of loco-regional failure was 45% in the adaptive group (ART) and 48% in the control group (noART). Median progression free survival time for the ART-group was 16 months (95%-CI: 13-20), and 19 months (95%-CI: 5-32) for the noART group. The pneumonitis (grade 2 or more) decreased significantly from 50% in the noART group to 33% in the ART group (p=0.001).

		noART (n=102)	ART (n=108)
GTV, cm <sup>3</sup>	Range	2-583	12-369
	Mean (SE)	94 (10)	98 (12)
PTV, cm <sup>3</sup>	Range	84-1398	89-1321
	Mean (SE)	509 (28)	400 (34)
MLD, Gy	Range	1.9-20	3.3-19
	Mean (SE)	13.8 (0.4)	12.6 (0.6)
MHD, Gy	Range	0.1-32	0-33
	Mean (SE)	9 (0.8)	8 (1.1)

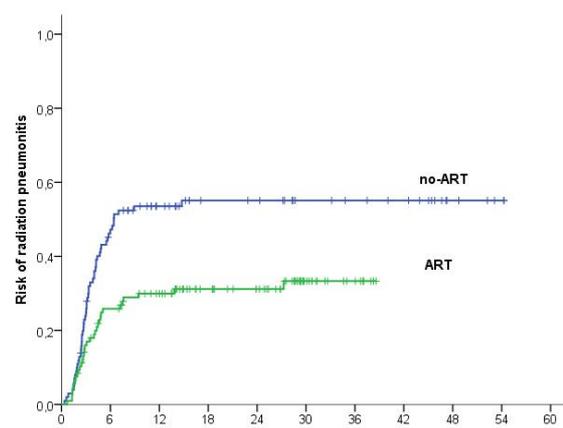

Figure 1. Kaplan-Meier analysis of risk of radiation pneumonitis according to ART (green line) and no-ART (blue line). Time in months from radiotherapy start

### Conclusion

Implementation of an adaptive strategy and daily tumour match for advanced lung cancer patients significantly decreases the pneumonitis incidence without affecting the loco-regional control rate.

### OC-0144 Dosimetric analysis of randomized lung proton and photon plans with respect to radiation toxicity

T. Deist<sup>1</sup>, P. Yang<sup>2</sup>, C. Oberije<sup>1</sup>, P. Allen<sup>2</sup>, Y. Luo<sup>2</sup>, Y. Van Wijk<sup>1</sup>, D. Gomez<sup>2</sup>, T. Xu<sup>2</sup>, S. Tucker<sup>3</sup>, R. Mohan<sup>4</sup>, S. Hahn<sup>2</sup>, P. Lambin<sup>1</sup>, Z. Liao<sup>2</sup>

<sup>1</sup>MAASTRO Clinic, Department of Radiotherapy, Maastricht, The Netherlands

<sup>2</sup>The University of Texas MD Anderson Cancer Center, Department of Radiation Oncology, Houston, USA

<sup>3</sup>The University of Texas MD Anderson Cancer Center, Department of Bioinformatics and Computational Biology, Houston, USA

<sup>4</sup>The University of Texas MD Anderson Cancer Center, Department of Radiation Physics, Houston, USA

### Purpose or Objective

Results from a Bayesian-randomized trial on intensity modulated radiotherapy (IMRT) vs. passively scattered 3D proton therapy (3DPT) show no significant difference in protocol failure (i.e., either grade $\geq$ 3 radiation pneumonitis (RP) or local recurrence within 12 months). We intend to analyze the differences in dose distribution between modalities, relations between dosimetric parameters and radiation-induced toxicities. The objective is to identify dosimetric constraints that would limit normal tissue complications in future trials.

### Material and Methods

We analyzed 149 (57 3DPT, 92 IMRT) randomized trial patients. DVH parameters for 3DPT and IMRT treatment plans were compared for lung, esophagus, and heart. To measure the predictive value of high- and low-dose parameters for toxicity in lungs and esophagus, we fitted V5 and V50Gy to RP and grade $\geq$ 3 radiation esophagitis (RE). Heart dose data was missing for 5 IMRT patients.

### Results

RP and RE are not significantly different between modalities ( $p > 0.1$ , two-tailed Wilcoxon rank-sum test).

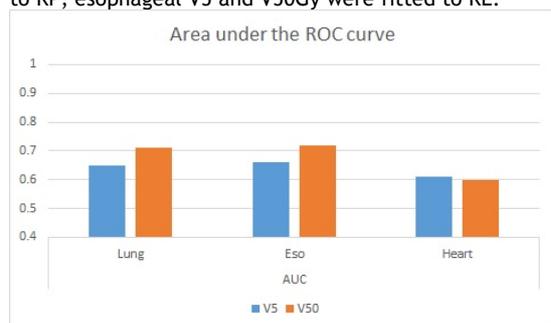

The difference between mean doses planned for IMRT and 3DPT plans was tested: Lung V5, V50, V60, V70Gy (in %), esophageal V5Gy, and heart V5, V10Gy are significantly different ( $p < 0.005$ , two-tailed Wilcoxon rank-sum test). The significant esophageal and heart dose parameters are smaller for 3DPT, lung V5Gy is smaller, while lung V50, V60, V70Gy are larger.

3DPT plan V5 and V50Gy are computed for each OAR and compared to the respective median values of IMRT plans. The percentage of 3DPT plans with V5Gy below or equal to the IMRT median and V50Gy above the IMRT median are reported:

	<=V5Gy IMRT Median	>V50Gy IMRT Median
3DPT Lung	0.93	0.68
Esophagus	0.67	0.49
Heart	0.93	0.54

3DPT plans yield smaller low dose regions in all three OARs. However, 3DPT yields larger high dose regions in the lungs.

To assess the relationship between low/high dose regions and toxicity, V5 and V50Gy of lung and heart were fitted to RP, esophageal V5 and V50Gy were fitted to RE:

There appears to be a stronger relationship between toxicity and high dose regions in the affected OAR. Heart doses have a weaker relationship with RP.

### Conclusion

Tucker et al. (2013) showed that high dose regions in lung tissue in lung IMRT have a pronounced effect on toxicity. This is also observable in this trial cohort of IMRT and 3DPT patients. In order to reduce toxicities, high dose regions in normal tissues need to be reduced. 3DPT reduces low dose regions significantly in all three OARs but high dose regions are significantly higher in the lungs. Future investigations should focus on stricter high dose constraints for 3DPT plans. If such constraints are not achievable due to penumbral and scattering characteristics of protons and the usage of passive scattering techniques, intensity modulated proton therapy should be considered.

### Joint Symposium: ESTRO-JASTRO: Oligometastatic disease

#### SP-0145 Biological rationale and clinical evidence

P. Ost<sup>1</sup>

<sup>1</sup>University Hospital Ghent, Gent, Belgium

In 1995, Hellman and Weichselbaum hypothesized that the number and location of the metastases are an important prognostic factor reflecting the metastatic phenotype and hence prognosis of the cancer patient. They suggested this based on the historical observation that some metastatic patients have a durable survival in case their limited metastases are surgically removed. For these cases, they proposed the term oligometastases, suggesting that eradicating oligometastases with metastasis-directed therapy (MDT) would have the potential to improve survival. This hypothesis would shift the paradigm for oligometastatic patients from a palliative to a potentially curable disease. Recent data in several solid tumors support the notion that patients with oligometastatic disease have a more favorable prognosis as compared to their counterparts and that these different phenotypes probably require a different therapeutic approach. Clinical data indicate that the number of patients with oligometastatic disease receiving aggressive treatment is increasing rapidly. We will discuss the key evidence supporting or refuting the existence of an oligometastatic state.

#### SP-0146 Oligometastatic disease: Radiophysics implementation and pitfalls

D. Verellen<sup>1</sup>

<sup>1</sup>GZA- Ziekenhuizen - St. Augustinus Iridium  
Kankernetwerk Antwerpen, Radiotherapy, Wilrijk, Belgium

As clinical evidence in favor of SBRT for treatment of oligometastatic disease increases, SBRT proves to be a safe and effective treatment modality to achieve local control and delay progression, which in turn also postpones the need for further treatment. Basically SBRT refers to a high-dose-per-fraction-high-precision technique and the mainstream adaptation of SBRT is the result of combined developments in image guided motion management, treatment planning and delivery. This presentation will cover some of the main issues related to clinical implementation of SBRT and quality assurance. A critical overview will be provided comparing dedicated equipment against mainstream technology. The different treatment modalities will be benchmarked allowing to assess an appropriate balance between technological needs and patient compliance. As the efficacy of SBRT in the management of the oligometastatic state increases, the need for treatment of multiple metastases and re-irradiation requires extra attention. In this presentation, some of the issues related to dose accumulation for this particularly challenging situation will also be highlighted.

#### SP-0147 Interpretation and management of oligometastases

H. Onishi<sup>1</sup>

<sup>1</sup>Yamanashi University, Department of Radiology, Chuo, Japan

All of cancer state with metastases is judged as stage IV even if the number of metastases is only one. However, it has been known that some of patients with a limited number of metastatic lesions regions have a good prognosis by a locally radical therapy combined with systemic chemotherapy, and the disease state was named "oligometastases" by Hellman in 1995. In addition, a limited disease state of oligometastases with primary

lesion controlled was named “oligorecurrence” in Japan, and it is considered to have a better survival than “oligometastases with uncontrolled primary site” (synchronous oligometastases, named by Niibe). There are aggressive cancer cells in the primary lesion from the initial state of synchronous oligometastases, so its prognosis is generally poor. In the oligorecurrence state, cancer cells are seeded in the metastatic site at the control of primary lesion, and Interleukin has been reported to play a key role in progression of micrometastases.

Locally radical therapy for oligometastases includes surgical resection, radiofrequency ablation, or radiotherapy, and in particular, stereotactic body radiation therapy (SBRT) is remarked as a promising treatment modality for oligometastases, accompanying not only a high local control rate with a mild toxicity, but also possibility of abscopal effect. In the NCCN guideline for non-small cell lung cancer, it is described that definitive radiotherapy to oligometastases, particularly SBRT, is an appropriate option in such cases if it can be delivered safely to the involved sites.

Longer survival would be expected in cases of indolent oligometastatic states such as limited number of metastases and destination organs, metastases to parallel organ, and metachronous or late-onset timing. Though some studies showed good clinical effectiveness of SBRT for patients with oligometastases, further prospective studies are mandatory to address the significance of SBRT for oligometastases and true prognostic factors, and a desirable treatment method according to each kind of primary cancer sites. Recently, drugs for immune checkpoint inhibitor appeared and are expected to have a synergistic effect with radiotherapy to each other, in particular SBRT or particle therapy. Many prospective studies of combined therapy with SBRT and immune checkpoint inhibitors for metastatic disease were just started, but there remains a big problem of high expensive cost of immune checkpoint inhibitors.

In this presentation, interpretation and management of oligometastases will be reviewed in order to evaluate and develop the significance of radiotherapy for oligometastases.

#### SP-0148 SBRT for oligometastases

T. Kimura<sup>1</sup>, Y. Nagata<sup>1</sup>

<sup>1</sup>Hiroshima University, Department of Radiation Oncology, Hiroshima, Japan

Stereotactic body radiotherapy (SBRT) is commonly used to treat patients with extracranial oligometastases in clinical settings. In addition, the “abscopal effect”, which is radiotherapy-induced immune-mediated tumor regression at sites distant to the irradiated field, and treatment with a combination of SBRT and immune checkpoint inhibitors have attracted attentions of researchers. According to an international survey of more than 1000 radiation oncologists reported by Lewis SL et al. [1], 61% of responders have been using SBRT for extracranial oligometastases, and the most commonly treated organs were the lung (90%), liver (75%) and spine (70%). Many authors have suggested that surgery for extracranial oligometastases might improve local control and overall survival. With the recent technical developments in SBRT, SBRT is also a promising modality for achieving a high rate of local control with minimal invasiveness. In this lecture, we would like to review the treatment results of SBRT for extracranial oligometastases, such as those located in the lung, liver and spine and discuss comparisons between surgery and SBRT, and cost-effectiveness.

1) SBRT for extracranial oligometastases, such as those located in the lung, liver and spine.

1. Lung Colorectal cancer (CRC) often presents with oligometastases, commonly in the lung and liver, and CRC

has a high risk of local failure [2]. The accepted selection criteria include a good performance status (PS), absence of extra-pulmonary disease, control of the primary tumor, 1-5 synchronous or metachronous metastases and adequate respiratory function [3, 4]. Several authors have reported that the 2-year local control rate ranges 49- 96%. The optimal dose is recommended at least 48 Gy in three fractions to achieve greater than 90% 2-year control.

2. Liver The best candidates are patients with a good PS, controlled or absent extra-hepatic disease,  $\leq 3$  hepatic lesions, size lesions  $\leq 3$  cm, lesion distance from organs at risk  $> 8$  mm, good liver function (Childs A) and a healthy liver [5]. Several authors have reported that the 2-year local control rate ranged from 79- 92%. The optimal dose is recommended 48- 60 Gy in three fractions for lesions with a diameter  $\leq 3$  cm, while for lesions with a diameter  $> 3$  cm a higher prescription dose, such as 60- 75 Gy is necessary to obtain similar local control [5].

3. Spine The goal of spinal SBRT is local control and pain control. Several authors have reported that the 1-year local control rate ranges 80- 98% and provides pain relief. Therefore, several dose/fractionation schedules, such as 24 Gy in 1 fraction or 27 or 30 Gy in 3 fractions have been used and the optimal dose/fraction schedule is still unclear.

2) Comparison between surgery and SBRT for extracranial oligometastases

According to several guidelines, surgery for extracranial oligometastases is still standard practice because of lack of evidence that SBRT has clinical advantages.

A retrospective analysis comparing surgery with SBRT for 110 patients with pulmonary oligometastases demonstrated that 3-years overall survival rates were 62% for surgery and 60% for SBRT ( $p = 0.43$ ) [6]. The authors concluded survival after surgery was not better than after SBRT although SBRT should be the second choice after surgery. However, no randomized trials have been conducted, and prospective randomized studies are required to define the effectiveness of each modality.

3) Cost-effectiveness

Extracranial oligometastases have been usually managed with systemic therapy with or without surgery. However, systemic therapy, including molecular targeted drugs, is expensive. A cost-effectiveness analysis using a Markov modelling approach demonstrated that video-assisted thoracic surgery wedge resection or SBRT could be cost-effective in selected patients with pulmonary oligometastases [7]. Increases in medical expenses are a social problem worldwide, but it can be said that SBRT is a promising modality in this aspect.

#### OC-0149 Lateral response heterogeneity of Bragg peak ion chambers for narrow-beam photon & proton dosimetry

P. Kuess<sup>1</sup>, T. Böhlen<sup>2</sup>, W. Lechner<sup>1</sup>, A. Elia<sup>2</sup>, D. Georg<sup>1</sup>, H. Palmans<sup>2</sup>

<sup>1</sup>Medizinische Universität Wien Medical University of Vienna, Department of Radiation Oncology and Christian Doppler Laboratory for Medical Radiation Research for Radiation Oncology, Vienna, Austria

<sup>2</sup>EBG MedAustron GmbH, Medical Physics, Wiener Neustadt, Austria

### Purpose or Objective

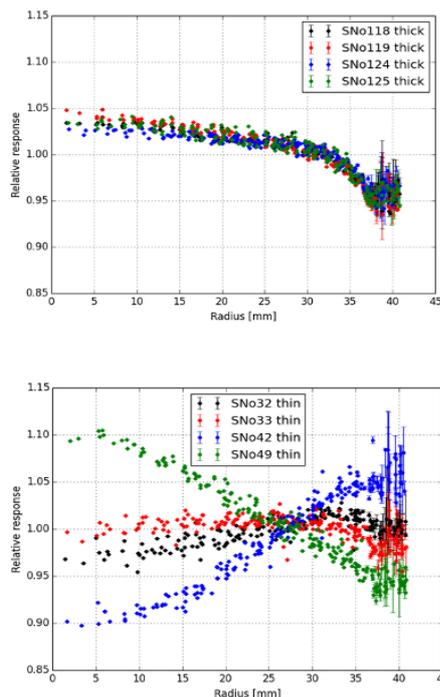

A large area ionization chamber (LAIC) can be used to measure output factors of narrow beams. In principle, dose area product measurements are an alternative to central-axis point dose measurements. Using an LAIC requires detailed information on the uniformity of the signal response across its sensitive area.

### Material and Methods

8 LAICs (sensitive area with nominal diameter of 81.6mm) were investigated in this study, 4 of type PTW-34070 (LAIC<sub>Thick</sub>) and 4 of type PTW-34080 (LAIC<sub>Thin</sub>) with water-equivalent entrance window thicknesses of 4mm and 0.7mm, respectively. Measurements were performed in an X-ray unit (YXLON) using peak voltages of 100-200kVp and a collimated beam of 3.1mm FWHM. The LAICs were mounted on the moving mechanism of an MP3-P (PTW) and moved with a step size of 5mm to measure the chamber's response at lateral positions. To account for beam positions where only a fraction of the beam overlapped with the sensitive area of the LAIC, a corrected response was calculated as the basis for determining relative response as a function of radial distance from the centre. The impact of a heterogeneous LAIC response, based on the obtained response maps was henceforth investigated for small field photon beams (as small as 6x6mm<sup>2</sup>) and proton pencil beams (FWHM=8mm).

### Results

A pronounced heterogeneity of the spatial responses was observed in both the thick and thin window LAICs. These heterogeneities could be calculated as a function of the radial coordinate as there was no pronounced angular dependency. All 4 LAIC<sub>Thick</sub> followed a monotonously increasing response towards the chamber centre, while the absolute response values varied up to 1.5%, excluding the 2mm borders of the LAICs. In contrast the LAIC<sub>Thin</sub> trends were not uniform and responses varied by up to 10% (Fig 1). Investigating absolute dosimetry for a proton pencil beam the signal varies with a systematic offset between 2.4% and 4.1% for LAIC<sub>Thick</sub> and between -9.5% and 9.4% for LAIC<sub>Thin</sub>. For relative dosimetry (e.g. depth-dose profiles) the increase of beam size with increasing depth was investigated as the influencing factor. Systematic response variation by 0.4% and 1% at the most were found for the investigated LAICs. The systematic offset for absolute dose measurements for decreasing photon field size showed that for 6x6mm<sup>2</sup> field sizes the response was systematically 2.5-4.5% higher for LAIC<sub>Thick</sub>. For LAIC<sub>Thin</sub> the response varies even over a range of 20%. The entrance window thickness was evaluated to be constant within measurement uncertainty by performing measurement at multiple peak voltages.

**Figure 1: Chamber responses for the four thick (top) and the four thin (bottom) investigated LAICs as a function of the radius. Error bars for the corrected responses were obtained by evaluating the response for varied sensitive chamber radius ( $\pm 0.1\text{mm}$ ) and varied beam size ( $\pm 10\%$ ) and indicate uncertainties.**

### Conclusion

This study highlights the need for chamber-depended response maps when using LAICs for absolute and relative dosimetry with proton pencil beams or small photon beams.

**OC-0150 Dual-energy CT-based proton treatment planning to assess patient-specific range uncertainties**

<sup>6</sup>German Cancer Consortiumion DKTK, Dresden, Germany

### Purpose or Objective

To reduce range uncertainties in particle therapy arising from a generic heuristic conversion (HLUT) of CT numbers in stopping-power ratios (SPRs), an accurate patient-specific SPR prediction is desirable. Treatment planning based on dual-energy CT (DECT) can account for tissue diversity and potentially contribute to shrink clinical safety margins. Consequently, in this study dose distributions derived from both a clinical HLUT and a patient-specific DECT-based SPR prediction are compared

and range deviations are quantified for two different treatment sites.

#### Material and Methods

Based on a database of more than 1000 clinical DECT scans acquired with a single-source DECT scanner (Siemens Somatom Definition AS), 10 prostate cancer and 54 head tumor patients were selected to assess intra- and interpatient tissue diversity and its impact on SPR prediction. To evaluate age- and sex-dependent variability, the head tumor cohort was divided in children, women and men. DECT scans were converted in 79 keV pseudo-monoenergetic CT scans (MonoCTs) and SPR datasets derived by voxelwise calculations of electron density and effective atomic number using syngo.via (Siemens Healthineers). In XiO (Elekta) clinical proton treatment plans were recalculated (a) on MonoCTs using the clinical HLUT and (b) on SPR datasets to quantify range and dose differences.

#### Results

The voxelwise correlation of SPR and CT number is similar for men and women, but differs considerably between adults and children in bony tissue, likely due to the amount of calcium embedded in bones, which increases with age. Based on voxelwise SPR comparisons, the clinical HLUT predicts on average ( $2.2 \pm 0.6$ ) % larger SPRs for head tumor patients and ( $1.7 \pm 0.3$ ) % larger SPRs for prostate cases. The impact of both approaches on dose distributions is shown in Fig. 1 and 2 for an exemplary head tumor and prostate cancer patient. In the head case, the HLUT predicts a 1.7 % shorter range (2.4 mm) resulting from a 0.7 mm range underestimation in water-filled ventricles (not precisely predicted by the HLUT) and different SPR predictions for brain. A range deviation of up to 3.0 % (7.1 mm) is obtained in the prostate case, which is mainly caused by different SPR predictions for bone marrow and muscle. These range differences in single beams are not compensated in the overall treatment plan.

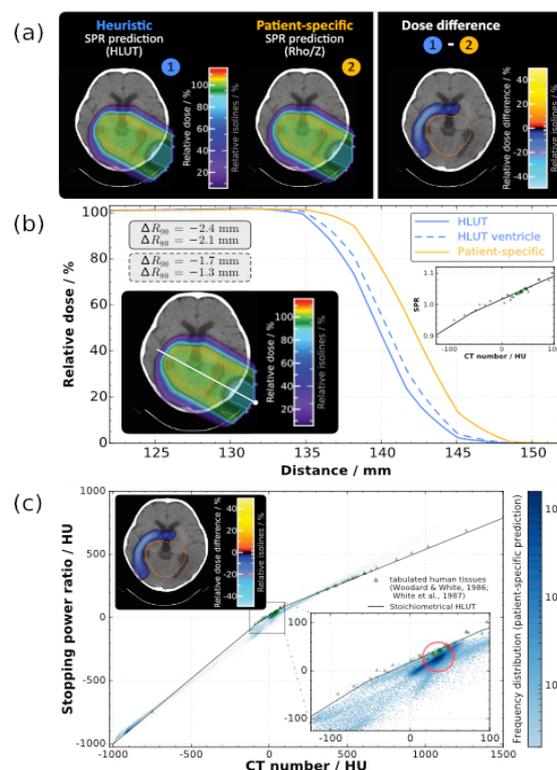

Figure 1: Dose distributions of a patient with ependyoma calculated using a HLUT-based and a patient-specific SPR prediction (a). Dose deviations up to 40% at the distal fall-off correspond to range differences of 2.4 mm (1.7 % of range). Water-filled ventricles lead to a range underestimation of 0.7 mm using a HLUT (b). The remaining range deviation is caused by different SPR predictions for brain tissue (c, red circle).

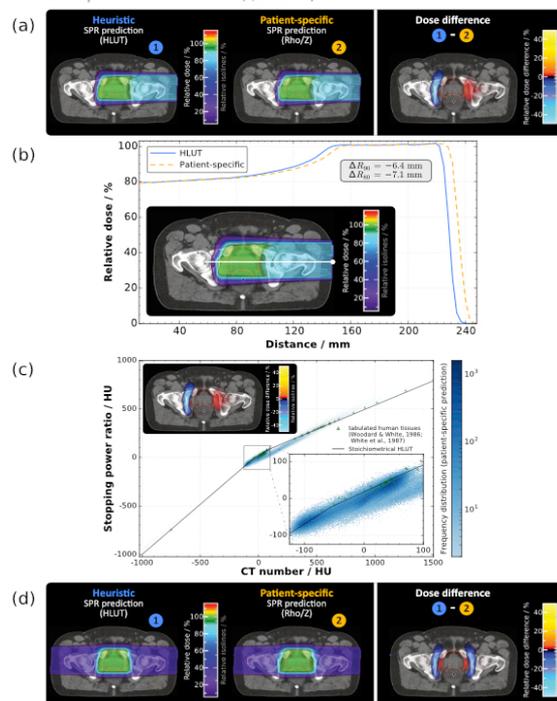

Figure 2: Dose distributions of a patient with prostate cancer calculated using a HLUT-based and a patient-specific SPR prediction for a single beam (a) and the overall treatment (b). Dose deviations at the distal fall-off (b) correspond to range differences up to 7 mm (3.0 % of range) resulting in a small dose reduction in the target volume. The range deviation is especially caused by different SPR predictions for bone marrow and muscles (c).

#### Conclusion

In contrast to a generic HLUT, a DECT-based SPR prediction can individually consider age- and sex-dependent tissue variability in proton treatment planning. This diversity information can also provide suggestions for subgroup-specific improvements of the heuristic CT calibration. The assessment of relative SPR and dose

differences underlines the clinical potential of DECT, which now needs to be confirmed against a ground truth. Further investigations of patients' DECT scans enable comprehensive SPR evaluations to quantify CT-related range uncertainties and to assess clinical safety margins.

#### OC-0151 Experimental assessment of relative stopping power prediction by single energy and dual energy CT

<sup>3</sup>University of Groningen- University Medical Center Groningen - Center for Medical Imaging North-East Netherlands CMI-NEN, Radiology, Groningen, The Netherlands

<sup>4</sup>University of Groningen- University Medical Center Groningen, Radiology, Groningen, The Netherlands

#### Purpose or Objective

To assess the accuracy of the single energy CT (SECT) stoichiometric calibration method and a new proposed dual energy CT (DECT) method for relative proton stopping power (RSP) calculation in proton therapy treatment planning.

#### Material and Methods

The accuracy of both methods has been assessed based on CT and proton stopping power measurements of 32 materials with known composition and density and of 17 bovine tissues. With CT, the 32 materials have been measured in a 33 cm diameter Gammex 467 tissue characterization phantom and the bovine tissues in a 30 cm diameter water phantom. The CT data has been acquired on a dual source CT system (SOMATOM Force) at 120 kV and 90 kV/150 kV Sn for SECT and DECT, respectively. The data has been reconstructed with a Qr40 strength 5 ADMIRE kernel and a slice thickness of 1 mm. A SECT calibration curve has been established relating CT numbers to RSPs based on average tissues described in literature. Using this calibration curve RSPs have been derived from measured CT numbers at 120 kV. With the DECT method effective atomic numbers and relative electron densities have been determined from CT numbers measured at 90 kV and 150 kV Sn. RSPs have been calculated from the DECT derived electron density and a relation between the effective atomic number  $Z'$  and mean excitation energy. Experimental RSPs have been obtained from residual range measurements of 190 MeV protons in water and compared to the predicted RSPs by SECT and DECT. For the proton measurements, all samples have been prepared with a water equivalent thickness of about 2 cm.

#### Results

The experimental RSPs of the 32 materials have been determined with an uncertainty <0.5%. The relative differences between SECT predicted and experimental RSPs for these 32 materials range from -21.4% ( $Al_2O_3$ ) to 16.4% (Silicone oil). The DECT predicted RSPs are predominantly within 3.5% of the experimental values (figure 1). For the 17 bovine tissues the differences between SECT and DECT are small except for lung, adipose and bone (figure 2). Compared to the experimental RSPs, the SECT and DECT predicted RSPs of the bovine tissues are within 3.7% and 3.3% respectively, except for the bone samples. For the two bone samples the SECT predicted RSPs deviate 19% and 24% from experimental values while for the DECT predicted RSPs the deviations are 5.4% and 5.2%. Due to partial volume averaging in the two bone samples between air and bone the density of the samples is smaller than expected by the SECT calibration curve

which introduces errors in the SECT derived RSPs. The DECT method determines the effective atomic number and relative electron density and on basis of these physical parameters enables a more accurate estimate of the RSP.

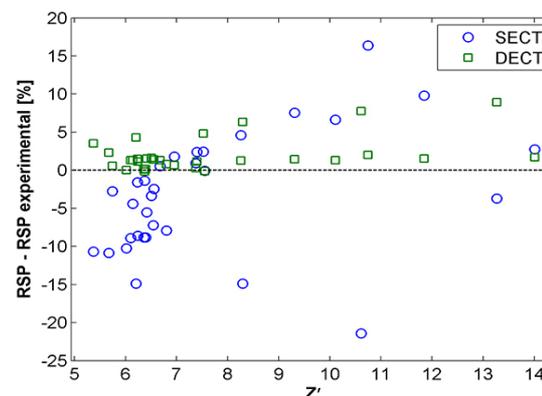

Figure 1. Relative difference of relative stopping powers (RSPs) for the 32 materials determined with SECT and DECT with respect to experimental RSPs as a function of the effective atomic number  $Z'$ .

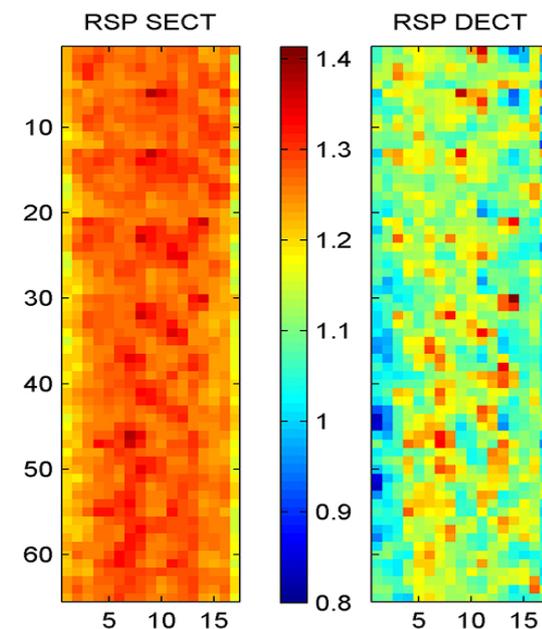

Figure 2. Relative stopping powers (RSPs) for bone determined from SECT and DECT in 3D volumes of interest where the x-axis represents the slice position.

#### Conclusion

The developed DECT method is more accurate in prediction of relative proton stopping powers than the SECT calibration method for a wide range of materials and tissues and can be of benefit to proton therapy treatment planning.

#### OC-0152 Innovative solid state microdosimeters for Radiobiological effect evaluation in particle therapy

<sup>2</sup>Australian Nuclear Science and Technology Organisation, Engineering Material Institute, Lucas Heights, Australia

<sup>3</sup>SINTEF, Microsystems and Nanotechnology, Oslo, Norway

<sup>4</sup>SPA-BIT, SPA-BIT, Kiev, Ukraine

### Purpose or Objective

Particle therapy has many advantages over conventional photon therapy, particularly for treating deep-seated solid tumors due to its greater conformal energy deposition achieved in the form of the Bragg peak (BP). Successful treatment with protons and heavy ions depends largely on knowledge of the relative biological effectiveness (RBE) of the radiation produced by primary and secondary charged particles. Different methods and approaches are used for calculation of the RBE-weighted absorbed dose in treatment planning system (TPS) for protons and heavy ion therapy. The RBE derived based on microdosimetric approach using the tissue equivalent proportional counter (TEPC) measurements in  $^{12}\text{C}$  therapy has been reported, however large size of commercial TEPC is averaging RBE which dramatically changes close to and in a distal part of the BP that may have clinical impact. Moreover, the TEPC cannot be used in current particle therapy technique using pencil beam scanning (PBS) delivery due to pile up problems associated with high dose rate in PBS.

### Material and Methods

The Centre for Medical Radiation Physics (CMRP), University of Wollongong, has developed new silicon-on-insulator (SOI) microdosimeter with 3D sensitive volumes (SVs) similar to biological cells, known as the "Bridge" and "Mushroom" microdosimeters, to address the shortcomings of the TEPC. The silicon microdosimeter provides extremely high spatial resolution and can be used for in-field and out-of-field measurements in both passive scattering and PBS deliveries. The response of the microdosimeter was studied in passive and scanning proton and carbon therapy beam at Massachusetts General Hospital (MGH), USA, Heavy Ion Medical Accelerator in Chiba (HIMAC) and Gunma University Heavy Ion Medical Center (GHMC), Japan, respectively.

### Results

Fig 1a shows the dose mean lineal energy, and frequency mean lineal energy, measured using the SOI microdosimeter irradiated by the 131.08 MeV pencil proton beam as a function of depth in water. The value was around 2 keV/ $\mu\text{m}$  in the plateau region, then approximately 3 to 5 keV/ $\mu\text{m}$  in the proximal part of the BP, and increasing dramatically to 9 to 10 keV/ $\mu\text{m}$  at the end of the BP. Fig 1b shows derived RBE along the BP for 2Gy dose delivered in a peak. Fig 2 shows the distribution with depth for the 290 MeV/u  $^{12}\text{C}$  ion pencil beam at GHMC. The inset graph in the left corner of Fig. 2 shows a detailed view of the  $\bar{y}_D$  distribution at the BP measured with submillimetre spatial resolution. It can be seen that the distribution at the peak illustrates the effect of ripple filter used in this facility which is impossible to observe with any TEPC based microdosimeters. RBE values and dose equivalent obtained near the target volume are also derived using the SOI microdosimeters and the results will be presented in a full paper.

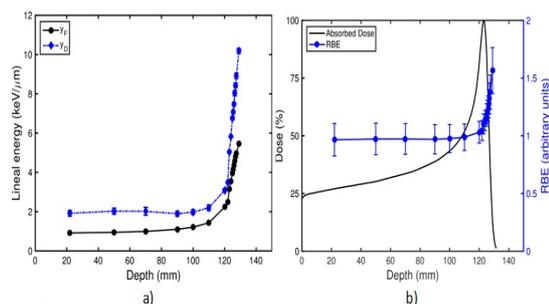

Fig. 1 Frequency-mean lineal energy,  $\bar{y}_F$  and dose-mean lineal energy  $\bar{y}_D$  obtained using the bridge microdosimeter as a function of depth in water for a proton PBS spot

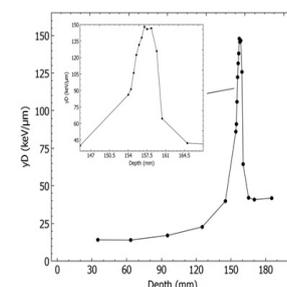

Fig. 2  $\bar{y}_D$  distribution with depth in a 290 MeV/u  $^{12}\text{C}$  ion pencil beam in water obtained with 3D Mushroom microdosimeter.

### Conclusion

This work presented an application of SOI microdosimeters for RBE determination in passive and scanning proton and  $^{12}\text{C}$  ion therapy and silicon microdosimetry has demonstrated a simple and fast method for routine Quality Assurance in charged particle therapy.

### OC-0153 Sensitivity evaluation of prompt $\gamma$ -ray based range verification with a slit camera

<sup>3</sup>Ion Beam Applications SA, Louvain-la-Neuve, Belgium

<sup>4</sup>Faculty of Medicine and University Hospital Carl Gustav Carus- Technische Universität Dresden, Department of Radiation Oncology, Dresden, Germany

<sup>5</sup>Helmholtz-Zentrum Dresden-Rossendorf, Institute of Radiooncology, Dresden, Germany

<sup>6</sup>German Cancer Consortium DKTK and German Cancer Research Center DKFZ, Dresden, Germany

### Purpose or Objective

The dose distribution and range of proton beams are exceedingly prone to uncertainties and anatomical changes, demanding for an in-vivo range verification. A promising approach is prompt  $\gamma$ -ray imaging (PGI), which was recently implemented clinically in Dresden using a so-called PGI slit camera [1,2] in double scattering (DS). However, the detectability of local range shifts, affecting only part of the lateral field in DS, is limited. The spot-wise dose deposition in pencil beam scanning (PBS) promises a finer spatial resolution of range shifts. The purpose of this study is to comprehensively investigate the sensitivity to detect range shifts in DS and PBS using a head phantom in a clinical setup.

### Material and Methods

For a realistic brain tumor treatment, treatment plans in DS and PBS (2 beams, 60 GyE, 2 GyE/fx), were created.

One beam (1 GyE) was applied to a CIRS head phantom and monitored with the PGI slit camera. To investigate the influence of the spot dose, the same beam with 5 GyE was also delivered and measured. Global and local (5 cm in diameter) range shifts were introduced and the PGI profiles (prompt- $\gamma$  counts over depth) with and without shifts were compared. Sum profiles containing prompt- $\gamma$  counts over the entire fraction were used for the comparison of DS and PBS. Moreover, PGI profiles measured in PBS were analyzed spot-wise and will also be compared with simulated profiles for absolute range determination.

### Results

A good agreement between introduced and measured global shifts was found in the sum profile evaluation for both modalities, PBS and DS (Table 1). Relative differences were below 2, 7 and 12 % for the 10, 7 and 4 mm shifts, respectively. Local shifts are not detectable using sum profiles. For the applied local shifts, a spot-wise comparison of PGI profiles in PBS allows the detection and localization of global and local shifts (Figure 1). For interpretation, neighbored spots should be clustered, as shifts detected for single spots are less reliable due to low statistics. Higher doses (5 vs. 1 GyE) allow the detection of smaller shifts as shown in Figure 1 for the 4 mm local shift.

Table 1: Measured global shifts between sum profiles in DS and PBS with 1 and 5 GyE.

Introduced Shift in mm	Measured shift in mm			
	DS 5 GyE	DS 1 GyE	PBS 5 GyE	PBS 1 GyE
10.0	9.8	not measured	10.2	10.2
7.1	7.2	7.6	6.6	6.8
5.0	5.6	4.8	4.6	4.4

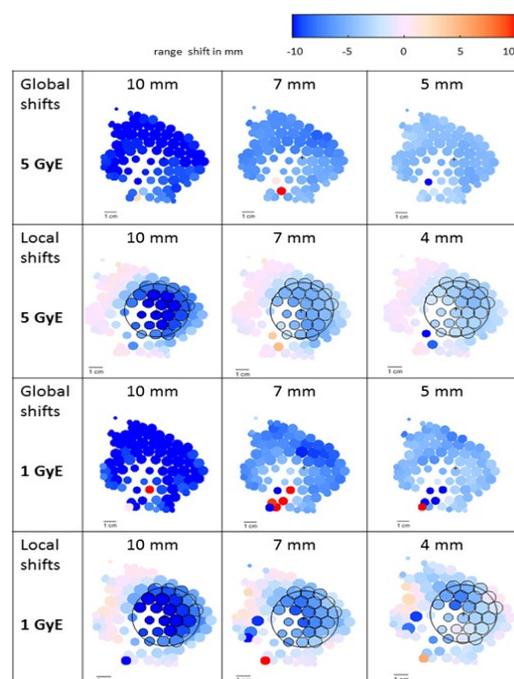

Figure 1: Spot-wise analysis of the determined range shifts: The points represent PBS spots of one energy layer, the size corresponds to the dose per spot, the color to the detected shift between two PGI profiles. Spots influenced by the local shifts (black ring) are highlighted with a black edge. Global and local shifts with 1 and 5 GyE were measured.

### Conclusion

The systematic sensitivity study revealed the capability of the PGI slit camera to detect range shifts under clinical conditions. In both treatment modalities, global range shifts can be detected. Additionally, in PBS a spot-wise comparison allows also the determination of interfractional local range shifts. Moreover, a still ongoing evaluation of PBS measured and simulated spot-wise profiles for absolute range verification will be presented.

### OC-0154 Proton therapy patient selection for oropharyngeal cancer patients: the impact of treatment accuracy

M. Hoogeman<sup>1</sup>, S. Breedveld<sup>1</sup>, M. De Jong<sup>2</sup>, E. Astreinidou<sup>2</sup>, L. Tans<sup>1</sup>, F. Keskin-Cambay<sup>1</sup>, R. Bijman<sup>1</sup>, S. Krol<sup>2</sup>, S. Van de Water<sup>1</sup>, T. Arts<sup>1</sup>  
<sup>1</sup>Erasmus MC Cancer Institute, Radiation Oncology, Rotterdam, The Netherlands  
<sup>2</sup>Leids University Medical Center, Radiation Oncology, Leiden, The Netherlands

### Purpose or Objective

Comparative treatment planning including Normal Tissue Complication Probability (NTCP) evaluation has been proposed to select patients for proton therapy. NTCP, however, does not only depend on the type of radiation used, but also on the size of the safety margins or degree of robustness needed to account for treatment-related uncertainties. In this study, for the first time to our knowledge, the impact of margins and robustness settings to the selection of oropharyngeal cancer patients is investigated using fully automated comparative treatment planning.

### Material and Methods

CT and contour data of 78 consecutive oropharyngeal patients were imported in our in-house developed system for automated treatment planning for Intensity-Modulated photon (IMRT) and proton radiotherapy (IMPT). Treatment plans were generated fully automatically for a simultaneously integrated boost scheme prescribing 70 Gy<sub>RBE</sub> to the primary tumor and pathological lymph nodes and 54.25 Gy<sub>RBE</sub> to the elective nodal areas in 35 fractions. IMRT treatment plans were generated with a 0, 3, or 5mm margin. IMPT 'minimax' robust optimized treatment plans were generated for five different setup and range robustness settings. Five validated NTCP models (see Fig. 1) proposed for IMPT patient selection were used in this study. Following Dutch consensus guidelines, patients were selected for IMPT if IMPT reduced NTCP by 10% or 5% for a grade II or a grade III complication, respectively.

### Results

In total 624 treatment plans were generated automatically and approved by the authors. Figure 1 shows that the percentage of patients selected for IMPT decreases with increasing robustness setting for a given margin and also decreases with decreasing margin for a given robustness setting. In contrast to the size of the margin, the degree of robustness has little impact on patient selection for tube feeding dependence, which is the only grade III complication. For the other complications the impact of the degree of robustness setting is noticeably higher. For patient-rated sticky saliva, nearly no patient is selected for IMPT if robustness is included. If we consider high-precision IMRT using a 3mm margin and high-precision IMPT using a robustness setting of 3mm for setup and 3% for range errors, most patients are selected for proton therapy based on problems swallowing solid food (51.3%), followed by tube feeding dependence (37.2%) and decreased parotid flow (29.5%). Patient-rated sticky saliva and patient-rated xerostomia contributed only with 1.3% and 7.7% respectively.

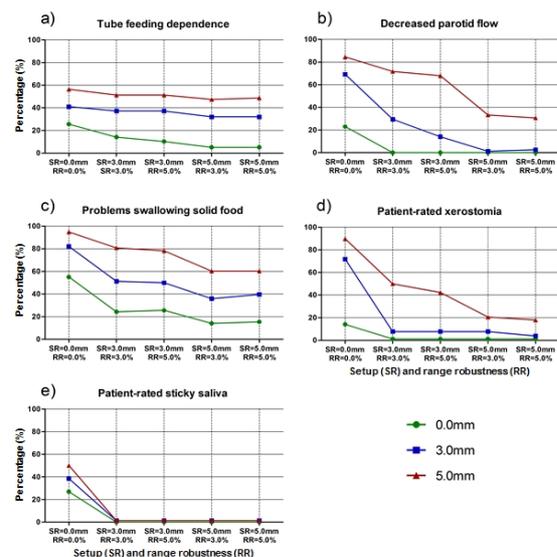

Figure 1: Percentage of patients selected for IMPT as a function of margins and robustness settings for each of the five NTCP models. A  $\Delta$ NTCP-threshold of 10% for the grade II models (b-e) and 5% for the grade III model (a) was used. a) Wopken et al., b) Dijkema et al., c) Christiansen et al., d) and e) Beetz et al.

## Conclusion

This study shows that treatment accuracy cannot be ignored in estimating the number of patients that will be selected for proton therapy based on comparative treatment planning and NTCP evaluation. We also conclude that IMRT as well as IMPT should be optimized for accuracy to ensure a sustainable use of proton therapy.

## Proffered Papers: Imaging and image analysis

### OC-0155 Automated lung tumour delineation in cine MR images for image guided radiotherapy with an MR-Linac

B. Eiben<sup>1</sup>, M.F. Fast<sup>2</sup>, M.J. Menten<sup>2</sup>, K. Bromma<sup>2</sup>, A. Wetscherek<sup>2</sup>, D.J. Hawkes<sup>1</sup>, J.R. McClelland<sup>1</sup>, U. Oelfke<sup>2</sup>

<sup>1</sup>University College London, Centre for Medical Image Computing, London, United Kingdom

<sup>2</sup>The Institute of Cancer Research and The Royal Marsden NHS Foundation Trust, Joint Department of Physics, London, United Kingdom

### Purpose or Objective

Respiratory-induced lung tumour movement is a significant challenge for precise dose delivery during radiotherapy. MR-Linac technology has the potential to monitor tumour motion and deformation using continuously acquired 2D cine MR images. In order to target tumours in their current shape and position the tumour outline must be established automatically. In this study we compared four automatic contouring algorithms that delineate the tumour in sequential cine MR images based on manually contoured training images.

### Material and Methods

Five 1 min 2D cine MR images (Fig. 1) were acquired for two patients. Each sequence was split into a training set of ten source images and a test set of about 100 images. Method (1) is a multi-template matching, with a template taken from each source image centred on the tumour. For every test image the best position of each template is evaluated and the most similar match is selected. Method (2) uses a pulse-coupled neural network (PCNN) to improve the grey-value contrast between tumour and healthy tissue thus aiding the auto-contouring. The PCNN and associated erosion and dilation parameters were trained on the training sets using an accelerated particle swarm

optimisation technique. For method (3) first the source image that is most similar to the current test image is selected. Then the source image is warped to the test image using an intensity driven B-spline registration. The last method, (4), uses image features (FAST/SIFT) to match distinct points of source and test images. The best source image is determined by the shortest mean descriptor distance. Residual misalignment is corrected for by a non-rigid transformation according to displacement vectors between matched features. All registration based methods (1,3,4) propagate contours according to the corresponding transformations.

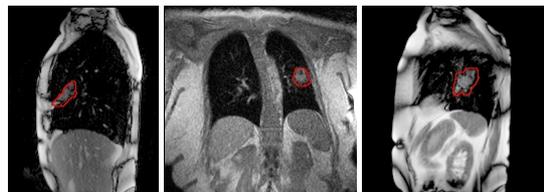

Fig 1: Example slices of the cine MR images (bSSFP and GRE) acquired with a Siemens Aera 1.5T. The in-plane resolution is 2mm isotropic and the slice thickness is 5mm. Manually delineated tumour contours are depicted in red.

## Results

Fig. 2 shows the averaged Dice coefficient and centroid distance, their standard deviation, and minimum / maximum value of the 5<sup>th</sup>/95<sup>th</sup> percentile of all cases after auto-contouring (1-4). Cases (w) and (b) represent the worst and best result, respectively, if only a single contour is propagated without considering motion. All methods improve the mean Dice overlap and centroid distance. Methods (1) and (3) achieve the best mean Dice score of 0.93 and a minimum 5<sup>th</sup> percentile of 0.86 and 0.88 respectively. Method (2) produces the lowest mean centroid distance of 1.3mm, while maximum 95th percentile values range between 4.4mm (3) and 5.0mm (4). Training of the PCNN takes about 1 min based on 100 initialisation points and 20 iterations and the mean contouring times per image are (1) 1ms, (2) 24ms, (3) 518ms, and (4) 144ms.

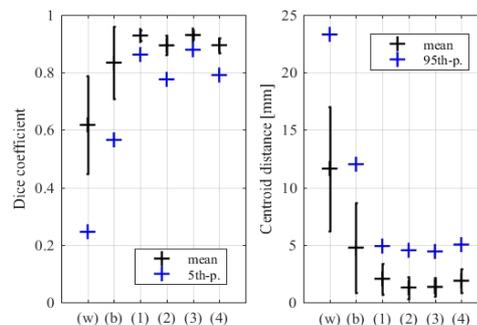

Fig. 2: Overlap evaluation results in terms of the Dice coefficient and the centroid distance. The mean values and the standard deviation for all five cases combined are given in black, whereas the global minimum 5th percentile of the Dice coefficient and maximum 95th percentile of the centroid distance are depicted in blue. Results without adapting the template contour to the test images are given for the worst case (w) and best case scenario (b). Application of methods (1) to (4) results in higher Dice coefficients and lower centroid distances.

## Conclusion

Despite its simplicity multi-template matching (1) produces good results with low computational cost. Although, more sophisticated approaches (2,3,4) can handle unseen deformations, such flexibility - potentially required for longer image acquisitions or treatments - comes at the cost of robustness (2,4) or computational load (3).

### OC-0156 Automated reference-free local error assessment in clinical multimodal deformable image registration

M. Nix<sup>1</sup>, R. Speight<sup>1</sup>, R. Prestwich<sup>2</sup>

<sup>1</sup>St James' Institute of Oncology, Radiotherapy Physics, Leeds, United Kingdom

<sup>2</sup>St James' Institute of Oncology, Clinical Oncology, Leeds, United Kingdom

#### Purpose or Objective

Multimodal deformable image registration (MM-DIR), for MR-CT fusion in RT planning, is a difficult problem. Algorithms in commercial applications can leave significant residual errors and performance can vary considerably through a 3D image set. Currently, quality assessment relies on clinical judgement or time-consuming landmarking approaches for quantitative comparison. Due to the variability of MM-DIR performance, a pre-clinical commissioning approach cannot be relied upon to quality assure clinical performance. The primary objective was to develop and validate an automated method for localised error assessment of clinical multimodal deformable image registrations, without reference data. This should aid clinical judgement of registration reliability across the volumetric data and hence increase clinical confidence in MM-DIR fusion for RT planning.

#### Material and Methods

A computational method for determining the local reliability of a given clinical registration has been developed. Two registration assessment algorithms, using blockwise mutual information (BMI) and pseudo-modal cross correlation (pmCC) respectively, have been implemented and compared. Error information is presented as a quantitative 3D 'iso-error' map, showing areas of a registered dataset where errors are greater than a certain magnitude and may not be reliable, e.g. for contouring tumour or organ at risk volumes. The developed software was validated using a 'gold-standard' rigidly-registered image set, derived from immobilised MR, registered to immobilised CT, which was deformed with known rotations, translations and more complex deformation fields. Detected and applied errors were compared across the dataset. Mean errors within the GTVs of 14 head and neck MR-CT registrations were analysed using the BMI method and used to identify cases where the registration may be clinically unacceptable.

#### Results

Both algorithms consistently detected applied errors larger than 2 mm. Errors detected using the BMI method, following intentional rotation of gold-standard pre-registered clinical MR data, were strongly correlated with applied errors, in magnitude and direction (Pearson's  $r > 0.96$ ).

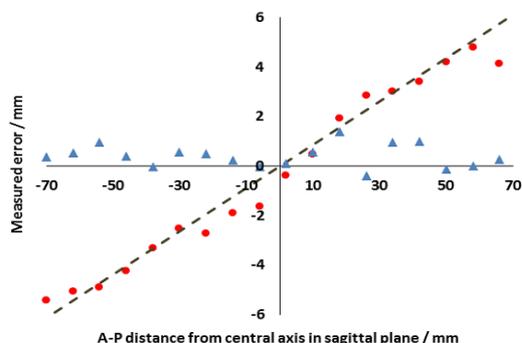

Figure 2: BMI registration analysis following application of a 5 degree rotation of pre-registered in-mask clinical H&N MR data. Determined errors (red circles) correlate well with applied errors (grey dashes). Errors in the orthogonal axis (blue triangles) are near zero as expected.

Analysis in the direction orthogonal to the applied deformation showed minimal errors, as expected ( $\langle E \rangle = 0.32$  mm,  $SD = 0.43$  mm). Across 14 clinical MR-CT registration datasets, mean magnitude registration errors within the GTV varied from 0.4 to 5.4 mm (population mean = 1.8 mm), indicating that MM-DIR errors can be significant for RT planning.

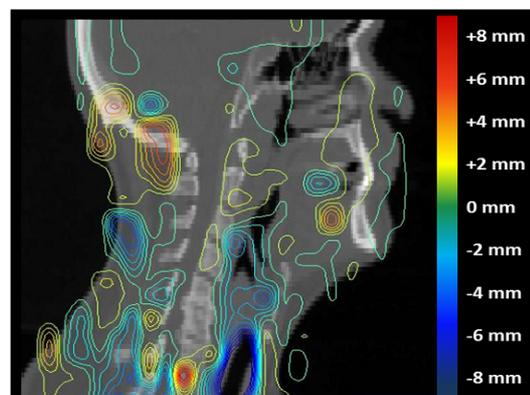

Figure 1: Sup-Inf axis error map (colour scale: +8 to -8 mm) determined by BMI method, following registration error analysis of diagnostic position H&N MR with RT planning CT for a clinical patient registration. Large errors are present in the oesophagus due to swallowing. The registration around the posterior skull base is poor, due to limitations of the registration process.

#### Conclusion

Reference free localised registration quality assessment offers clinicians a tool to judge registration reliability, which could increase confidence in and clinical usage of MM-DIR in radiotherapy. A software tool was developed and validated to achieve this. A strong correlation was found between detected and applied registration errors. Mean GTV error is a potential indicator for clinical acceptability of registrations.

### OC-0157 Atlas-based segmentation of prostatic urethra in the planning CT of prostate cancer

O. Acosta<sup>1</sup>, M. Le Dain<sup>1</sup>, C. Voisin<sup>1</sup>, R. Bastien<sup>1</sup>, C. Lafond<sup>2</sup>, K. Gnep<sup>2</sup>, R. De Crevoisier<sup>2</sup>

<sup>1</sup>LTSI-INSERM UMR 1099, Université de Rennes 1, Rennes,

<sup>2</sup>Centre Eugene Marquis, Radiotherapy, Rennes, France

#### Purpose or Objective

to the dose delivered mainly to the bladder) and likely also to the urethra (obstructive symptoms). Identification of urethra for dose assessment from planning CT scans is however challenging as the organ lies inside the prostate and is not visible. Moreover, the dose received by the urethra may not be superposed to the dose received by the whole prostate. In case of prostate IMRT, the goals of this work were therefore: i) to propose an automatic method for urethra segmentation from the planning CT and ii) to quantify the dose received by the urethra.

#### Material and Methods

An original weighted multi atlas-based segmentation method was devised standing on a global characterization of the urethra wrt the surrounding organs. For building the atlas a first set of CT scans (512x512 0.63x0.63 mm axial pixels and 3 mm slices) from 80 patients treated for localized prostate cancer with Iodine 125 brachytherapy was used. All the patients had an urinary probe allowing an ease manual urethra segmentation. Prostate, bladder and urethra were delineated by a radiation oncologist. An average patient, in terms of prostate volume, was selected as common reference system where all the patients were rigidly aligned. Each segmented urethra was characterized by its central line, the relative bladder position and prostate characteristics (height, excentricity and volume). An in-house demons based registration using prostate contours and Laplacian maps was performed to

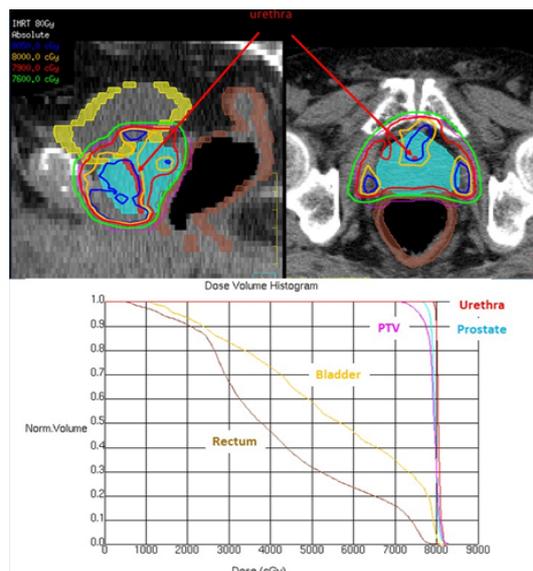

propagate urethra delineation to the test patients. The *n*-most similar individuals were selected and final segmentation was obtained by a weighted vote. Leave-one out cross validation of the atlas for urethra segmentation was first performed on the training data set. Mean Centerline Dispersion (MCD) and Hausdorff Distance (HD) were used for accuracy assessment. The method was then applied to a second set of 95 patients having received 78 Gy by IMRT for prostate cancer. Target volume and organs at risks (bladder, prostate) were delineated on computed tomography (CT) slices according to the French GETUG group recommendations. Then, the urethra was segmented using the proposed approach and dose was measured inside the resulting segmentation and compared to the dose to the prostate.

### Results

From the training data set, the number of most similar atlases was optimized to 10 in the leave one out scheme. Average MCD of 2.3 mm and HD of 3.5 mm were thereby obtained. In the testing data base dose received by the segmented urethra were significantly higher than the whole prostate in a range of dose from 74 Gy to 79 Gy (Wilcoxon test  $p < 0.01$ ).

### Conclusion

An accurate atlas based segmentation method was proposed allowing assessment of dose within prostatic urethra. Dose in this organ was significantly higher than the whole prostate, mainly in the highest dose range. Results open the way to further NTCP studies relating urinary toxicity such as obstructive symptoms to the urethra dose.

### OC-0158 a priori scatter correction of cone-beam CT projections in photon vs. proton therapy gantries

A.G. Andersen<sup>1</sup>, Y. Park<sup>2</sup>, O. Casares-Magaz<sup>3</sup>, U. Elstrøm<sup>1</sup>, J. Petersen<sup>1</sup>, B. Winey<sup>2</sup>, L. Dong<sup>3</sup>, L. Muren<sup>1</sup>

<sup>1</sup>Aarhus University Hospital, Department of Medical Physics, Aarhus V, Denmark

<sup>2</sup>Massachusetts General Hospital, Department of Radiation Oncology, Boston- Massachusetts, USA

<sup>3</sup>Scripps Proton Therapy Center, Department of Medical Physics, San Diego- California, USA

### Purpose or Objective

Cone-beam (CB) CT is becoming available on proton therapy gantries, to allow image/dose-guidance and adaptation for protons. To use these techniques clinically, the challenges related to image quality and Hounsfield Unit accuracy need to be solved. Algorithms for scatter correction have been developed, and have been explored for CBCT systems on photon therapy gantries but so far not

on gantries for proton therapy that have a different geometry and did not use a bow-tie filter. The performance of an *a priori* scatter correction algorithm was in this study compared for the first time on CBCT systems for photon vs. proton therapy gantries.

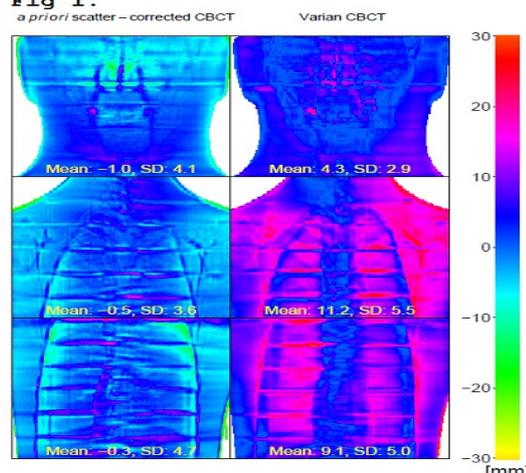

### Material and Methods

The *a priori* scatter correction algorithm used a plan CT (pCT) and raw CB projections. The projections were acquired with On-Board Imagers of a Varian photon therapy Clinac and of a Varian proton therapy ProBeam system. The projections were initially corrected for beam hardening followed by reconstruction using the RTK back projection Feldkamp-Davis-Kress algorithm (rawCBCT). Manual, rigid and deformable registrations were applied using Plastimatch on the pCT to the rawCBCT. The resulting images were forward projected onto the same angles as the raw CB projections. The two projections sets were then subtracted from each other, Gaussian and median filtered, and then subtracted from the raw projections and finally reconstructed to a scatter corrected CBCT. To evaluate the algorithm, water equivalent path length (WEPL) maps were calculated from anterior to posterior on different reconstructions of the data sets (CB projections and pCT). Initially we evaluated CB projections of an Alderson phantom acquired on the Clinac system before comparing CB projections of the same CatPhan phantom acquired on both the Clinac and the ProBeam systems.

### Results

In the analysis of the Clinac projections of the Alderson phantom, the scatter correction resulted in sub-mm mean WEPL difference from the rigid registration of the pCT, considerably smaller than what was achieved with the regular Varian CBCT reconstruction algorithm (Figure 1). The largest improvement was for the half-fan (below neck) scans. With the Catphan phantom the rawCBCT was very similar to the Varian reconstruction, due to a refitting of beam hardening curve. When comparing reconstructions of photon to proton gantry CB projections (Figure 2) we found that the *a priori* scatter correction improved the mean WEPL difference while preserving image quality (the number of countable line pairs) for both gantry types. The photon gantry showed less WEPL difference, however used a higher pulse current per acquisition ( 2.00 mAs), compared to the proton gantry (1.4 mAs). The complete scatter correction is performed within three minutes on a desktop with NVIDIA graphics.

**Fig 1.**

**Fig. 1:** The WEPL was measured from anterior to posterior. **Left column:** *a priori* corrected reconstruction. **Right column:** Varian reconstruction. Each column is a different cut of the Alderson phantom, the first being full-fan. The scale is the residual difference from the rigid registration in mm.

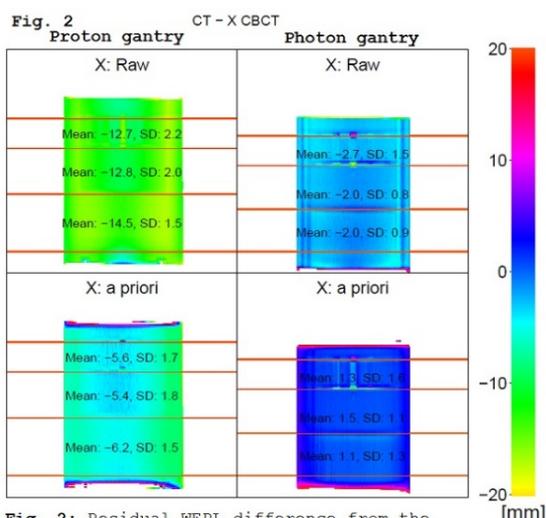

Fig. 2: Residual WEPL difference from the rigid registration. For the Catphan phantom. Left column: Proton Gantry. Right column: Photon gantry.

### Conclusion

We have shown that an *a priori* scatter correction algorithm for CB projections improves CBCT image quality on both photon- and proton therapy gantries, potentially opening for CBCT-based image/dose-guided proton therapy.

### OC-0159 Dual energy CBCT increases soft tissue CNR ratio and image quality compared to standard CBCT in IGRT

M. Skaarup<sup>1</sup>, D. Kovacs<sup>1</sup>, M.C. Aznar<sup>1</sup>, J.P. Bangsgaard<sup>1</sup>, J.S. Rydhög<sup>1</sup>, L.A. Rechner<sup>1</sup>

<sup>1</sup>The Finsen Center - Rigshospitalet, Clinic of Oncology, Copenhagen, Denmark

### Purpose or Objective

We investigate a method for enhancing soft tissue contrast to noise ratio (CNR) and clinical image quality of cone-beam computed tomography (CBCT) by using a dual energy CBCT protocol.

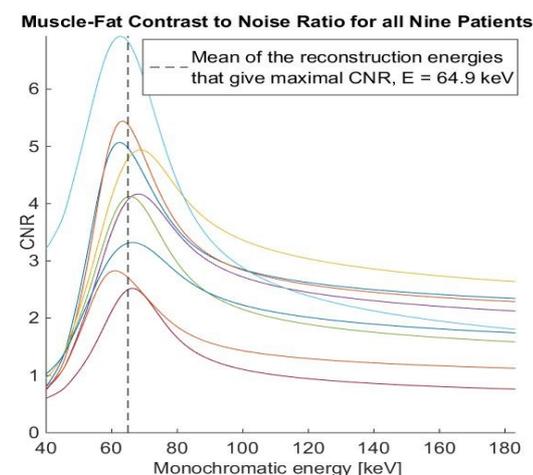

### Material and Methods

Nine patients were scanned using a standard CBCT protocol of either 100 or 125 kVp and a DE-CBCT protocol of two separate scans of 80 and 140 kVp respectively. Other scan parameters were identical and total radiation dose was kept at a similar level for both protocols. Virtual monochromatic dual energy (VMDE) images were reconstructed using a linear mix of the 80 and 140 kVp scan.

The weight, with which the two images were combined, was calculated based on known attenuation coefficients of two basis materials at a specific monochromatic energy. A linear combination of these can be used to express the attenuation coefficients of the 80 and 140 kVp scan at that same monochromatic energy. To find the optimal virtual reconstruction energy for soft tissue imaging, multiple reconstructions were done for energies in the range 40-180 keV.

CNR measurements were performed on both standard CBCT and VMDE images for a number of different tissue combinations, e.g. contrast between tumour-fat, tumour-surrounding tissue, muscle-fat, rectum-surrounding tissue, parotid-fat, seminal vesicle-surrounding tissue and lung-heart (see figure 1 for an example). In addition, 5 experienced observers conducted a blinded ranking between VMDE images (reconstructed at 55, 65, 75 and 100 keV) and the standard CBCT images, i.e. five image series per patient. For each combination of image series the observers were asked to compare the images side-by-side, focusing on soft tissue image quality as well as

presence of metal artefacts. To eliminate left-right bias, each combination was shown twice.

### Results

VMDE images reconstructed at energies in the range 60 to 70 keV showed improved CNR for all soft tissue regions when compared to the standard CBCT. On average, the reconstruction energy corresponding to the maximum CNR improvement is  $65.5 \pm 2.4$  keV. The increase in maximum CNR varied from 29% to 78%.

The clinical observer comparison gave a series of rankings for each image series for each patient (see table 1). Using signed rank Wilcoxon comparison test, the observers found the VMDE images at 65 keV preferable to the standard CBCT image. The p-value was found to be  $< 0.01$ , where  $p < 0.05$  is considered significant. An estimate of inter-observer variability test was done with Fleiss' kappa and found to be moderate with a kappa-value of 0.47, where values above 0.4 is considered acceptable and 1 is perfect agreement. Occasionally, an observer ranked the 75 keV reconstruction as the most preferable image while the overall preferred image was the 65 keV reconstruction. Except in the case of patient one where the standard CBCT image was ranked the highest of all.

Patient # (scan region)	Standard	65 keV	75 keV
Patient 1 (Pelvic)	7	5	6
Patient 2 (H&N) *	3	6.8	6
Patient 3 (H&N)	6.4	6.4	5.2
Patient 4 (H&N)	3.8	7.4	6.6
Patient 5 (Pelvic)	4.8	7.4	5.8
Patient 6 (H&N) *	1	8	6
Patient 7 (Thorax) *	3.2	7.8	6
Patient 8 (Pelvic)	5	7.2	5.8
Patient 9 (Thorax)	4.2	8	4.8

Table 1: Table of average rankings amongst all observers for each patient. Only the standard CBCT, 65 keV and 75 keV reconstructions are included as 55 keV and 100 keV was consistently ranked the lowest. The ranking can take values between 0 and 8. H&N is the head and neck region and \* denotes patients with metal implants.

### Conclusion

VMDE images can increase soft tissue contrast and improve clinical image quality for image-guided radiotherapy compared to the standard CBCT protocol.

### OC-0160 Radiomics Features Harmonization for CT and CBCT in Rectal Cancer

R. Luo<sup>1</sup>, J. Wang<sup>1</sup>, H. Zhong<sup>1</sup>, J. Gan<sup>1</sup>, P. Hu<sup>1</sup>, L. Shen<sup>1</sup>, W. Hu<sup>1</sup>, Z. Zhang<sup>1</sup>

<sup>1</sup>Fudan University Cancer Hospital, Radiation Oncology, Shanghai, China

### Purpose or Objective

Inter-scanner variability can lead to degradation of radiomics model quality. Therefore, feature harmonization is necessary for consistent findings in radiomics studies, especially for multi-institution studies. The purpose of this study is to establish harmonization

methods for CT and CBCT radiomics features in rectal cancer, and to provide a harmonization evaluation method.

### Material and Methods

Three harmonization strategies were tested in this study, including no correction, simple correction and phantom based correction. 50 rectal cancer patients with both planning CT images and positioning CBCT images before the first fraction of treatment were collected for harmonization performance evaluation. 203 features were extracted from CT and CBCT images. For the phantom based correction, a texture phantom comprised of 30 different materials was designed for features selection and nonlinear functions generation for normalizing CT and CBCT features. The Main workflow was shown in Figure 1. Mixed datasets consisting of CT and CBCT features were generated for harmonization performance evaluation using cluster analysis. The harmonization performance was evaluated by Chi-square testing between clustering results and scanner machines, and the clustering consistency with original CT feature. These tests were repeated for 50 times with randomized sample generation.

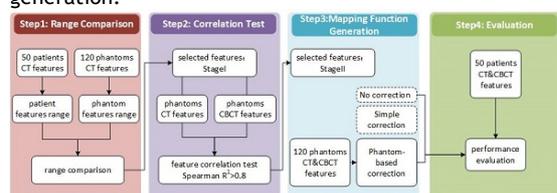

Figure 1. Main Workflow. Four steps of this study: (I) Feature selection by features range comparison. (II) Feature selection by spearman correlation test. (III) Nonlinear mapping function generation using texture phantom. (IV) Correction methods performance evaluation on patients.

### Results

41 of the 203 radiomics features were selected by range comparison and spearman correlation test. Among 50 randomized sampling processes, all clustering (100%) results without any correction showed high correlation with imaging machine ( $p > 0.05$ ,  $\chi^2$  test), while this probability reduced to 0% and 42% respectively when simple correction or phantom based correction were applied. Average accuracy and Kappa index increased significantly ( $p < 0.05$ , t-test), respectively to  $0.71 \pm 0.07$  and  $0.42 \pm 0.12$  for simple correction method and  $0.68 \pm 0.06$  and  $0.36 \pm 0.14$  for phantom based correction method, from  $0.61 \pm 0.06$  and  $0.23 \pm 0.13$  without any correction.

	Original	Simple correction	Phantom based correction
<b>Chi-square testing</b>			
Number of significant times (p-value < 0.05)	50	0	21
Percentage	100%	0%	42%
<b>Consistency testing</b>			
Accuracy (ACC)	$0.61 \pm 0.06$	$0.71 \pm 0.07$	$0.68 \pm 0.06$
Kappa	$0.23 \pm 0.13$	$0.42 \pm 0.12$	$0.36 \pm 0.14$

Table 1. Performance evaluation result for different harmonization strategies.

### Conclusion

This is the first study focused on feature harmonization for CT images. Two proposed correction methods, simple correction and phantom based correction, were verified to be feasible for CT and CBCT harmonization, which could significantly improve the modeling consistency.

### Proffered Papers: Novelties in image guidance

**OC-0161 patient tolerance of stereotactic MR-guided adaptive radiation therapy: an assessment using PRO's**  
 R. Bakker<sup>1</sup>, M. Jeulink<sup>1</sup>, S. Tetar<sup>1</sup>, S. Senan<sup>1</sup>, B. Slotman<sup>1</sup>, F. Lagerwaard<sup>1</sup>, A. Bruynzeel<sup>1</sup>  
<sup>1</sup>VU University Medical Center, Radiotherapy, Amsterdam, The Netherlands

### Purpose or Objective

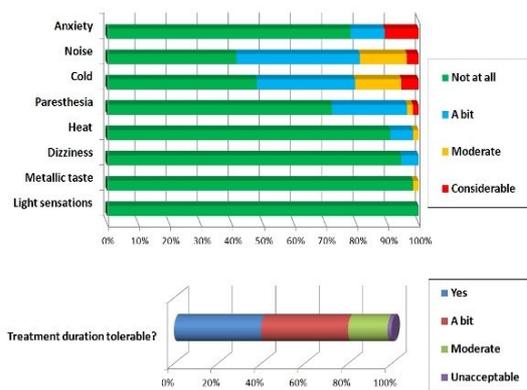

Recently, SMART has been introduced in our center using the MRIdian (Viewray). One key feature of SMART is delivery of radiation while patients are positioned for a prolonged period within the MRI bore, and therefore may experience procedure-related problems such as anxiety, noise and other MR-related undesired signals. Briefly, patients are positioned on the MRIdian with body coils and headphones, after which 0.35T MR-scans are performed prior to each fraction. After alignment of the target volume and re-contouring, re-optimization of the original treatment plan and patient-specific QA is performed while patient remains in treatment position. Treatment is delivered under real-time MR-guidance, with or without breath-hold, depending on location. On average, the duration of a single fraction ranges from 45 minutes (prostate SBRT) up to 75 minutes (breath-hold pancreas SBRT). To gain insight into patient tolerance and experiences of SMART delivery, we prospectively collected patient-reported outcome questionnaires (PRO-Q) in treated patients since May 2016.

### Material and Methods

The intake visit of SMART patients includes providing procedural information by the radiation oncologist, and in case of video-feedback for breath-hold, also by dosimetrists. During the same visit, a MRI-safety questionnaire is completed. Immediately after the intake, a simulation MR-scan is performed on the MRIdian. PRO-Q were collected in 55 patients after the last SMART fraction. The PRO-Q includes questions on anxiety, temperature, noise, and other potential MR-related undesired signals. It also includes a question on the tolerance of the duration of the SMART procedure. Items could be scored as: 1) 'not at all', 2) 'a bit', 3) 'moderate' and 4) 'considerable'.

### Results

Two of 57 patients withdrew from SMART because of severe claustrophobia during the simulation MRI. Furthermore, anxiety during treatment was reported by 12/55 patients (22%), with half of these reporting anxiety to be considerable. A majority of patients (52%) reported sensations of feeling cold related to the cooling air flow of the MRIdian. Although the MRIdian combines noise of the gradient coils of the MR and retraction of the radiation sources, this sound was experienced to be really disturbing by two patients only. Troublesome paresthesia was reported by two patients, mainly related to prolonged positioning of the arms above the head. Other relevant MR-related undesired signals such as dizziness, local heat sensations or metallic taste sensations were only occasionally reported. Although the total fraction duration was judged to be long by some extent in 22% of patients, only a single patient scored this as being unacceptably long (Fig.1).

**Conclusion**

Despite standardized information and performing simulation on the treatment machine, anxiety remains an item that needs specific attention. Even with fraction duration times of up to 75 minutes, only a single patient perceived this as being unacceptably long.

**OC-0162 Optimizing sequences for MRI-guided radiotherapy in cranial and head and neck regions**  
 W.W.K. Fung<sup>1</sup>, S.Y. Man<sup>1</sup>, J. Yuan<sup>2</sup>, L.H. FUNG<sup>2</sup>, W.P. LUK<sup>2</sup>, G. Chiu<sup>1</sup>

<sup>1</sup>Hong Kong Sanatorium & Hospital, Department of Radiotherapy, Happy Valley, Hong Kong SAR China  
<sup>2</sup>Hong Kong Sanatorium & Hospital, Medical Physics & Research Department, Happy Valley, Hong Kong SAR China

**Purpose or Objective**

MR sequences using parallel acquisition technique (PAT) with increasing acceleration factors could reduce the scan time for treatment verification, but with the cost of losing image quality that could affect verification accuracy. This study assessed the effect of different PAT factors on image quality, scan time and fusion accuracy, thus choosing a sequence which is clinically suitable for MRI-guided RT in cranial (C) and HN regions.

**Material and Methods**

Ten healthy volunteers were set up in treatment position using headrest and immobilization mask on the flat couch of a 1.5T MRI-simulator (Siemens MAGNETOM Aera). High resolution isotropic (1.05mm) 3D TSE T1W and T2W MR sequences were acquired (MR-ref). Based on MR-ref, 11 low-resolution (isotropic 1.4mm) verification sequences (MR-P<sub>xy</sub>s) were acquired with GRAPPA where acceleration factors x and y were altered in respectively phase encoding and slice encoding directions. Effective PAT factor (PAT-f) equals x times y. Four therapists (2 seniors & 2 juniors) performed two sets of fusions: MR-ref & MR-P<sub>xy</sub>s and MR-ref & duplicated MR-ref (control set) for C and HN region. Shift results (6DOF) were recorded. Survey was given to observers for scoring the image quality. Logistic and linear regression were used.

**Results**

The scan time for MR-ref were 301s and 330s, and for MR-P<sub>xy</sub>s it ranged from 249s to 49s and 254s to 59s for T1W and T2W images respectively when PAT-f increased from 3 (MR-P<sub>3,1</sub>) to 16 (MR-P<sub>4,4</sub>). Subjective analysis showed that the scores of all verification series were lower than the reference and decreased with increasing PAT-f. Image quality decreased when reducing the scan time (Fig.1). Significant reduction of image quality (p<0.05) occurred when PAT-f reached 12 for T1W and 6 for T2W images. Observers favored T1W over T2W images (p<0.0001). Scores from senior observers were significantly better than juniors (p<0.0001).

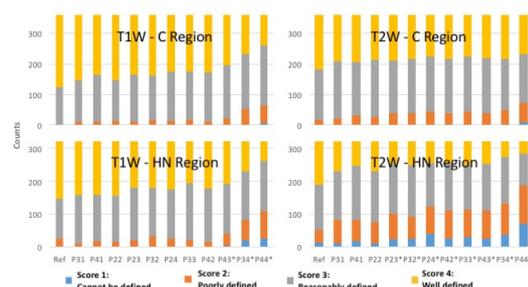

Fig.1- Graphs displaying the observers' scoring of reference and different verification series. PAT-f increases and scan time decreases from MR-ref (left) to MR-P44 (Right). \* Indicates statistical significant results comparing to MR-ref.

About 80% of absolute shift errors in all MR-P<sub>xy</sub>s were not significantly different from MR-ref in all directions. No specific trend between PAT-f and shift error was observed, implying fusion accuracy could not be predicted by PAT-f value. The errors of T2W were significantly smaller than T1W in almost all of the shifts (p<0.05). Junior observers performed significantly better than seniors when fusing T1W images (p<0.05). For treatment verification purpose, T1W MR-P<sub>4,2</sub> (88s) and T2W MR-P<sub>2,2</sub> (173s) were chosen since they were the fastest sequences with comparable image quality to MR-ref. However when considering fusion errors, MR-P<sub>4,4</sub> for T1W (49s) and T2W (59s) images, with an even shorter scan time, should be opted instead as its verification accuracy had no significant difference in most shift directions from MR-ref (Fig.2) despite significantly degraded image quality.

Fig. 2: Table showing the mean errors of the opted verification MR (i.e. with comparable verification accuracy as MR-ref while having shortest scan time) in different shift directions. MR-P44 performed best in majority of shift directions for T1W & T2W images. Data from reference MR are listed for comparison.

		Shift results (degree or mm, Mean ± SD)					
		Pitch	Yaw	Roll	Lateral	AP	SI
T1W C Region	MR-ref	0.06 ± 0.07	0.09 ± 0.11	0.11 ± 0.15	0.14 ± 0.14	0.13 ± 0.14	0.22 ± 0.47
	Opted ver. MR	MR-P44 0.11 ± 0.11	MR-P34 0.12 ± 0.12	MR-P44 0.14 ± 0.20	MR-P42 0.19 ± 0.09	MR-P44 0.21 ± 0.23	MR-P44 0.27 ± 0.31
T1W HN Region	MR-ref	0.11 ± 0.20	0.09 ± 0.13	0.12 ± 0.19	0.15 ± 0.19	0.15 ± 0.19	0.30 ± 0.41
	Opted ver. MR	MR-P44 0.10 ± 0.11	MR-P44 0.10 ± 0.10	MR-P44 0.15 ± 0.13	MR-P34 0.25 ± 0.22	MR-P44 0.25 ± 0.28	MR-P44 0.29 ± 0.31
T2W C Region	MR-ref	0.06 ± 0.06	0.08 ± 0.07	0.08 ± 0.07	0.11 ± 0.09	0.11 ± 0.09	0.11 ± 0.10
	Opted ver. MR	MR-P44 0.12 ± 0.13	MR-P44 0.05 ± 0.05	MR-P44 0.05 ± 0.05	MR-P44 0.16 ± 0.08	MR-P44 0.18 ± 0.21	MR-P44 0.17 ± 0.12
T2W HN Region	MR-ref	0.06 ± 0.06	0.07 ± 0.07	0.08 ± 0.07	0.10 ± 0.08	0.11 ± 0.09	0.10 ± 0.10
	Opted ver. MR	MR-P44 0.08 ± 0.14	MR-P44 0.05 ± 0.04	MR-P44 0.08 ± 0.06	MR-P42 0.14 ± 0.08	MR-P44 0.17 ± 0.20	MR-P44 0.13 ± 0.10

**Conclusion**

The degradation of image quality by increasing PAT-f does not necessarily affect the fusion accuracy. MR-P<sub>4,4</sub> with acceptable verification accuracy and shortest scan time is therefore proposed for MRI-guided RT in C and HN regions.

**OC-0163 Online workflow for the First-in-Man study on bone metastases at the MRI-linear accelerator**

L.T.C. Meijers<sup>1</sup>, S.J. Hoogcarspel<sup>1</sup>, A.N.T.J. Kotte<sup>1</sup>, C.N.N. Nomden<sup>1</sup>, G.G. Sikkes<sup>1</sup>, I.H. Kieboosch<sup>1</sup>, E.N. Groot de<sup>1</sup>, G.H. Bol<sup>1</sup>, B. Asselen van<sup>1</sup>, J.M. Jurgentliemk-Schulz<sup>1</sup>, L.G.W. Kerkmeijer<sup>1</sup>, B.W. Raaymakers<sup>1</sup>  
<sup>1</sup>UMC Utrecht, Radiotherapy department, Utrecht, The Netherlands

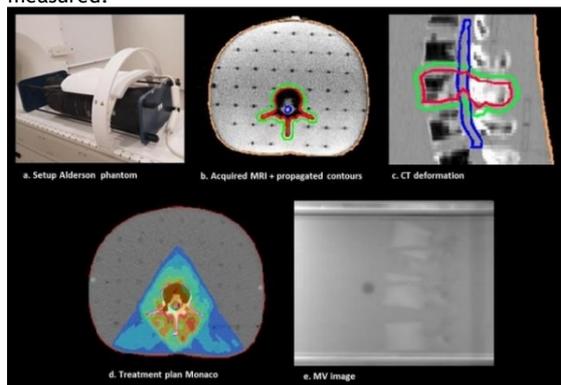

**Purpose or Objective**

The first treatment on the MR-Linac in the UMC Utrecht includes patients with bone metastases, the first-in-man study. A fast workflow is required since all processes will be performed in an online setting. The aim of the present study is to test the feasibility of an online workflow for these patients at the MR-Linac within a 30 minute time limit.

**Material and Methods**

A workflow with offline and online procedures was developed for the MR-Linac. To test this workflow, the Alderson phantom was used, a human body shaped phantom with tissue-equivalent material. The phantom yields sufficient CT and MR contrast. The offline workflow included acquisition of a reference CT scan and manual delineation of the spinal cord and one lumbar vertebra (vertebra = CTV, PTV-CTV margin = 5 mm). The online workflow at the MR-Linac, shown in figure 1, included setup of the patient (= Alderson phantom) and acquisition

of a transversal 3D T1-weighted TSE MR image (optimized MR sequence for bone metastases). A deformable registration was performed (ADMIRE, v1.13.5, Elekta AB, Sweden) of the obtained MR-images with the reference CT for automatic contour propagation and CT deformation. Furthermore a 3-field IMRT technique treatment plan was generated automatically using a research version of Monaco (v5.19.01, Elekta AB, Sweden) with a prescribed dose of 8 Gy. Additional to the MRI, independent position verification was performed using two orthogonal MV beams and the plan was delivered to the phantom. The offline and online procedures were tested three times, each time for a different lumbar vertebra. The duration of the individual procedures within the online workflow was measured.

## Results

Time measurements of the individual procedures were as follows (table 1); MRI acquisition time of 5:02 minutes, deformable image registration, contour propagation and generation of the deformed CT within a range of 40-44 seconds, development of an automatic treatment plan within a range of 6:20-6:30 minutes and position verification and dose delivery within a range of 2:32-2:42 minutes. The total time of these online procedures ranges from 14:34-15:01 minutes. These time measurements do not include the additional time for patient setup, data transfer and the time needed for a physician to evaluate the propagated contours and treatment plan at the MR-Linac. This can potentially increase the total workflow time.

Online procedure	Time measurement (minutes)
MRI acquisition	5:02
Deformable registration, contour propagation and CT deformation	0:40 – 0:44
Treatment plan	6:20 – 6:30
Position verification and dose delivery (8 Gy)	2:32 – 2:42
<b>TOTAL TIME</b>	<b>14:34 – 15:01</b>

## Conclusion

From a technical perspective, the online workflow developed for the first-in-man study on the MR-Linac can be performed well within 30 minutes to treat patients with bone metastases. Current work is focused on automation of the data transfer process.

### OC-0164 Set-up reproducibility on an MR-Linac

A. Betgen<sup>1</sup>, T. Vijlbrief<sup>1</sup>, L. Wiersema<sup>1</sup>, V.W.J. Van Pelt<sup>1</sup>, J.J. Sonke<sup>1</sup>, U.A. Van der Heide<sup>1</sup>

<sup>1</sup>Netherlands Cancer Institute Antoni van Leeuwenhoek Hospital, Department of Radiation Oncology, Amsterdam, The Netherlands

#### Purpose or Objective

MRI integrated Linacs are becoming available for improving the accuracy of radiation therapy. The MR-Linac (1ATL, Elekta AB, Sweden) is an integration of a 7MV linear accelerator and a modified 1.5T Ingenia MRI (Philips Healthcare, NL). Like on a conventional MRI, the table only moves in longitudinal direction while the patient is in the bore. No laser system is available. An indexation at

the tabletop for the patients' positioning devices has to provide a reproducible position. The treatment plan will be adapted to the patients' position, anatomical variation and organ motion of the day. The aim of this study was to characterize the accuracy of patient set-up with a table indexing system in the absence of lasers and skin marks.

#### Material and Methods

This investigation was performed on a conventional MRI. MR-scans were acquired at 3 different time points from 8 volunteers. The pelvis was chosen as anatomical region of interest. The tabletop of this MRI is comparable with the tabletop of the MR-Linac. A head support and a knee support, indexed on the table, were used for stability and reproducibility. The first MR-scan was defined as reference scan and the following two MR-scans were registered to this reference on bony anatomy. The setup variability was analyzed in terms of group mean (M), systematic ( $\Sigma$ ) and random errors ( $\sigma$ ) for both translations and rotations. The results were compared to retrospective set-up data of 79 patients treated for rectum carcinoma (5x5 Gy), aligned with lasers and skin marks and measured with CT-scan and Cone Beam-CT position verification. Because the group of volunteers is relatively small, the comparison to the rectal cancer patient group is on a descriptive basis only.

#### Results

When comparing retrospective set-up data of rectal cancer patients to the group of volunteers in this investigation, for translations, the group mean for the patient group seem to show a better set-up reproducibility in the LR and CC direction as compared to the volunteers. This resulted in group means closer to zero with corresponding smaller  $\Sigma$  errors and  $\sigma$  errors. In the AP direction, the mean and standard errors did not seem to show apparent differences. For rotations the results for both groups were comparable. The results are presented in table 1.

	Volunteers Translations (cm, n=8)			Volunteers Rotations (degrees, n=8)		
	LR	CC	AP	LR	CC	AP
M	-0.31	0.23	0.11	0.6	0	-0.1
$\Sigma$	0.31	0.42	0.13	1.3	0.3	0.6
$\sigma$	0.71	0.40	0.14	0.8	0.4	0.6
	Patients Translations (cm, n=79)			Patients Rotations (degrees, n=79)		
	LR	CC	AP	LR	CC	AP
M	0.02	0.03	-0.11	0.3	-0.3	0.2
$\Sigma$	0.24	0.21	0.24	1.5	0.7	0.4
$\sigma$	0.2	0.15	0.15	1.1	0.6	0.4

Table 1. Setup variability in terms of group mean (M), systematic ( $\Sigma$ ) and random errors ( $\sigma$ ) for both translations and rotations.

#### Conclusion

For volunteers, without the use of laser alignment, translations seem to be larger in LR and CC direction. Rotations were comparable for both groups. However, for daily practice, the impact of this increased uncertainty is likely small relative to uncertainties of internal organ motion that can be in the cm range. In daily on-line corrections, the combination needs to be considered in positioning pelvic cancer patients without skin marks, on an MR-Linac.

### OC-0165 TPUS vs CBCT: comparison of daily inter-modality derived setup shifts for prostate radiotherapy.

E.P.P. Pang<sup>1,2</sup>, K. Knight<sup>2</sup>, M. Baird<sup>2</sup>, J.M.Q. Loh<sup>1</sup>, E.T.Y. Chen<sup>1</sup>, G.K. Low<sup>1</sup>, C.C.C. Yap<sup>1</sup>, A.H.S. Boo<sup>1</sup>, J.K.L. Tuan<sup>1,3</sup>

<sup>1</sup>National Cancer Centre Singapore, Division of Radiation Oncology, Singapore, Singapore

<sup>2</sup>Monash University, Faculty of Medicine- Nursing and Health Sciences Medical Imaging & Radiation Sciences, Melbourne, Australia

<sup>3</sup>Duke-NUS, Graduate Medical School, Singapore, Singapore

### Purpose or Objective

Kilovoltage cone-beam computed tomography (kVCBCT) has often been regarded as the preferred imaging modality for the visualisation of soft tissues and verification of treatment position due to its superior spatial resolution [1-3]. Transperineal ultrasound (TPUS) is an alternative imaging tool that can be employed for pre-treatment verification and in-treatment monitoring as it is non-invasive and does not involve additional imaging dose [4, 5]. This study aimed to compare the daily inter-modality derived setup shifts using TPUS versus kVCBCT (gold standard) for prostate radiotherapy.

### Material and Methods

A total of 1927 paired datasets (TPUS versus kVCBCT) from 55 patients were compared in three directions (i.e. x,y,z shifts representing left/right, anterior/posterior and superior/inferior directions respectively). The derived setup shifts were reported to the nearest mm. Data were analysed using PASW for windows, version 20.0 (SPSS Inc, Chicago, IL). Observed differences in the derived shifts for each imaging modality were reported. Statistical tests were conducted under a two-tailed significance level, at a minimum 95% confidence interval.

### Results

A Shapiro-Wilk test revealed that the data was not normally distributed ( $p < 0.05$ ). A non-parametric Wilcoxon Signed Ranks test demonstrated no statistically significant difference between the derived setup shifts from TPUS and kVCBCT for all planes; x ( $p = 0.376$ ), y ( $p = 0.244$ ) and z ( $p = 0.253$ ). The proportion (%) of datasets where the difference in the derived shifts between the two imaging modalities were within 5/4/3mm in the x, y and z directions are reported in Table 1. Spearman's rank correlation coefficients of the derived shifts were moderate (0.612-0.671) for all three directions ( $p < 0.005$ ), signifying that the accuracy of TPUS-derived setup shifts was comparable to kVCBCT.

**Table 1:** Proportion of datasets where the difference in the derived shifts between the two imaging modalities were within 5/4/3mm in the x, y and z directions.

	x	y	z
Mean diff (mm)	0.0	0.0	0.0
% diff within +/-5mm	97.0%	92.7%	93.6%
% diff within +/-4mm	93.4%	88.0%	87.2%
% diff within +/-3mm	86.2%	76.8%	77.9%

### Conclusion

Measured differences were acceptable considering the planning target volume (PTV) margin expansion was 10mm in all directions, except posteriorly (6mm). Findings were in agreement with the recent report by Trivaldi *et al.* [6] who found no significance difference in the x, y and z coordinates between TPUS and fiducial-based CT localisation of the prostate gland. With specialised training and user experience, TPUS is a promising imaging modality in treatment setup and verification for prostate radiotherapy without the need for additional exposure to ionising radiation.

### OC-0166 Fast 3D CBCT imaging for Lung SBRT: Is image quality preserved ?

B. De Rijcke<sup>1</sup>, R. Van Geeteruyen<sup>1</sup>, E. De Rijcke<sup>1</sup>, Y. Lievens<sup>1</sup>, E. Bogaert<sup>1</sup>

<sup>1</sup>Ghent University Hospital, Radiation Oncology, Gent, Belgium

### Purpose or Objective

Irradiation of Early Stage Non-Small Cell Lung Cancer (ES-NSCLC), through Stereotactic Body Radiotherapy (SBRT) requires image guidance. At our institute double pre-treatment CBCT, with manual registration is performed at every fraction. Speeding up CBCT gantry rotation and implementation of automated registration allows for faster decision taking. It also offers the possibility of intrafraction CBCT, without severe prolongation of treatment time. In a first step we investigated the image quality and performance of a CBCT protocol with lower dose and faster acquisition time.

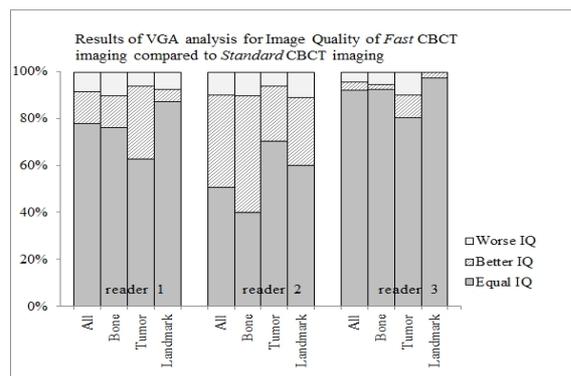

### Material and Methods

Standard (S) and Fast (F) scan protocols only differed in gantry speed (180°/min (S) and 360°/min (F)) and were performed on XVI Elekta® CBCT. For six patients receiving lung SBRT (60Gy in 3 or 4 fractions) for upper lobe ES-NSCLC, dual pre-treatment imaging consisted of a S scan followed by a F scan. This resulted in 17 useful S and F image sets. Tumor movement amplitude stayed below 1cm<sup>(1)</sup>, removing the necessity for 4D-CBCT. All CBCT images were retrospectively exported to Raystation® (RaySearch Laboratories, Sweden) for easy and blended side-by-side evaluation. The resolution was 1x1x1mm<sup>3</sup> for all scans. All CBCT images were matched to planning CT. WW/WL was set fixed per patient. Zooming was allowed.

Visual Grading Analysis (VGA) comprised well defined criteria over the three planes (T, C, S), categorized in three Image Quality (IQ) Focus groups: bony anatomy (N=11), tumor characteristics (N=3) and anatomical landmarks (N=7). Examples are: visualization of corpus vertebrae (C, S plane), tumor edge (3 planes); carina bifurcation (C, T plane). Scoring was done independently by 3 routined RTTs. Possible answers were: equal, better or worse for 'upper' scan (randomly assigned to F or S). Data were analyzed using SPSS software v24 (IBM Corp., New York, NY).

### Results

In 73.7 % of all cases, visualization of anatomical structures was appreciated equally on S and F scans. When differences emerged, visualization on F scan was appreciated more in 71.3 % of the cases (71.8 % for bony anatomy, 75.0 % for tumor characteristics and 67.2 % for anatomical landmarks). Binary Logistic Regression in these cases did not reveal significant dependence on patient (for which BMI or tumor location are most relevant; however not evaluated separately) ( $p = 0,638$ ), not on IQ focus group ( $p = 0,540$ ) and not on reader ( $p = 0,883$ ). Thus, in 92.4 % of all cases, image quality was scored equal or better for fast imaging protocol compared to the standard protocol (Figure 1).

### Conclusion

Fast CBCT imaging can be safely used for ES-NSCLC tumors with tumor movement amplitude < 1cm. In 73.7 % of the cases there is no image quality loss and even more, in 18.8 % of the cases IQ of the fast scan is preferred compared to the standard scan.

### Symposium: Novel approaches in particle biology

#### SP-0167 The ESTRO initiative on biological effects of particle therapy

B.S. Sørensen<sup>1</sup>

<sup>1</sup>Aarhus University Hospital, Exp. Clin. Oncology, Aarhus C, Denmark

Particle therapy as cancer treatment, with either protons or heavier ions, provide a more favourable dose distribution compared to x-rays. While the physical characteristics of particle radiation have been the aim of intense research, less focus has been on the actual biological responses particle irradiation gives rise to. One of the biggest challenges for the radiobiology is the RBE, with an increasing concern that the clinical used RBE of 1.1 is an oversimplification, as RBE is a complex quantity, depending on both biological and physical parameters, as dose, LET, biological models and endpoints. Most of the available RBE data is in vitro data, and there is very limited in vivo data available, although this is a more appropriate reflection of the complex biological response. There is a need for a systematic, large-scale setup to thoroughly establish the RBE in a number of different models, in a clinical relevant fractionated scheme. The aim of the ESTRO initiative is to form a network of the research and therapy facilities. This would open for the possibility of standardising radiobiological experiments, and coordinating the research in order to deliver the needed experimental data.

#### SP-0168 RBE of protons

B. Jones<sup>1</sup>

<sup>1</sup>Jones Bleddyn, CRUK-MRC Oxford Institute- Department of Oncology, Oxford, United Kingdom

**Introduction.** Increasing clinical use of proton therapy (PT) is not simply an extension of photon radiotherapy (RT), but requires more detailed knowledge of clinical physics and radiobiology in order to achieve optimal outcomes. A critical difference is that megavoltage RT has linear energy transfer (LET) of around  $0.22 \text{ keV} \cdot \mu\text{m}^{-1}$ , but LET further increases towards and within proton Bragg peaks. 'Spread-out' Bragg peaks (SOBP), depending on their volume, normally have LET of  $1-2 \text{ keV} \cdot \mu\text{m}^{-1}$ , but

higher values between  $2-10 \text{ keV} \cdot \mu\text{m}^{-1}$  can be found in treatment plans.

### Methods and Results:

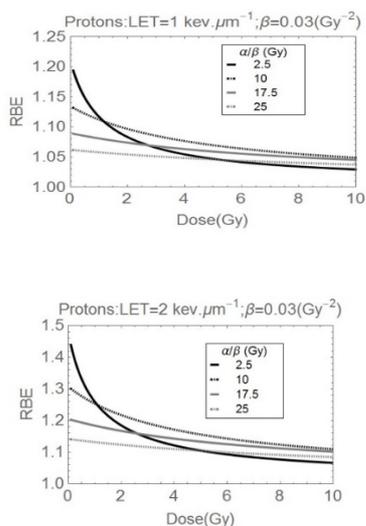

Studies concluding that the mid-SOBP relative biological effect (RBE) of protons is 1.1 for all tissues and tumours at all doses per fraction have recently been criticised due to their use of:

1. kilovoltage x-ray controls (which mostly provide RBE values less than 1 and should be excluded),
2. a very limited number of cell lines,
3. a predominance of high doses per fraction (as used for eye melanomas),
4. linear-only fitting (rather than linear quadratic),
5. animal based studies that used only acute reacting tissues (with high  $\alpha/\beta$  ratios), known to show little RBE change with dose per fraction when using fast neutrons (which ionise mostly by forming recoil protons). No classical late reacting (low  $\alpha/\beta$ ) tissue RBEs have been published so far: it is these tissues that will influence PT late effects for important normal tissues within the PTV and closely around it. Of prime concern is neurological tissue with  $\alpha/\beta$  of 2 Gy. Using a scaling model based on the original work of Wilkens & Oelfke, but with added saturation effects for increases in both  $\alpha$  and  $\beta$  with LET, figures 1 and 2 shows the predicted RBEs in the range of LET normally in the SOBP ( $1-2 \text{ keV} \cdot \mu\text{m}^{-1}$ ) and the general increase in RBE with LET and decrease of RBE with dose per fraction; at higher values of LET ( $2-10$ ) further increases in RBE occur, in some cases to beyond 2 at LETs of  $6-10$ .

Outside the brain, other normal tissue types may carry lesser importance so that, for example, a slightly raised RBE in muscle may not produce enhanced late effects in a very confined volume, as may serially organised tissues such as lung and liver, but cardiac tissue, bowel and kidney remain at risk depending on the volume irradiated. One intriguing aspect is the fall of RBE with increased dose per fraction, especially in tissues with low  $\alpha/\beta$  values, which may encourage the use of carefully estimated hypofractionated total doses, using BED equations with imbedded RBE limits: the  $RBE_{max}$  and  $RBE_{min}$  (respectively reflecting the change in  $\alpha$  and  $\beta$  with LET): Figures 1 and 2 show how different  $\alpha/\beta$  ratio bio-systems may behave with the lowest  $\alpha/\beta$  system crossing over to have the lowest RBE at higher doses. Values lower than 1.1 can occur in high  $\alpha/\beta$  systems, with risk of underdosage if a 1.1 RBE is used.

**Conclusions.** There should be no complacency about RBE values, even within SOBP's: 1.1 is not be appropriate. These higher values may explain some reported adverse toxicities following PT, such as necrosis of the optic chiasm and temporal lobe, and failure to cure some very radiosensitive tumour types with high  $\alpha/\beta$  (lymphomas and many childhood cancers). Comprehensive RBE studies are urgently indicated.

<sup>4</sup>Helmholtz-Zentrum Dresden - Rossendorf, Institute of Radiooncology, Dresden, Germany

<sup>5</sup>OncoRay - National Center for Radiation Research in Oncology- Faculty of Medicine and University Hospital Carl Gustav Carus-Technische Universität Dresden, Department of Radiation Oncology, Dresden, Germany

<sup>6</sup>German Consortium for Translational Cancer Research DKTK and German Cancer Research Center DKFZ, Dresden Site, Dresden, Germany

**Introduction:** The long-term aim of developing laser-based acceleration of protons and heavier ions towards clinical radiation therapy application requires not only substantial technological progress, but also the radiobiological characterization of the resulting ultra-short and ultra-intensive particle beam pulses. Recent in vitro data showed similar effects of laser-accelerated versus conventional proton beams on clonogenic cell survival and DNA double-strand breaks. As the proton energies currently achieved for radiobiological experiments by laser-driven acceleration are too low to penetrate standard tumour models on mouse legs, a small animal tumour model allowing for the penetration of low energy protons (~20 MeV) was developed to further verify the effects in vivo.

**Methods:** The mouse ear tumour model was established for human HNSCC FaDu and human glioblastoma LN229 cells. For this, cells were injected subcutaneously in the right ear of NMRI nude mice and the growing tumours were characterized with respect to growth parameters and histology. After optimizing the number of injected cells and used medium (PBS, Matrigel) the radiation response was studied by 200 kV X-ray irradiation. Furthermore, a proof-of-principle full scale experiment with laser-accelerated electrons was performed to validate the FaDu

tumour model under realistic, i.e. harsh, conditions at experimental laser accelerators.

**Results:** Both human tumour models showed a high take rate and continuous tumour growth after reaching a volume of ~5 - 10 cubic millimetres. Moreover, immunofluorescence analysis revealed that already the small tumours interact with the surrounding tissue and activate endothelial cells to form vessels. By analysing the dose dependent tumour growth curves after 200 kV X-ray treatment a realistic dose range, i.e. for inducing tumour growth delay but not tumour control, was defined for both tumour entities under investigation. Beside this basic characterization, the comparison of the influence of laser-driven and conventional (clinical Linac) electron beams on the growth of FaDu tumours reveal no significant difference in the radiation induced tumour growth delay. **Conclusion:** The mouse ear tumour model was successfully established and optimized providing stable tumour growth with high take rate for two tumour entities (HNSCC, glioblastoma) which are of interest for patient treatment with protons. Experiments comparing laser-driven and conventional proton beams in vivo as the next step towards clinical application of laser-driven particle acceleration are under way.

**Acknowledgement:** The work was supported by the German Government, Federal Ministry of Education and Research, grant nos. 03ZIK445 and 03Z1N511.

#### SP-0170 Novel models in particle biology research

P. Van Luijk<sup>1</sup>

<sup>1</sup>van Luijk Peter, Department of Radiation Oncology, Groningen, The Netherlands

The unique behaviour of particles that causes them to reach maximum dose deposition at the end of their track makes them useful for facilitating both treatment intensification and reduction of normal tissue damage. On a macroscopic scale particles facilitate reducing normal tissue dose and irradiated volume. Though it has been known for a long time that reducing the amount of irradiated normal tissue reduces toxicity, the increased precision of particles also makes sparing of substructures possible and offers more flexibility in choosing how to distribute inevitable excess dose over the normal tissues. However, it is also these unique properties that limit the information in available clinical data that can be used to guide optimal use of particles. Filling this gap is an important topic of particle radiobiology that has been approached with various in vivo models.

On a microscopic scale particles deposit dose with a higher ionization density, especially near the end of the particle track, usually positioned in the target volume. Increased ionization density has been demonstrated to change response, both in terms of severity and potentially even in type. These effects have been studied mostly in 2D in vitro models. However, even though in 2D cell cultures differential effects between high- and low-LET radiation are observed, these models seem to be more radiosensitive than one would expect based on clinical data. Interestingly it has been observed that cells respond markedly different when irradiated in a more tissue-equivalent 3D culture system.

Moreover, recent insights from stem cell biology indicate a potentially critical role of stem cells both in tumour and normal tissue response. Taken together, 3D culture systems based on tissue-specific stem cells may offer new opportunities to better understand the response of tumours and normal tissues to particle irradiation.

#### OC-0171 Multiparametric MRI margin characterization for focal brachytherapy in low-grade prostate cancer

S. Ken<sup>1</sup>, F. Arnaud<sup>1</sup>, R. Aziza<sup>2</sup>, D. Portalez<sup>2</sup>, B. Malavaud<sup>3</sup>, J. Bachaud<sup>4</sup>, P. Graff-Cailleaud<sup>4</sup>, S. Arnault<sup>5</sup>, A. Lusque<sup>5</sup>, T. Brun<sup>1</sup>

<sup>1</sup>Institut Universitaire du Cancer - Oncopole - Institut Claudius Regaud, Medical Physics and Engineering, Toulouse, France

<sup>2</sup>Institut Universitaire du Cancer - Oncopole - Institut Claudius Regaud, Radiology, Toulouse, France

<sup>3</sup>Institut Universitaire du Cancer - Oncopole - CHU de Toulouse, Urology, Toulouse, France

<sup>4</sup>Institut Universitaire du Cancer - Oncopole - Institut Claudius Regaud, Radiotherapy, Toulouse, France

<sup>5</sup>Institut Universitaire du Cancer - Oncopole - Institut Claudius Regaud, Bureau des Essais Cliniques, Toulouse, France

### Purpose or Objective

Focal brachytherapy is proposed in our institute as an alternative treatment to active surveillance for low-grade prostate cancer (PCa). This study aims at characterizing the tumor focus and its margin with multiparametric Magnetic Resonance Imaging (mpMRI) in order to prepare the clinical protocol of focal brachytherapy.

### Material and Methods

Patients pre-qualified for this study were positive for PCa (Gleason 3+3) on a previous standard biopsy series. New series of mp-MRI-guided and ultrasound-targeted biopsies were performed and in total, 17 patients with confirmed tumor and diameter <20mm were included in this phase II clinical trial (NCT01902680). mpMRI were acquired on a 1.5T Magnetom Aera Siemens scanner with 18-channel surface body coil. Anatomic imaging consists in Fast Spin Echo T2-weighted MRI (T2-MRI). In addition, same in-plane acquisition of functional Diffusion Weighted MRI (DWI-MRI) and Dynamic Contrast Enhanced MRI (DCE-MRI) were performed.

After mpMRI registration, tumor volumes of interest (VOI) were drawn on anatomic T2-MRI. VOI and VOI+2mm were reported on functional DWI-MRI and DCE-MRI (Figure 1). Extracted parameters were Apparent Diffusion Coefficient (ADC) and KTrans. All parameters distributions were analyzed with Olea Sphere v3.0 and compared to contralateral normal appearing tissue.

Focal brachytherapy was then delivered to all patients with linked <sup>125</sup>I seeds with a dose prescription of 152 Gy on the Planning Target Volume (PTV=VOI+2mm).

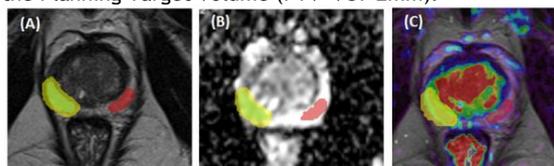

Figure 1: Tumor volume of interest (VOI) defined on abnormal T2-MRI (A) is highlighted in green. VOI+2mm margin is delineated in yellow and contralateral normal appearing tissue is defined in red. All these volumes are reported on ADC (B) and Ktrans (C) modalities for multi-parametric analysis.

### Results

ADC parameters (mean, median, 25th and 75th percentiles) are found to be significantly lower in tumor volume (VOI) compared to contralateral normal tissue ( $p < 0.012$  for all ADC parameters), confirming diffusion tumor mass restriction. Different distributions of ADC and Ktrans were observed among patients (Figure 2). Majority (66.66%) of low ADC and abnormal Ktrans values were included in the VOI. Interestingly, the 2mm margin allows us to treat additional abnormal ADC and KTrans volumes on 1/3 of the patients.

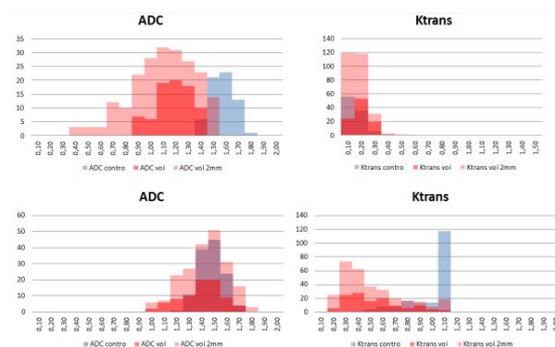

Figure 2: Examples of ADC and Ktrans histograms. On top line, the patient presents important volumes of abnormal low values of ADC in VOI and VOI+2mm where as the distribution of Ktrans values in VOI and VOI+2mm follow the same distribution as in the contralateral volume. On bottom line, the patient has a distribution of ADC in VOI and VOI+2mm similar to the normal ADC values where as low values of Ktrans are observed.

### Conclusion

This study confirms that mpMRI is a non-invasive technique able to characterize tumor margin in low-grade PCa. Tumor characterization and delineation is a crucial step in focal brachytherapy as only sub-volume of the prostate is treated with high gradient dose levels. Target volume margin definition is a hot topic when focal treatments (e.g. cryotherapy or HIFU) are considered and mpMRI can bring quantitative answers.

### OC-0172 interstitial salvage HDR-brachytherapy for recurrent prostate cancer after radiation therapy

P. Jiang<sup>1</sup>, C. Van der Horst<sup>2</sup>, B. Kimmig<sup>1</sup>, F. Zinsser<sup>1</sup>, B. Poppe<sup>3</sup>, U. Luetzen<sup>4</sup>, K.P. Juenemann<sup>5</sup>, F.A. Siebert<sup>1</sup>, J. Dunst<sup>1</sup>

<sup>1</sup>UKSH- Campus Kiel, Department of Radiation Oncology, Kiel, Germany

<sup>2</sup>Community Clinic Kiel, Department of Urology-, kiel, Germany

<sup>3</sup>Medical Campus Pius-Hospital- Carl von Ossietzky University, University Clinic for Medical Radiation Physics-, Oldenburg, Germany

<sup>4</sup>UKSH- Campus Kiel, Department of Nuclear Medicine, Kiel, Germany

<sup>5</sup>UKSH- Campus Kiel, Department of Urology, Kiel, Germany

### Purpose or Objective

There is growing literature on local salvage treatments following definitive radiation. However, data employing interstitial high dose rate brachytherapy (HDR-BT) for salvage treatment are rare, especially those with long-term outcomes. This is a report of our results as a unique published cohort with salvage HDR-BT after previous HDR-BT treatment (Jiang et. al. 2016, brachytherapy, paper in pressed). Emphasis was put on 5-year outcome and toxicity.

### Material and Methods

From 2009 to 2014, 29 patients with local failure after previous radiotherapy for prostate cancer were treated with salvage interstitial HDR-BT. Primary treatment was combined external beam irradiation (EBRT) with 50Gy plus HDR-BT-boost with 30 Gy in 27 patients. The primary treatment carried the total dose to a combined biologic equivalent dose in 2 Gy per fraction of about 178 Gy, by assuming an  $\alpha/\beta$  ratio of 1.5 for the tumor and about 146 Gy by an  $\alpha/\beta$  ratio of 3. 2 patients had undergone EBRT with 66.6 Gy of the prostate bed as salvage treatment after prostatectomy. The interval between primary treatment and salvage treatment was 5.5 years (mean  $\pm$  SD: 5.5  $\pm$  2.8 years).

All 29 patients had biochemical failure according to the Phoenix definition. The diagnosis of local recurrence was made on the basis of F-18 labeled cholin-PET. The presence or co-existence of regional lymph node and/or distant metastases was excluded by imaging methods.

Salvage HDR-BT was given in 3 fractions with weekly intervals. The target volume covered the peripheral zone of the prostate and the PET-positive area and was treated with 10 Gy per fraction. The isodose coverage of the treatment in clinical practice followed this priority: the peripheral zone > rectum > urethra > the whole gland. The biologic equivalent dose of the salvage brachytherapy in 2 Gy per fraction was 98 Gy by assuming an  $\alpha/\beta$  ratio of 1.5 and 78 Gy by a  $\alpha/\beta$  ratio of 3.

Overall survival (OS) and biochemical failure were calculated after the salvage brachytherapy using the Kaplan-Meier method. Acute and late genitourinary and gastrointestinal toxicities were documented according to common terminology criteria for adverse events (CTCAE v 4.0).

#### Results

22 patients had a minimum follow-up of 60 months after salvage treatment. 3 patients died after salvage treatment; causes of death were malignant melanoma, multiple organ failure and pneumonia. The 5-year OS was 95.5% with a disease-specific survival of 100% after 5 years. The 5-year biochemical control was 45%. Late grade 2 gastrointestinal toxicities were observed in 2 patients (9%). No grade 3 or higher gastrointestinal late toxicities were observed. Urinary incontinence was found in 2 patients (9%) and grade 2 obstruction of urinary tract occurred in 1 patient (4%).

#### Conclusion

Interstitial HDR brachytherapy was feasible and effective in the treatment of locally recurrent prostate cancer after definitive radiotherapy. The long-term toxicity was low and acceptable.

#### OC-0173 Low incidence of severe toxicity by focal salvage HDR brachytherapy in prostate cancer recurrences

M. Maenhout<sup>1</sup>, M. Van Vulpen<sup>1</sup>, M.A. Moerland<sup>1</sup>, M. Peters<sup>1</sup>, M.A.A. Van den Bosch<sup>2</sup>, J.R.N. Van der Voort van Zyp<sup>1</sup>

<sup>1</sup>UMC Utrecht, Department of Radiation Oncology, Utrecht, The Netherlands

<sup>2</sup>UMC Utrecht, Department of Radiology, Utrecht, The Netherlands

#### Purpose or Objective

Whole gland salvage treatment for locally recurrent prostate cancer after primary radiotherapy has a high rate of severe toxicity. The standard of care in case of a local recurrence is androgen deprivation therapy (ADT), which has significant side-effects and influence on quality of life. Focal salvage treatment might lead to acceptable toxicity and concurrently postpone or even avoid the use of ADT. Here, acute toxicity and preliminary biochemical outcomes are described after MRI-guided focal salvage high dose rate (HDR) brachytherapy in patients with radiorecurrent prostate cancer.

#### Material and Methods

17 patients with a pathology proven local recurrence have been treated with an outpatient single fraction of 19Gy focal HDR brachytherapy in a suite equipped with a 1.5 Tesla MRI scanner for treatment guidance. Primary radiotherapy consisted of external beam radiotherapy or brachytherapy. Gross tumor volume (GTV) delineation was performed using Ga-68-PSMA or F18-Choline PET together with multiparametric 3.0Tesla MRI in all patients. A margin inside the prostate of 5 mm was added to define clinical target volume (CTV) and no margin for planning target volume (PTV) was added. Catheters were inserted under ultrasound guidance and definitive treatment planning was based on the actual MRI based catheter positions and delineations. All patients had a PSA at time of recurrence of <10ng/mL and a PSA-doubling time of  $\geq 1$  year. Toxicity was measured using the CTCAE version 4.

#### Results

In all treatments constraints to rectum, bladder and urethra were met. Average dose to the treatment volume was D95: 18.9Gy (SD 2.4Gy). On average 9.4 catheters (range 6-13) were used. Treatment volume was on average 7.4cc (SD 2.9cc). With a median follow-up of 6 months (range 1-24 months) a biochemical recurrence according to Phoenix criteria (rise of > 2 ng/mL) had occurred in 1 of 17 patients. There was one patient with late grade 3 urinary incontinence toxicity.

#### Conclusion

Focal salvage treatment for local recurrence after primary external beam radiotherapy or brachytherapy is an effective treatment modality with regards to acute toxicity. Whether this treatment option might lead to cure or successfully postpone ADT with acceptable long term toxicity needs further investigation.

#### OC-0174 Salvage LDR-brachytherapy for recurrent prostate cancer: results from a single institution

S. Magrini<sup>1</sup>, F. Barbera<sup>1</sup>

<sup>1</sup>Spedali Civili di Brescia, Department of Radiation Oncology "Istituto del Radio", Brescia, Italy

#### Purpose or Objective

To evaluate the results of whole gland salvage brachytherapy (SBT) after primary external beam radiotherapy in terms of toxicity/QoL and efficacy.

#### Material and Methods

We retrospectively analyzed the clinical data of 19 patients consecutively treated with SBT at our Institution from June 2012 through November 2015. Local recurrences were identified with 11C-Choline PET/CT and MRI after biochemical recurrence according to Phoenix criteria. The prescription dose was 130Gy-LDR-BT to the whole prostate gland. Acute and late toxicities were graded with the CTCAE-4.0 scoring system. Data from IPSS (International Prostatic Symptoms Score) and IIEF (International Index of Erectile Function) questionnaires at baseline and at 6, 12 and 24 months after SBT were also reported (higher IPSS and lower IIEF indicate deterioration). Univariate analysis was done to identify predictors of biochemical control and toxicities.

#### Results

Median follow up after SBT was 24 months. Observed severe late toxicities were as follows: 2/19 G3 cystitis (10,2%) and 1/19 G4 proctitis (5,3%). Median IPSS scores pre-SBT and after 6,12,24 months were respectively 4,11,12 and 5. Median IIEF score pre-SBT and after 6,12,24 months were respectively 5,2,4 and 4. At the time of analysis 2/19 patients showed biochemical relapse (3-years-FFBF 85,2%). At univariate analysis only interval to relapse after primary EBRT < 70 months ( $p=0,05$ ) and PSA reduction between pre-and post SBT level > 80% ( $p=0,008$ ) were significantly related to further biochemical failure. No statistically significant correlations were found between IPSS and IIEF score before SBRT and post treatment toxicity.

#### Conclusion

SBT for recurrent prostate cancer after primary EBRT seems to be a feasible treatment for selected patients. The severity of the observed toxicities shows a peak after 6 months/1 year after local re-treatment and then decreases. Early FFBF rates are good. These preliminary results suggest further accrual of patients and the collection of longer term data.

#### OC-0175 Salvage HDR-BT in prostate local recurrence after radiation therapy: Retrospective analysis

C. De la Pinta<sup>1</sup>, T. Muñoz<sup>1</sup>, C. Vallejo<sup>1</sup>, S. Sancho<sup>1</sup>, F. López<sup>1</sup>, M. Martín<sup>1</sup>, A. Hervás<sup>1</sup>

<sup>1</sup>Hospital Ramon y Cajal, Radiation Oncology, Madrid, Spain

### Purpose or Objective

The aim of this study was to evaluate the acute and late toxicities and biochemical disease-free survival and overall survival after high-dose-rate brachytherapy as a salvage modality for locally recurrent prostate radiotherapy failure.

### Material and Methods

Between 2007 and 2014, we retrospectively analyzed 20 consecutively patients. Median age of first treatment was 62 years (range 51-73). The majority of the patients in this study (65%) were low risk. 5p received hormonal blockade. 11p received treatment with low-dose-rate brachytherapy (LDR-BT) and 9p received treatment with external beam radiotherapy with median dose of 75Gy (70-78Gy). Time to biochemical recurrence was 62 months (range 14-119). Median presalvage PSA was 3.72 (range 1.83-12.29). After biochemical relapse, we confirm local recurrence with biopsy. Patients received high-dose-rate brachytherapy (HDR-BT). The schedule was three implantations, every two weeks, with 10,5Gy per implant. By the time of salvage BT, only 1p received ADT. Acute and late genitourinary and gastrointestinal toxicities were graded using Common Terminology Criteria for Adverse Events (CTCv4.0). Overall survival (OS) and biochemical (bDFS) control were calculated using Kaplan-Meier method.

### Results

After first treatment, acute toxicities consisted of genitourinary toxicities grade 1 (3p) and grade 3 (1p). Not late gastrointestinal toxicities.

After HDR-BT, acute toxicities consisted of genitourinary grade 1 (4p), grade 2 (5p) and grade 3 (3p), gastrointestinal toxicities grade 1 (3p) and grade 2 (4p) and impotence in 4p. Not acute toxicities grade 4 were reported.

Late toxicities consisted of genitourinary grade 3 were observed in 2p. Not grade 4 complications.

With a median follow-up after salvage HDR-BT of 47 months (range 11-112 months), local control was achieved on PSA levels in all patients.

Among 20 patients studied, 1 lost follow-up and he was excluded from the survival analysis.

Using Kaplan-Meier analysis the 2-year and 5-year OS were 100% and 84,2%, respectively. The 2-year and 5-year biochemical disease-free survival (bDFS) were 85% and 81%, respectively.

### Conclusion

Prostate BT is an effective salvage modality in some selected prostate local recurrence patients after radiation therapy.

HDR-BT is a good choice to deliver high-dose radiation in prostate recurrence tumors after external beam radiotherapy or LDR-BT. This treatment offers adequate locoregional control with acceptable range of complications.

### OC-0176 Identifying Patients Who Benefit the Most from Salvage HDR Brachytherapy

G. Valdes<sup>1</sup>, A.J. Chang<sup>1</sup>, O. Kenton<sup>1</sup>, A. Cunha<sup>1</sup>, T.D. Solberg<sup>1</sup>, H. I-Chow<sup>1</sup>

<sup>1</sup>University of California at UCSF, Radiation Oncology, San Francisco CA, U SA

### Purpose or Objective

To use machine learning to better identify patients that could benefit from prostate salvage HDRB (HDR brachytherapy).

### Material and Methods

Data was analyzed for 52 consecutively accrued patients that underwent salvage HDRB between 1998 and 2009 for locally recurrent prostate cancer following previous definitive radiation therapy at the University of California, San Francisco (UCSF). All patients were treated with 36 Gy in 6 fractions after pathologic confirmation of locally recurrent disease without evidence of metastatic

disease. Determination of biochemical failure after salvage HDRB was based on the Phoenix definition. All non-failure patients were followed for a minimum of 5 years. Eighteen different clinical risk features were collected from each patient. Machine Learning was used to identify subpopulations that would most likely to remain biochemically disease free after the treatment. Decision tree algorithms were constructed using Matlab R 2011a. The complexity of the decision tree was fine-tuned by selecting the optimum number of observations per terminal node that minimized the "Leave One Out Cross-Validation" estimation of the deviance. Results were compared to those obtained using Ensemble Methods. Random permutation experiments were also performed to estimate the probability that the tree found was the result of random variations.

### Results

A subpopulation of patients with a high risk of biochemical failure after salvage HDRB was identified. Those patients with a fraction of positive nodes from those sample that was greater than 0.354 and disease free interval less than 4.12 years had a failure rate after salvage HDRB of 0.75 vs 0.38 for the remainder of the population, Figure 1. The probability that the conclusions reached in this paper are not due to random fluctuations is 0.7, Figure 2.

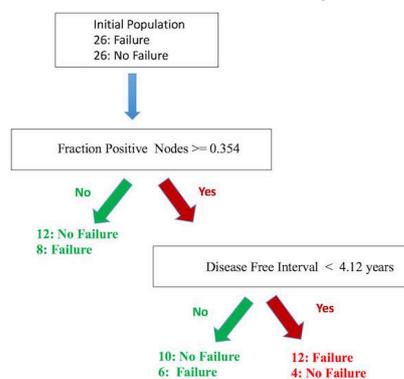

Figure1. The Optimal Decision Tree obtained for predicting failure after Salvage HDRB.

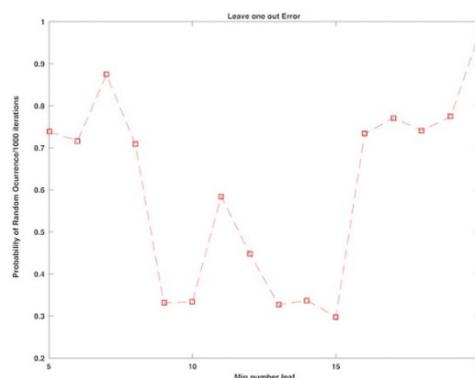

Figure 2. Random permutation of output labels. 1000 iterations were created in each case were the outcome of was randomly permuted. Not correlation between features and outcome should be present in this case. The probability of obtaining a cross-validated leave one out error smaller than the one obtained by the tree in Figure 1 was calculated.

### Conclusion

Patients with a fraction of positive nodes higher than 0.35 and a disease free interval bigger than 4.12 years are at higher risk of biochemical failure after salvage HDRB. Machine Learning is effective in identify subtle variables that can affect the treatment outcome.

**OC-0177 Brachytherapy for the Palliation of Dysphagia Owing to Esophageal Cancer: A Systematic Review.**

L. Fuccio<sup>1</sup>, D. Mandolesi<sup>1</sup>, A. Farioli<sup>1</sup>, C. Hassan<sup>2</sup>, L. Frazzoni<sup>1</sup>, A. Guido<sup>3</sup>, F. Violante<sup>1</sup>, C. Pierantoni<sup>1</sup>, A. Galuppi<sup>3</sup>, F. Bazzoli<sup>1</sup>, A. Repici<sup>4</sup>, A. Morganti<sup>3</sup>

<sup>1</sup>*S.Orsola-Malpighi University Hospital, Department of Medical and Surgical Sciences, Bologna, Italy*

<sup>2</sup>*Nuovo Regina Margherita Hospital, Gastroenterology Unit, Rome, Italy*

<sup>3</sup>*S.Orsola-Malpighi University Hospital, Radiation Oncology Unit, Bologna, Italy*

<sup>4</sup>*Humanitas Research University Hospital, Endoscopy Unit, Rozzano MI, Italy*

**Purpose or Objective**

The management of dysphagia owing to esophageal cancer is challenging. Brachytherapy has been proposed as an alternative option to stent placement. We performed a systematic review to examine its efficacy and safety in the resolution of dysphagia.

**Material and Methods**

Prospective studies recruiting at least 20 patients with malignant dysphagia and published up to April 2016 were eligible. The dysphagia-free survival (DFS) and adverse event rates were pooled by means of a random effect model.

**Results**

Six studies for a total of 9 treatment arms (623 patients) were eligible for inclusion. After 1 month since treatment, the DFS rate was 86.9% [95%CI: 76.0%-93.3%]; after 3 months, it was 67.2% [95%CI: 56.1%-76.7%]; after 6 months, it was 47.4% [95%CI: 38.5%-56.5%]; after 9 months, it was 37.6% [95%CI: 30.0%-45.9%]; and, finally, after 12 months, it was 29.4% [95%CI: 21.6%-38.7%]. The heterogeneity between studies was high at 1-, 3- and 6-month assessment; the values of  $I^2$  were 86.3%, 80.0% and 57.8%, respectively. The meta-regression analysis showed total radiation dose and number of fractions as the only positively influencing factors. Severe adverse event rate was 22.6% (95%CI 19.4-26.3). The main reported adverse events were brachytherapy-related stenosis (12.2%) and fistula development (8.3%). Two cases (0.3%) of deaths were reported due to esophageal perforation.

**Conclusion**

Brachytherapy is a highly effective and relatively safe treatment option therefore its underuse is no longer justified. Further studies should investigate the optimal radiation dose and number of fractions able to achieve the highest DFS rates.

**OC-0178 Demonstration of Catheter Insertion Using Electromagnetic Guidance in Breast Brachytherapy**

H. Brastianos<sup>1</sup>, T. Vaughan<sup>2</sup>, A. Lasso<sup>2</sup>, M. Westerland<sup>1</sup>, J. Gooding<sup>1</sup>, T. Ungi<sup>2</sup>, G. Fichtinger<sup>2</sup>, C. Falkson<sup>1</sup>

<sup>1</sup>*Queen's University Cancer Research Institute, Radiation Oncology, Kingston- Ontario, Canada*

<sup>2</sup>*Queen's University, School of Computing, Kingston- Ontario, Canada*

**Purpose or Objective**

Accelerated partial breast irradiation using multi-catheter interstitial brachytherapy may be used for early stage breast cancers. To ensure ideal dosimetry over the tumor bed, the catheters need to be placed in parallel with equal spacing. The breast is a deformable organ; thus, placing catheters in the correct position is challenging. To ensure adequate spacing and position, we will apply real-time electromagnetic guidance (EM) in combination with ultrasound (US) to optimize the catheter insertions. This study will discuss the use of electromagnetic tracking catheter with ultrasound to insert catheters in phantoms.

**Material and Methods**

Anthropomorphic plastic phantoms were made with each having a simulated tumor bed that can be visualized using both ultrasound and CT. In the control, arm, the tumor is identified using ultrasound and inserted under ultrasound guidance.

A tissue-locking needle and US probe are equipped with a real-time EM tracker. Under US guidance, the localization needle is placed within the tumor bed, which provides a rigid reference. The cavity is then contoured on US, creating a model in a virtual view. An EM tracked needle guide is pointed at the tumor bed and the catheter needle is inserted through the guide into the tissue. Additional parallel catheters are planned on the virtual view based on the first insertion and implanted in the target. The guidance software is built on the 3D Slicer ([www.slicer.org](http://www.slicer.org)) and SlicerIGT ([www.slicerigt.org](http://www.slicerigt.org)) open source platforms.

In these experiments, a total of 10-15 catheters were inserted in each of the six phantoms. The goal was to place each catheter within the tumor bed. Three phantoms had catheter needles inserted with ultrasound only, while the other three had catheters inserted with combined EM tracking and US guidance. All six insertions were conducted by the same operator and the placement of the catheters was determined with CT.

**Results**

Under US guidance only in the three phantoms, 17 out of 26 catheters passed through the tumor bed. The average mean spacing was 0.86 cm +/- 0.33 cm. Under combined EM tracking and US guidance, 35 out of 40 catheters passed through the tumor bed. The average mean spacing was 1.05 +/- 0.19 cm.

**Conclusion**

These phantom experiments verify that EM tracking can be used to target catheter needles to the tumor bed. Additional research is currently being performed to translate this technique to patient trials.

**OC-0179 Dosimetric impact of errors in HDR-iBT of the breast using a catheter tracking method**

M. Kellermeier<sup>1</sup>, B. Hofmann<sup>1</sup>, V. Strnad<sup>1</sup>, C. Bert<sup>1</sup>

<sup>1</sup>*Universitätsklinikum Erlangen- Friedrich-Alexander- Universität Erlangen-Nürnberg, Department of Radiation Oncology, Erlangen, Germany*

**Purpose or Objective**

Electromagnetic tracking (EMT) was used to measure the implant geometry in fractionated HDR interstitial brachytherapy (iBT) of the breast. Based on the tracking data the dosimetric impact of common clinical errors, e.g. as reported in the United States by the Nuclear Regulatory Commission, were assessed using treatment planning quality criteria (QC).

**Material and Methods**

For tracking of implant catheters, 28 patients were accrued within an institutional review board-approved study. The geometry of interstitial single-leader catheters (median: 18 pcs) was tracked on the HDR treatment table directly after each of the treatment fraction (up to nine during five days). Tracking has been performed by manual insertion of a small EMT sensor into each of the catheters. The breathing motion was compensated by computing the center of mass from three additional EMT sensors on the breast. Taking the tracking-based catheter data, different errors (swaps and shifts of catheters, changing the tracking direction of catheters, i.e. tip-end swap) were simulated.

For dose calculation, the dwell positions (DPs) were determined along the catheter traces and the dwell times were taken from the approved treatment plan. Common contour-independent QC like the dose non-uniformity ratio (DNR) were analyzed. For investigation of contour-dependent QC, like the coverage index (CI) of the PTV, the corresponding EMT-derived DPs were registered to the CT-

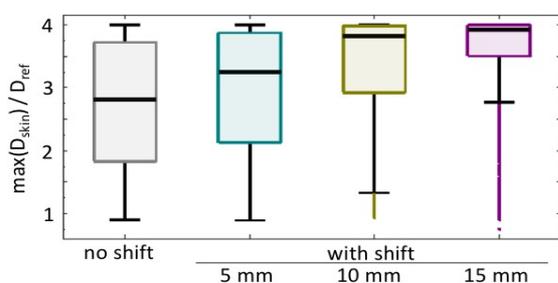

derived DPs from treatment planning. In addition, the maximal dose to the skin was determined. QC of EMT-based dose distributions were normalized to the corresponding values from treatment planning, so the relative changes are reported.

#### Results

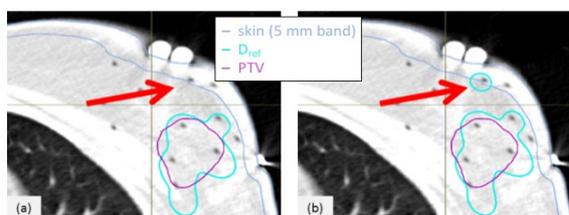

Without simulated errors, the maximum dosimetric deviations to the treatment plan were found on the 2<sup>nd</sup> treatment day in median -6.2% for the DNR and -4.3% for the CI of the PTV.

For error simulation, 15,107 pairwise swaps of catheters were analyzed. The reconstructed dose distributions resulted in DNR changes from -22.7% to 38.9% (mean: 0.6%, SD: 5.5%) and CI changes from -63.5% to 11.4% (mean: -7.4%, SD: 7.8%).

For each shift of single catheters, 2,264 combinations of dose distributions were calculated. Relative dosimetric changes for DNR ranged from -4.1% to 3.5%, from -6.8% to 6.2% and from -8.8% to 8.1% for catheter shifts of 5, 10 and 15 mm, respectively at mean values between 0.0% and -0.3%. The CI for the PTV showed a mean change of -0.3%, -1.3% and -2.8%, respectively. Increased catheter shifts correlated with a higher local dose at the skin (see figures). In addition, each 3D dose distribution was analyzed to identify individual local dose deviations.

**Figure 1:** Boxplots of the maximum skin dose relative to reference dose for the initial EMT-derived data and the different catheter shifts. The approach for dose calculation defines a cut-off value at  $4 \cdot D_{ref}$

**Figure 2:** An example of a local dose distribution ( $D_{ref}$ ) based on EMT-determined dwell positions: (a) for the initial data and (b) for a catheter shift (15 mm) of the tip-end outward the breast. The arrow indicates overdosing in the skin contour-band

#### Conclusion

Statistically, the maximum dose deviation was found on the 2<sup>nd</sup> day, what might impact boost treatments with two fractions only. Based on EMT-determined dose calculations adaptive treatment protocols and tests for possible treatment delivery errors should be implemented. Further work is required for the registration method.

#### OC-0180 Prospective study of APBI With Multicatheter Brachytherapy in Local Relapses of Breast Cancer

E. Villafranca Iturre<sup>1</sup>, L. Rubi<sup>2</sup>, M. Barrado<sup>1</sup>, A. Sola<sup>1</sup>, P. Navarrete<sup>1</sup>, A. Manterola<sup>1</sup>, M. Dominguez<sup>1</sup>, G. Asin<sup>1</sup>, M. Campo<sup>1</sup>, I. Visus<sup>1</sup>, G. Martinez<sup>1</sup>

<sup>1</sup>Hospital of Navarra, Radiation Oncology, Pamplona, Spain

<sup>2</sup>Hospital Juan Ramon Jimenez, Radiation Oncology, Huelva, Spain

#### Purpose or Objective

To examine 5-year rates of local control for breast cancer patients with local relapses after second conservative surgery and accelerated partial breast irradiation (APBI).

#### Material and Methods

Eligibility included local relapses of breast cancer <3 cm in size after lumpectomy with negative surgical margins. The APBI dose delivered was 34 Gy in 10 twice-daily fractions over 5 days for high-dose-rate. This analysis focuses on ipsilateral breast recurrence (LBR), regional recurrence (RR), and distant metastases (DM), disease-free and overall survival.

#### Results

The median follow-up was 49.6 months (5-98m). Fifty two patients (p) were accrued from Sep 2008 to August 2015.

Histology: Intraductal carcinoma 15 p, Ductal carcinoma 31 p, Lobulillar carcinoma: 5 p; Papilar carcinoma: 1p; 50 p had T1 tumors and 2 p had T2. Seventy-five percent were estrogen receptor and/or progesterone receptor positive. There have been 4 local breast recurrences, 1 regional recurrence (RR), and 1 distant metastases (DM). The 5-year Local Recurrence Disease Free rate was 91.6%. The 5-year Disease Free Survival and Overall Survival rates are 87% and 100%, respectively.

#### Conclusion

This prospective trial studying APBI in local relapses of Breast Cancer show a high local control, so this treatment is an real option to Mastectomy in these patients

#### OC-0181 Long-term clinical and cosmetic outcomes of high-dose-rate brachytherapy for early breast cancer

F. Arcidiacono<sup>1</sup>, L. Chirico<sup>1</sup>, M. Italiani<sup>1</sup>, P. Anselmo<sup>1</sup>, M. Casale<sup>1</sup>, L. Draghini<sup>1</sup>, F. Trippa<sup>1</sup>, S. Fabiani<sup>1</sup>, M. Basagni<sup>1</sup>, E. Maranzano<sup>1</sup>

<sup>1</sup>"S.Maria" Hospital, Radiotherapy Oncology Centre, Terni, Italy

#### Purpose or Objective

To report long-term clinical and cosmetic outcomes of partial breast irradiation (PBI) with <sup>192</sup>Ir high-dose-rate brachytherapy (HDR-BRT) in early breast cancer patients.

#### Material and Methods

From May 2005 to February 2012, 124 patients undergoing conservative surgery for early breast cancer were recruited in a phase II trial of exclusive <sup>192</sup>Ir HDR-BRT. Inclusion criteria were: age >40, PS 0-2, unifocal invasive ductal cancer, intraductal cancer component <25%, negative axillary nodes and tumor size  $\leq 2.5$  cm. Treatment schedule was 4 Gy twice a day for 4-5 days, up to a total dose of 32 Gy in 8 fractions with a minimum interval between daily fractions of at least 6 hours. Late toxicity was graded at each follow-up visit according to RTOG/EORTC scoring criteria and cosmetic outcomes according to Harvard criteria and scored as excellent, good, fair and poor.

#### Results

Median age was 67 years (range, 42-85). There were 10 (8%) pT1a, 38 (31%) pT1b, 68 (55%) pT1c and 8 (6%) pT2. Estrogenic and progesterone receptors were positive in 113 (91%) and 104 (85%) cases, respectively. 110 (88%) and 15 (12%) patients received adjuvant hormonal therapy and chemotherapy, respectively. Median follow-up was 77 months (range, 8-132). 1 (0,8%) isolated out-field breast relapse occurred 109 months after HDR-BRT. 1 (0,8%) patient developed contralateral breast cancer and another one (0,8%) regional relapse in axillary node. 13 (10,5%) patients reported a second primary cancer. 5- and 10-year overall survival and cancer specific free survival were 95% and 88%, 100% and 98%, respectively. At last follow-up, 114 (92%) patients were alive without disease and 3 (2,5%) with systemic disease. 10 (8%) patients died: 1 (0,8%) for breast cancer, 2 (1,6%) for other cancers and 7 (5%) for other causes. Cosmetic outcomes were excellent in 102 (82%), good in 11 (9%), fair

in 8 (6%) and unknown in 3 (2,5%) patients. Late skin toxicity was registered in 29 (23,4%) patients, grade 1-2 in 28 (22,5%), grade 3 in 1 (0,8%). Late toxicity was significantly related to the skin administered doses ( $\leq 55\%$  vs.  $> 55\%$ ,  $P < 0.05$ ).

#### Conclusion

PBI delivered with  $^{192}\text{Ir}$  HDR-BRT in selected breast cancer patients was associated to high local control and survival with excellent cosmetic outcomes. An appropriate patient selection and skin dose  $\leq 55\%$  provided optimal clinical outcomes.

#### OC-0182 2nd breast conserving therapy with interstitial BT vs mastectomy for treatment of local recurrences

V. Smánykó<sup>1</sup>, N. Mészáros<sup>1</sup>, M. Ujhelyi<sup>2</sup>, G. Stelczer<sup>1</sup>, T. Major<sup>1</sup>, Z. Mátrai<sup>1</sup>, C. Polgár<sup>1</sup>

<sup>1</sup>National Institute of Oncology, Center of Radiotherapy, Budapest, Hungary

<sup>2</sup>National Institute of Oncology, Center of Surgery, Budapest, Hungary

#### Purpose or Objective

To compare the clinical outcomes of second breast conserving therapy (BCT) with perioperative high-dose-rate (HDR) interstitial brachytherapy (iBT) versus salvage mastectomy (SMT) for the treatment of ipsilateral breast tumor recurrences (IBTRs).

#### Material and Methods

Between 1999 and 2016, 92 patients who presented with an IBTR after previous BCT were salvaged either with reexcision and perioperative HDR multi-catheter iBT (n=35) or SMT (n=57). In the BCT + HDR iBT group a median of 7 (range: 4-23) catheters were implanted intraoperatively. A total dose of 22 Gy in 5 fractions of 4.4 Gy was delivered to the tumor bed with a margin of 1-2 cm perioperatively on 3 consecutive days. Similar proportion of patients received adjuvant chemotherapy in the two groups (17% after BCT + HDR iBT vs 21% after SMT) and/or hormonal treatments (71% vs 70%, respectively). Five-year oncologic outcomes (including ultimate local tumor control, regional tumor control, disease-free survival [DFS], cancer specific survival [CSS], and overall survival [OS]) were estimated by the Kaplan-Meier method. Survival curves were compared with the log-rank test.

#### Results

Mean follow up time was 63 months (range: 2-183) in the BCT + HDR iBT group vs 30 months (range: 4-164) in the SMT group. The mean diameter of IBTRs was 16.8 mm (range: 2-70) vs 24.5 mm (range: 2-60), respectively. There was no significant difference in any other patient (e.g. age, menopausal status) or IBTR related (e.g. grade, vascular invasion, margin status, receptor status) parameters between the two groups. Three out of 35 (8.6%) and 7 out of 57 (12.3%) second local recurrences occurred in the BCT + HDR iBT and the SMT group, respectively. The 5-year actuarial rate of second local recurrence was 7.4% after BCT + HDR iBT vs 17.5% after SMT ( $p=0.11$ ). The respective 5-year rates of regional recurrence were 7.2% vs 5.3% ( $p=0.17$ ). The 5-year probability of DFS, CSS, and OS were 69.7% vs 73.5% ( $p=0.79$ ), 74.9% vs 80.5% ( $p=0.72$ ), and 74.9% vs 69.6% ( $p=0.73$ ), respectively. At the time of analysis data on cosmetic results were available for 31 patients (88.6%) in the BCT + HDR iBT group. Among these, 3 (9.7%), 16 (51.6%), 5 (16.1%), and 7 (22.6%) patients had excellent, good, fair, and poor cosmetic results. Grade 2 and 3 late skin toxicity occurred in 2 (5.7%) and 1 (2.9%) patients, while grade 2 and 3 fibrosis developed in 9 (25.7%) and 1 (2.9%) patients. Asymptomatic fat necrosis was detected in 11 (31.4%) women.

#### Conclusion

Second BCT + HDR iBT is a safe and feasible option for the management of IBTRs resulting similar 5-year oncologic

outcomes compared to standard SMT. HDR iBT may decrease the risk of second IBTR with acceptable cosmetic results and low rate of late side effects.

#### PV-0183 Microbrachytherapy: even more localised dose profiles?

R. Brown<sup>1,2</sup>, X. Franceries<sup>1,2</sup>, M. Bardiès<sup>1,2</sup>

<sup>1</sup>INSERM, UMR1037 CRCT- F-31000, Toulouse, France

<sup>2</sup>Université Paul Sabatier, UMR1037 CRCT- F-31000, Toulouse, France

#### Purpose or Objective

Owing to its intrinsic ability to deliver increased dose rates to tumours whilst respecting organ at risk (OAR) constraints, brachytherapy (BT) is being increasingly used for the treatment of radioresistant tumours.

A new form of BT, microbrachytherapy (MBT), is proposed for small tumours. For this treatment, the grains used in BT are replaced by a solution containing  $\beta$ -emitters. More injections can be used with MBT than grains with BT, allowing for greater precision when targeting the tumour. As with all forms of radiotherapy, treatment planning is required. In this work, a method of generating optimal MBT treatment plans is proposed.

#### Material and Methods

The non-dominated sorting genetic algorithm II (NSGA2) [1] is used to generate treatment plans. This is a multi-objective algorithm, permitting the objective functions to be optimised independently.

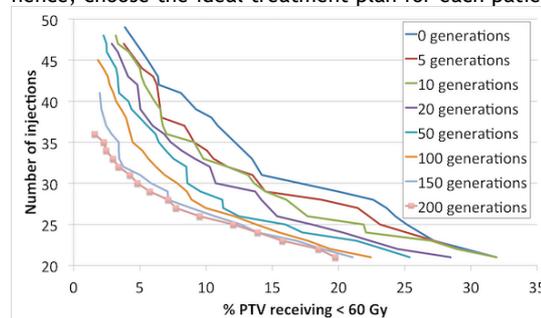

Two objective functions were used: the first to minimise the fraction of the tumour receiving less than the target absorbed dose (60 Gy) and the second to minimise the number of injections.

The algorithm was validated on a spherical tumour of 20 mm radius. 20 mm was chosen because it represents the typical size of tumour that could be targeted with this new technique.

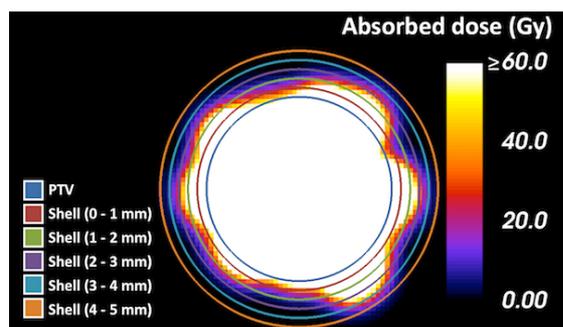

#### Results

The evolution of the Pareto front during the optimisation of the spherical tumour is shown in Figure 1. The optimisation finished after 200 iterations (generations), and so the final Pareto front represents the final results of the optimiser.

Each point along the Pareto front represents a different treatment plan. The front can be seen as a set of compromises; it is impossible to decrease one objective function without increasing another. This enables the user to *a posteriori* decide relative objective importance and, hence, choose the ideal treatment plan for each patient.

As an example, the treatment plan using 30 injections was chosen. Its absorbed dose distribution through the central slice is shown in Figure 2. To highlight the steep absorbed dose gradient obtained with this treatment concentric spherical shells, surrounding the tumour were also included. Very satisfying treatment plans have been defined using this new method of MBC.

### Conclusion

A new form of BT, MBT, has been proposed, as well as a promising method of generating optimal treatment plans. It can be seen that the treatment plans proposed by the optimiser (NSGA2) deliver satisfactory absorbed dose distributions to the tumour, whilst sparing surrounding tissue, which in turn spares more OARs. This method can be used in real time during clinical treatment of MBT.

### PV-0184 Quantitative study on position margin in Intraluminal Brachytherapy Planning for lung treatment

C.W. Kong<sup>1</sup>, H. Geng<sup>1</sup>, Y.W. Ho<sup>1</sup>, W.W. Lam<sup>1</sup>, K.Y. Cheung<sup>1</sup>, S.K. Yu<sup>1</sup>

<sup>1</sup>Hong Kong Sanatorium & Hospital, Medical Physics and Research Department, Happy Valley, Hong Kong SAR China

### Purpose or Objective

In Intraluminal Brachytherapy for lung treatment, a Lumincath applicator, normally 5F flexible nylon catheter, is inserted through the Trachea and Bronchus. High activity radioactive source is loaded through the catheter for treating the tumor site. Unlike external radiotherapy, there is no motion control technique for afterloading brachytherapy treatment. Breathing motion should affect the position accuracy of Intraluminal Brachytherapy as both Trachea and Bronchus move with the breathing motion of the patient. It is not practical for the patient to do breath-hold during treatment since the whole treatment can last for several cycles of breathing depending on the source activity. The additional margin for treatment length should be considered in Intraluminal Brachytherapy to compensate such effect. The objective of this study is to investigate the position margin of treatment planning on intraluminal brachytherapy for lung treatment.

### Material and Methods

We applied two-dimensional (2D) projection reconstruction methods to measure the movement of catheter due to the breathing motion. In 2D projection reconstruction an orthogonal pair of isocentric radiographs were taken on the patient inserted with the Lumincath catheter. By localizing difference position markers on the catheter in two separate projections, the catheter can be reconstructed in three-dimensional (3D) space for the planning calculation. The average position difference of reconstructed points between two projections reflects the accuracy of 2D reconstruction method. By comparing the reconstruction accuracy between two scenarios: patient doing free breathing and breath-hold, the impact of breathing motion on the position of catheter can be derived. In the study an orthogonal pair of radiographs were done on patients with free breathing and breath-hold; The discrepancy in the average position difference between 2D projection reconstructions with free breathing and breath-hold was

calculated. Such comparison was done for 12 times on different patients.

### Results

The average position difference between two radiographs in the breath-hold reconstruction was  $1.3 \pm 0.5$  mm among different patients. Such difference was greatly increased to  $6.5 \pm 2.5$  mm in free-breathing reconstruction. Assume the position difference in the reconstruction due to breathing motion was independent from other factors such as isocenter precision and reconstruction calculation accuracy, the derived average position error of catheter in the reconstructions due to breathing motion was  $6.4 \pm 2.5$  mm.

### Conclusion

Our study showed that in Intraluminal Brachytherapy for lung treatment, the breathing motion can significantly affect the catheter position by  $6.4 \pm 2.5$  mm on average. Position margin of such value should be added in the treatment length during Intraluminal Brachytherapy planning to compensate such effect.

### PV-0185 Retina dose as risk factor for worse visual outcome in <sup>106</sup>Ru plaque brachytherapy of uveal melanoma

G. Heilemann<sup>1</sup>, L. Fetty<sup>1</sup>, M. Blackner<sup>2</sup>, N. Nesvacil<sup>3</sup>, D. Georg<sup>3</sup>, R. Dunavoelgyi<sup>4</sup>

<sup>1</sup>Medical University of Vienna/AKH Vienna, Department of Radiotherapy, Vienna, Austria

<sup>2</sup>Austrian Institute of Technology GmbH, Health and Environment Department Biomedical Systems, Vienna, Austria

<sup>3</sup>Medical University of Vienna/AKH Vienna, Department of Radiotherapy/Christian Doppler Laboratory for Medical Radiation Research for Radiation Oncology, Vienna, Austria

<sup>4</sup>Medical University of Vienna/ AKH Vienna, Department for Ophthalmology and Optometry, Vienna, Austria

### Purpose or Objective

Visual acuity is a common side effect in <sup>106</sup>Ru plaque brachytherapy. The purpose of this study was to evaluate the retina dose as a risk factor associated with visual outcome.

### Material and Methods

45 Patients treated with <sup>106</sup>Ru plaque brachytherapy were included in this retrospective study. A minimum of 100 Gy was prescribed to the tumor apex using one of two available plaque (types CCB, CCA) manufactured by BEBIG (Eckert & Ziegler, Germany). Treatment planning and dose calculation was performed using an in-house developed 3D treatment planning system with Monte Carlo based dose calculation. Dose volume histograms (DVH) were generated for both physical absorbed dose and biological equivalent dose (BED), according to the definition introduced by Dale and Jones [1]. Visual acuity was reported using Snellen charts. To analyze potential predictors in anterior tumor locations, a subgroup of 20 patients was selected presenting with a minimum distance of 5 mm between tumor and macula. Statistical calculations were performed in SPSS (version 21, IBM). Risk factors associated with loss of visual acuity were evaluated using the Cox proportional hazards models. The loss of visual acuity was correlated to risk factors using Pearson correlation coefficients. Statistical significance was assumed to be  $p \leq 0.05$ .

### Results

Median follow-up time was 29.5 months (IQR, 15.0-29.8). A median apex dose of 131 Gy (IQR, 113.0-150.4) was delivered to tumors with median apex heights of 4.6 mm (IQR, 3.5-6.0), largest basal diameters of 10.8 mm (IQR, 8.3-12.6) and smallest diameter of 9.3 mm (IQR, 7.9-11.4). The baseline visual acuity (Snellen  $0.82 \pm 0.23$  SD) was significantly higher ( $p < 0.001$ ) than the mean visual acuity at last individual follow-up ( $0.59 \pm 0.28$  SD). The Pearson Correlation analysis showed a significant

correlation of visual acuity loss with the mean ( $r = 0.49$ ,  $p = 0.001$ ) and maximum ( $r = 0.47$ ,  $p = 0.001$ ) retina dose and tumor basal diameter ( $r = 0.50$ ,  $p < 0.001$ ). The dose to the macula showed no correlation with visual outcome ( $r = 0.24$ ,  $p = 0.12$ ). In the subgroup of patients with anterior tumor locations the maximum retina dose remained the only predictive factor ( $r = 0.46$ ,  $p = 0.043$ ). Evaluating the Cox proportional hazards model yielded a significantly higher risk for visual acuity loss (of more than 0.3 Snellen) for patients receiving a maximum dose of 500 Gy or higher ( $p = 0.009$ ). A Cox multivariate analysis including the macula dose ( $p = 0.11$ ) and basal diameter ( $p = 0.78$ ) showed that a high maximum retinal dose is the highest risk factor ( $p = 0.017$ ). The evaluation of the BED metrics showed no better correlation with the investigated endpoints and in some cases BED was even inferior.

#### Conclusion

The study showed that retina dose ( $D_2$  and  $D_{\text{mean}}$ ) is a suitable predictor for visual acuity loss, especially in case of anterior tumors where other risk factors (i.e. basal diameter) fail.

#### PV-0186 MaxiCalc: a tool to calculate dose distributions from measured source positions in HDR brachytherapy

M. Hanlon<sup>1</sup>, R.L. Smith<sup>2</sup>, R.D. Franich<sup>1</sup>

<sup>1</sup>RMIT University, School of Science, Melbourne, Australia

<sup>2</sup>The Alfred Hospital, Alfred Health Radiation Oncology, Melbourne, Australia

#### Purpose or Objective

Dosimetric treatment verification via source tracking in HDR brachytherapy requires evaluation of the delivered dose as source dwell positions are detected. Current TPSs are not configured to perform this function, hence a fast dose calculation engine (DCE) that can accept the input of arbitrary dwell positions from the source tracking system is required. Here we present a TG-43 based DCE that computes 3D dose grids for measured dwell positions and performs a comparison with the treatment plan.

#### Material and Methods

The DCE, dubbed MaxiCalc, takes the input of measured dwell positions and times and calculates a dose grid of nominated dimensions and grid spacing for direct comparison to the treatment plan. MaxiCalc was validated against Oncentra Brachy (OCB v4.3) at 27 single dose points, as per OCB commissioning, as well as a 3D dose grid of 13 dwells.

Dwell positions and times delivered in a phantom were measured by our source tracking system, as previously published.<sup>1</sup> The measured dwell positions were then used as input to MaxiCalc and the resultant dose grid compared to that from OCB. Observed dose differences due to source position measurement uncertainties were investigated.

#### Results

For the 27 dose points, MaxiCalc differed from OCB by a mean of 0.08% ( $\sigma=0.07\%$ , max 0.41%) demonstrating differences that are similar to those between published values<sup>2</sup> and OCB. In a multi-source plan for doses between 50-200% of the prescription dose, MaxiCalc yields a maximum difference of <1%, which arises due to minor calculation differences in the steep dose gradients near the source. There was a gamma pass rate of >99% at 1mm/1%.

A dose grid was calculated for a plan of 25 dwell positions acquired using our source tracking system, there was maximum difference of 12.2% (mean = 0.7%). The maximum difference arises from a small shift in the apparent dwell positions causing large differences due to the high dose gradients near the source, which is only significant within 10 mm of the source. For this volume of

interest, only 0.2% of voxels differ by >5%, showing good agreement throughout. Results from measured delivery errors, such as those in figure 1, will also be presented.

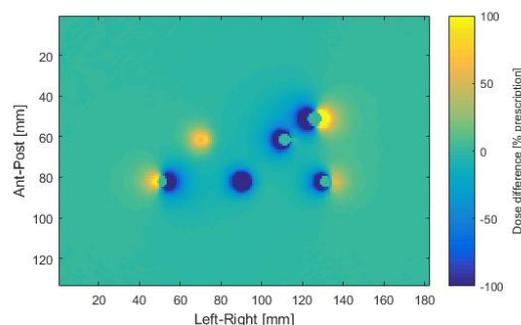

Figure 1: Dosimetric comparison between planned and delivered doses for a HDR brachytherapy treatment in a phantom with an introduced error.

#### Conclusion

Real-time dosimetric treatment verification is possible with our source tracking system combined with MaxiCalc. Fast dose calculation based on measured source dwell positions is achieved and overcomes the limitation of current TPSs.

#### PV-0187 Source dwell time and transit time measurement for a HDR afterloading unit

T.L. Chiu<sup>1</sup>, B. Yang<sup>1</sup>, H. Geng<sup>1</sup>, W.W. Lam<sup>1</sup>, C.W. Kong<sup>1</sup>, K.Y. Cheung<sup>1</sup>, S.K. Yu<sup>1</sup>

<sup>1</sup>Hong Kong Sanatorium & Hospital, Medical Physics & Research Department, Happy Valley, Hong Kong SAR China

#### Purpose or Objective

To evaluate dwell time and transit time of HDR brachytherapy treatment by an in-house fluorescent screen based QA system. Since dosimetric effect would be directly affected by source dwell time, an accurate QA method on temporal accuracy is essential.

#### Material and Methods

The system included a fluorescent screen (Kodak, Lanex regular screen) which converts the radiation signal to optical signal and a high-speed camera with frame rate up to 500 fps and pixel resolution of 1280X720. The temporal resolution was 2 ms. A catheter in which an Ir-192 source would be loaded was fixed on the fluorescent screen and the camera was placed 30 cm away from the screen. The whole system was light-shielded. When the source travelled inside the catheter, the camera would capture images on the fluorescent screen sequentially. Source position was traced out by locating the centroid of the captured image. The accuracy of dwell time was assessed by measuring 3 different dwell times, namely, 1 s, 0.5 s & 0.1 s. According to a white paper from vendor, transit time for separations below 35 mm would occupied part of the next dwell time and those for separations above 35 mm would have 0.1 s compensation. Thus, the influence of transit time on dwell time was studied by measuring 0.5 s dwell time under 3 different dwell separations, namely, 6 cm, 4 cm & 0.5 cm. Dwell time was assessed by counting the number of images in which source positions were unchanged to the subsequent image. Transit time was the time between two dwell positions.

#### Results

Fig. 1 demonstrated the capability of this QA system by showing a source transit process and Fig. 2 indicated that measured dwell time was affected by source separation. Table 1(a) tabulated the measured dwell time for 3 different assigned dwell times with 5 mm separation between source dwell positions. In all three scenarios, the dwell time at starting position was close to the assigned value. Dwell time at next dwell position experienced a larger discrepancy up to 40% for 0.1 s dwell time. This discrepancy in dwell time was due to the transit time for which control computer could not fully account. Hence, dwell time would be shorter than the assigned value except at the starting position. Table 1(b) tabulated measured dwell times at 3 different source separations with 0.5 s assigned dwell time to assess the compensation method stated. Discrepancy could be up to 0.33 s in 6 cm separation. Transit time occupied a larger portion of the dwell time for longer source separation.

(a)			
Assigned dwell time	(i) 1 s	(ii) 0.5 s	(iii) 0.1 s
Measured dwell time (First position) (s)	0.983	0.493	0.099
Measured dwell time (5 mm apart) (s)	0.946	0.460	0.060
Difference between assigned and measured dwell time	0.054	0.04	0.04
(b)			
Separation between dwell positions	(i) 5 mm	(ii) 40 mm	(iii) 60 mm
Measured dwell time (s)	0.460	0.253	0.173

Table 1 (a) 3 different dwell times with fixed source separation, 0.5 mm (b) 3 different source separations with the same assigned dwell time 0.5 s.

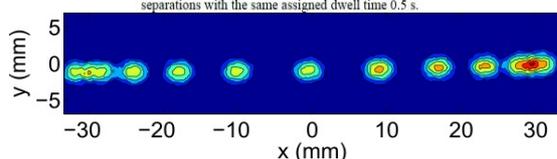

Fig. 1 Combined image of selected time instances during source transit

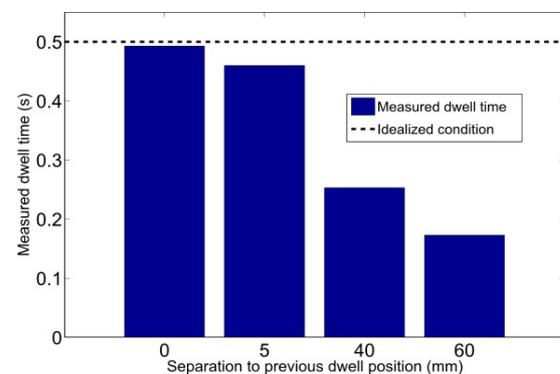

Fig. 2 Dependence of dwell time to source separations with 0.5 s assigned dwell time

### Conclusion

Dwell time and transit time could be measured using the fluorescent QA system with uncertainty down to 2 ms. High temporal resolution in this system helped measure the transit time accurately which could hardly be achieved in commonly used QA systems. The effect of transit time on actual source dwell time could be significant and was not fully accounted for by treatment computer. Clinically possible combinations, like 0.5 s dwell time and 5 mm separation, could have a dosimetric error of 8%.

### PV-0188 Improved class solutions for prostate brachytherapy planning via evolutionary machine learning

S.C. Maree<sup>1</sup>, P.A.N. Bosman<sup>2</sup>, Y. Niatsetski<sup>3</sup>, C. Koedooder<sup>1</sup>, N. Van Wieringen<sup>1</sup>, A. Bel<sup>1</sup>, B.R. Pieters<sup>1</sup>, T. Alderliesten<sup>1</sup>

<sup>1</sup>Academic Medical Center, Radiation oncology, Amsterdam, The Netherlands

<sup>2</sup>Centrum Wiskunde & Informatica, Amsterdam, The

Netherlands

<sup>3</sup>Elekta, Veenendaal, The Netherlands

### Purpose or Objective

In PDR and HDR prostate brachytherapy (BT), treatment plans have to be created in a reasonably short time. In our clinic, an initial plan is automatically generated with an optimization algorithm using a standard parameter set, called a class solution (CS). Next, the plan is fine-tuned manually using graphical optimization. The better the CS, the less fine-tuning is required. We developed a method to automatically find a CS such that the plans resulting from the use of this CS match given reference plans as good as possible, regardless of how these reference plans were created.

### Material and Methods

Twenty patients consecutively treated with PDR BT for intermediate/high-risk prostate cancer were included. Clinically acceptable reference plans were created in Oncentra Brachy using manual graphical optimization according to our clinical protocol.

To demonstrate our method, we learn CSs for Inverse Planning Simulated Annealing (IPSA). Per organ, the IPSA parameter set consists of an acceptable dose range and a penalty value for violating this range. The ranges follow from our clinical protocol, and the penalty values are automatically learned for each patient individually (IPSA-I) by minimizing the difference between the reference and IPSA-generated plan using the evolutionary algorithm known as AMaLGaM. Then, three CSs are compared:

- (CS-C) is the current clinical CS,
- (CS-M) results from a frequently used strategy for IPSA by computing the mean of the IPSA-I parameters found for the individual patients,
- (CS-S) is learned by using AMaLGaM again, but this time aimed at minimizing the sum of plan differences for multiple patients simultaneously.

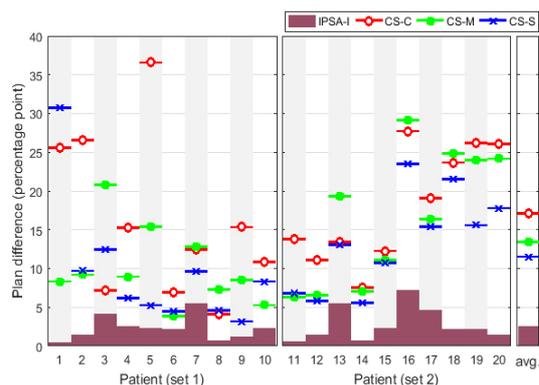

Plan difference was measured by the root mean square of the differences in selected DVH indices (Table). To prevent overfitting, the data was randomly split into two sets of 10 patients so that both CS-M and CS-S could be learned twice: once on each half and validated on the other half (2-fold cross validation).

### Results

Our method is highly accurate when determining IPSA parameters for individual patients (IPSA-I; dark purple bars, Figure), with DVH indices of the reproduced plans differing on average less than 2% of the reference plans (Table). CS-S performs best for 13 of the patients, and has the lowest average plan difference. CS-M has a larger plan difference on average, but outperforms the current clinical CS-C as well.

### Conclusion

Our method for automatically determining class solutions was found to be advantageous for our patient group, outperforming the commonly used approach of taking the mean of IPSA parameters. For individual patients, IPSA parameters could automatically be found such that the corresponding plans were very similar to the reference plans. The performance gap between the latter and the use of class solutions shows that there is still much room for improvement by moving toward a patient-tailored approach for automated BT planning. Our work achieves a first step in that direction.

**Figure:** The plan difference of the three class solutions (CS-C, CS-M, CS-S) is shown for each patient, for both patient sets used in the 2-fold cross validation (i.e., results of CS-M and CS-S shown for patient set 1 are obtained after learning these class solutions on patient set 2, and vice versa). The dark purple bars represent the plan difference of the plans resulting from optimizing the IPSA parameters for individual patients (IPSA-I). On the right, the average plan difference over all patients is shown. Per-DVH index values are shown in the Table.

	PTV				Vesiculae		Urethra		Rectum		Bladder	
	V <sub>100%</sub>	V <sub>150%</sub>	V <sub>200%</sub>	D <sub>90%</sub>	V <sub>40%</sub>	D <sub>1cc</sub>	D <sub>2cc</sub>	D <sub>3cc</sub>	D <sub>4cc</sub>	D <sub>5cc</sub>	D <sub>6cc</sub>	
Reference Plan	94 (3)	38 (5)	15 (3)	106 (6)	44 (23)	131 (7)	63 (11)	55 (10)	76 (11)	66 (9)		
CS-C	2 (1)	6 (4)	3 (2)	4 (3)	37 (22)	8 (5)	7 (13)	6 (11)	6 (5)	6 (5)		
CS-M	2 (1)	5 (3)	2 (2)	4 (3)	25 (20)	11 (12)	6 (3)	5 (3)	6 (5)	5 (4)		
CS-S	2 (2)	7 (6)	4 (5)	5 (4)	18 (16)	13 (15)	4 (3)	3 (3)	5 (5)	5 (4)		
IPSA-I	1 (2)	2 (2)	2 (1)	2 (3)	3 (3)	2 (2)	3 (3)	2 (2)	2 (2)	2 (2)		

**Table:** DVH indices used to assess the similarity between plans. The indices are measured in percentage of volume or prescription dose. For the reference plan, the average (standard deviation) over all patients is shown. Absolute differences between the (learned) class solutions and the reference plan are shown in percentage points.

#### PV-0189 Ring applicator source path determination using a high resolution ionisation chamber array

M. Gaaney<sup>1,2</sup>, M. Kollerfrath<sup>1</sup>, D. Baltas<sup>1</sup>

<sup>1</sup>University Medical Centre, Division of Medical Physics-Department of Radiation Oncology, Freiburg, Germany

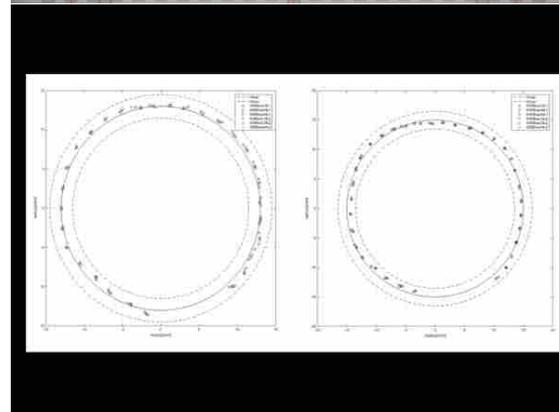

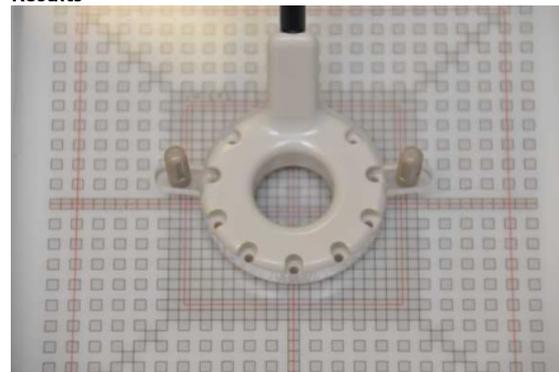

<sup>2</sup>German Cancer Consortium DKTK, Partner Site Freiburg, Freiburg, Germany

**Purpose or Objective** Commissioning brachytherapy applicators can be very time consuming. Brachytherapy has recently seen efforts to perform array based QA (Espinoza et al. 2013, Espinoza et al. 2015, Kollerfrath 2015, Gaaney 2015). Previously we described a technique for determining one source dwell position per measurement using the OD1000 (PTW-Freiburg) analogous to film measurements (Kollerfrath 2015). In this work we employ a time resolved high spatial resolution dose measurement with OD1000 to determine the entire source path for each interstitial ring applicator (Elekta AB, Sweden), available in three diameters (R26, R30, R34), within a single measurement.

#### Material and Methods

Two microSelectron (Elekta AB, Sweden) v2 afterloaders (AL1, AL2) were employed to perform all measurements with <sup>192</sup>Ir. A special PMMA jig consisting of a base plate and a central insert was constructed to mount onto the OD1000 array. A time resolved (100ms per frame) dose measurement of the entire source path within the respective ring applicator was contrived: a single plan for each ring diameter consisting of 5.0 s dwell time for each position (associated source strength 42000U). The resulting data was analysed using an in-house MATLAB script (version 8.4.0, The Mathworks NA). Typically three measurements were repeated for both (blue and green) clinically commissioned rings and for a number of source exchanges.

#### Results

Mechanical uncertainties (type B) of PMMA jig position relative to OD1000 array were estimated to be 0.2mm. Repeated measurements with different afterloaders (without dismantling set-up) are plotted in figure 2. The maximum standard deviation was found to be 0.6mm for R26, 0.5mm for R30 ring. A non-linear least squares fit was made (Gander et al. 1994) to the mean positions R26 and R30 rings resulting in a radius of 13.2mm and 14.9mm, geometric centre location of (0.15,0.13) and (0.20,0.10) respectively.

#### Conclusion

Initial results indicate that the measurement technique is robust and reproducible. Repeated measurements with different afterloaders indicate a maximum standard deviation of 0.6mm (R26), 0.5mm (R30). Other central inserts can be devised for other applicators, and afterloader systems. Thus the technique is versatile but requires an high resolution 2D array and specialized measurement jig. Moreover our technique is currently limited to 2D source path determination viz. in the measurement plane, parallel to the ring plane.

#### PV-0190 The analysis of prostate cancer with median lobe hyperplasia treated I-125 brachytherapy

K. Muraki<sup>1</sup>, H. Suefujii<sup>1</sup>, E. Ogo<sup>1</sup>, H. Eto<sup>1</sup>, C. Tsuji<sup>1</sup>, C. Hattori<sup>1</sup>, Y. Miyata<sup>1</sup>, H. Himuro<sup>1</sup>, T. Abe<sup>1</sup>, S. Hayashi<sup>2</sup>, K. Chikui<sup>2</sup>, M. Nakiri<sup>2</sup>, T. Igawa<sup>2</sup>

<sup>1</sup>Kurume University, Radiology, Kurume, Japan

<sup>2</sup>Kurume University, Urology, Kurume, Japan

#### Purpose or Objective

Most patients with median lobe hyperplasia (MLH) have a large-volume prostate and severe dysuria. Prostate cancer with MLH is a relative contraindication of permanent prostate brachytherapy (PPB), because of the increased risk of post-implant urination disorder and the technical difficulties of stability while implanting intravesical tissue. We examined that the treatment outcome, seed migration, urination disorder after treatment in MLH patients who received PPB. The purpose of our research concerns is to what degree could MLH implant be stabilized.

### Material and Methods

Between March 2007 and December 2014, 250 patients with localized prostate cancer underwent PPB, of which 32 patients had MLH identified radiologically on the MRI scan. These patients were divided into three MLH groups, mild (<5mm), moderate (5-10mm), severe (>10mm), by measuring the distance of MLH (dMLH); between the posterior transitional zone and the prostatic tissue protruding into the bladder. We retrospectively analyzed seed migration, DVH, operation time, genitourinary (GU) toxicity, and DFS.

### Results

Median follow-up is 53.5 months (range; 9-104months) and median age is 68.5 years old (range; 57-75yo). MLH group were respectively classified mild in 12, moderate in 12, severe in 8. D'Amico risk classification were low risk in 21, intermediate risk in 11. Median prostate volume was such as 34.4cc/32.8cc/28.6cc (severe/moderate/mild). The median D90 was 145Gy. All patients still have achieved relapse-free survival. Implant migration and low-dose level of median lobe tended to increase in severe MLH. There was no relapse and PSA failure. The IPSS (International Prostate Symptom Score) for most patients worsened during the immediate post-implant period, but most of these patients were resolved by their second follow-up at 6 months. The median IPSS one month or six months after post-implant were respectively 21.5 or 13. We observed Grade 2 acute toxicity. The late toxicity such as Grade 2 was observed in 25%, such as erectile dysfunction, urinary hemorrhage and urethralgia. Hemorrhage in Grade 3 was observed in just one case, who had taken an aspirin for cerebral infarction. There was no Grade 4 complication and the all complication was acceptable.

### Conclusion

In our study, MLH does not appear to be a strong contraindication to PPB because there were no significant differences in DFS and GU toxicity. However, we experienced that seed migration and cold spot degree tended to increase in severe MLH cases, we have to pay attention to treat severe MLH.

#### SP-0191 Optimizing the Treatment of HPV-related Oropharyngeal Cancer: the difficult journey back

B. O'Sullivan<sup>1</sup>

<sup>1</sup>Princess Margaret Cancer Centre University Health Network, Toronto, Canada

Traditional approaches to head and neck cancer (HNC) have used either surgery +/- adjuvant radiotherapy, or radiotherapy +/- chemotherapy. Thus treatment was practiced with a paradigm that head and neck cancer (HNC) is one disease requiring the same treatment, modulated according to anatomic constraints influencing whether function might be preserved, largely governed by psychosocial attitudes directed at avoidance of surgical ablation with resulting loss of function and esthetic appearance. In fact, while avoiding surgery, a philosophy evolved that greater intensity of non-surgical management is optimal. However, current evidence suggests the contrary and strong evidence that treatment-related death (e.g. pharyngeal disabilities or other problems) is claiming 10-20% of contemporary HNC survivors (Forastiere et al JCO 2013). For the recently emerged HPV-related oropharyngeal cancer (OPC), approaches are even more complex since the traditional cause of death (local or regional recurrence) is now rare and most patients who die of disease succumb to distant metastases (DM). Stage-for-Stage HPV-related OPC has extremely favorable outcomes in terms of locoregional control, overall survival, and outcome of salvage

treatments compared to traditional HNCs and the evolution to current treatment intensity did not consider HPV-related disease. The profiles of patients with HPV-related OPC at risk of DM are now being better understood. There is opportunity to modify approaches so that intensive local treatment can be minimized while patients at risk of DM are still selected for systemic treatments. These strategies are being carefully explored in clinical trials using risk-stratified approaches directed by relevant end-points intended to safely return to less intensive treatments analogous to those used in a previous era.

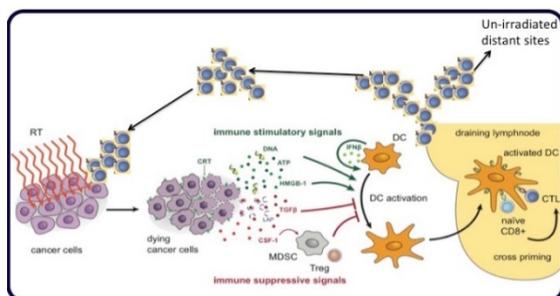

#### SP-0192 Potential of radiation therapy to convert the tumor into an in situ vaccine

S. Formenti<sup>1</sup>

<sup>1</sup>Weill Cornell Medical Center of Cornell University, New York- NY, USA

Radiation therapy contributes both immunogenic and immunosuppressive signals to the tumor microenvironment. Preclinical strategies to enhance the formers and/or mitigate the latter have demonstrated the concrete possibility to shift this balancing act toward a therapeutic success (J Natl Cancer Inst. 2013;105(4):256-265). Preclinical experiments in several syngeneic mouse models that mimic the setting of advanced cancer have demonstrated promise of combining radiation and immunotherapy. The preclinical data has consistently found clinical confirmation. Particularly when combined with immune checkpoint blockade, radiotherapy has demonstrated to be a powerful adjuvant to immunotherapy (Clin Cancer Res. 2005;11:728-734). Clinical examples of synergy between radiation and immune checkpoint inhibitors have been reported (N Engl J Med. 2012;366(10):925-931; Transl Oncol. 2012;5(6):404-407; Int J Radiat Oncol Biol Phys. 2013;85(2):293-295; Cancer Immunol Res 2013;1(6):365-372) and interim results in our prospective clinical trial confirm this finding (presented in room 1, May 17 session 051). Currently, multiple clinical trials are exploring optimal combinations and scheduling of radiotherapy and immunotherapy. Early evidence from these trials confirms the hypothesis that radiation can enhance responses to immune checkpoint inhibitors but in the majority of patients tumors remain unresponsive, warranting research to identify markers that predict response. A recent study testing radiation with ipilimumab in melanoma suggested that tumor expression of PDL-1 may predict lack of response to radiation and ipilimumab. However, in lung cancer patients treated with radiation and ipilimumab we found high PDL-1 expression among patients achieving durable complete and partial responses, without addition of PD-1 pathway inhibitors (ASTRO Proceedings 2015, abstract #149). In fact, higher expression of immune checkpoints has been hypothesized as a marker of more immunogenic tumors (Science, 2015, October 9: 207-211). In addition, pre-treatment mutational load has been found to be associated with responses to immune checkpoint inhibitors (Science, 2015 Apr 3: 124-8). It will be important to determine if radiation can compensate tumors with a low mutational load, by inducing de novo T cell priming to multiple tumor antigens (12) and could, therefore, achieve responses in the absence of pre-existing neoantigens (Science 2015;348(6230):69-74). The overall degree of immune impairment of the patients may also be a critical predictor of response to radiation + immunotherapy. For instance, we found the pretreatment neutrophil / lymphocyte ratio might enable *a priori* selection of individuals with a propensity to develop abscopal responses to the combination of radiation and GM-CSF (Lancet Oncol. 2015 Jul;16(7):795-803). Strategies at reducing radiation-induced lymphopenia are warranted to assure adequate availability of naïve T cells when

radiotherapy is harnessed to convert the tumor into an individualized cancer vaccine. Overall, while radiation has emerged as a promising partner for immunotherapy and current research is focusing at identifying tumor and patient characteristics that can predict which patients should receive upfront the combination of immunotherapy with radiotherapy instead of immunotherapy alone.

### SP-0193 Quality improvement in radiotherapy: history, significance and impact of dosimetry audits

J. Izewska<sup>1</sup>

<sup>1</sup>IAEA - International Atomic Energy Agency, Dosimetry and Medical Radiation Physics Section, Vienna, Austria

The concept of verification of radiation doses in medical applications was introduced in early 20th century, not long after radiation started to be used for treating cancer. Initially, to estimate the adequate daily fraction of radiation to be given to patients physicians exposed the skin of their own arms to radiation to produce the 'erythema dose'. Since then, the methodologies, dose measurement tools and radiation therapy equipment have made a great progress. In 1925 R. Sievert established a circulating physical department for standardizing the Roentgen radiation used in cancer therapy in Sweden. The department found some unreliable dose meters and identified the need for better protective equipment. At the same time, the measurements of percentage depth doses collected during the visits were used as a reference dataset for the Roentgen facilities in Sweden. Another example of early dosimetry audits was documented in Poland; following the idea by Marie Curie, the Measurement Laboratory was established in 1936 for radiation dose measurements at Polish hospitals using radium and X-ray beams.

The Dosimetry Laboratory of the International Atomic Energy Agency (IAEA) was set up in early 1960s with the aim of the provision of dosimetry audits for radiotherapy centres worldwide and for ensuring international consistency in radiation dosimetry. First trial inter-hospital comparisons were implemented by the IAEA in 1965-1966. In parallel, dosimetry comparisons of Co-60 and high energy beams from early medical accelerators were conducted among hospitals of France, Sweden, and in other countries. In USA, the Radiological Physics Center was established in 1968 to operate as an independent quality assurance office for multi-institutional cooperative group clinical trials.

Since 1969, the calibration of radiotherapy beams in 2200 hospitals in 132 countries has been verified by the IAEA jointly with the World Health Organization (WHO) through postal dosimetry audits. One important part of the auditing process is related to resolving dosimetry discrepancies occurring in the audit; errors are traced, analysed and corrected. In early years, only approximately 50% audited centres had the acceptable beam calibration. Over the time, several radiotherapy centres improved

their practices, and the current percentage of acceptable results exceeds 97%.

With the development of advanced radiotherapy technologies resulting in greater complexity of radiation treatments, it was necessary to extend basic dosimetry audits. More complex audit programmes involve tests of different beam parameters, machine performance characteristics and treatment delivery techniques. Examples include audits of small beam dosimetry, complex irradiations, combined beams, audits of treatment planning, and 'end-to-end' methodologies. Although the accurate clinical dosimetry is essential for the effective radiation treatment, the desired patient outcome cannot be achieved without the adequate quality of clinical, physical and technical processes. A comprehensive IAEA audit methodology called the Quality Assurance Team for Radiation Oncology (QUATRO) was developed to review the entire radiotherapy chain and infrastructure. Since 2005 QUATRO audits have been conducted in approximately 90 radiotherapy centres in various world regions.

The experiences above demonstrate that quality audits improve dosimetry and clinical practices. Audits have been effective in identifying discrepancies in dosimetry and in providing support to participating centres in resolving them. Audits can lessen the likelihood of major dosimetry errors and the resulting consequences for patient outcomes. Audits also address smaller errors and help in reducing uncertainties in the dose delivery thus improving the treatment quality for many patients. Audits can provide support and confidence when introducing new technologies and complex processes in radiotherapy. Audits verify the consistency of dosimetry practices among centres in different countries and world regions. They strengthen the confidence in clinical dosimetry both for physicists and clinicians who obtain assurance that their patients are given accurate doses in accordance with medical prescription.

The significance of quality audits in radiotherapy and their impact on dosimetry and clinical practices have been widely recognized. Still, a large number of radiotherapy centres do not participate in such audit programmes. Due to obvious benefits, all centres should be encouraged to take part in quality audits in radiotherapy.

SUNDAY, 7 MAY 2017

**Teaching Lecture: Role of radiotherapy in extranodal lymphomas**

**SP-0194 Role of radiotherapy in extranodal lymphomas**  
L. Specht<sup>1</sup>

<sup>1</sup>*Rigshospitalet- University of Copenhagen, Department of Oncology- Section 3994, Copenhagen, Denmark*

Extranodal lymphomas are lymphomas arising in tissues other than the lymph nodes, spleen or bone marrow. In clinical practice they present with lesions wholly or predominantly confined to an extranodal organ, with or without involvement of adjacent or draining lymph nodes. This is stage IE or IIE disease in contrast to stage IV disease, in which extranodal involvement is part of a disseminated process. Approximately 1/3 of all cases of non Hodgkin lymphomas (NHL) are primary extranodal lymphomas, whereas it rarely occurs in Hodgkin lymphoma.

Extranodal lymphomas may arise in any organ, and prognosis and treatment depend not only on the histologic subtype and disease extent, but also on the particular involved extranodal organ. Moreover, the histopathologic subtypes occur in distinct patterns in different extra-nodal areas. The clinical course and response to treatment for the more common extra-nodal organs, e.g., stomach, Waldeyer ring, skin and brain, are fairly well known and demonstrate significant variation. A few randomized trials have been carried out testing the role of radiotherapy (RT) in these lymphomas. However, for the large majority of extra-nodal lymphomas randomized trials have not been carried out, and treatment decisions are made on small patient series and extrapolations from nodal lymphomas. RT is the most effective single modality for local control of NHL, and it is an important component of the treatment of many patients with extranodal lymphomas. In aggressive extranodal lymphomas combined modality treatment with initial chemotherapy (CT) followed by RT is the standard, whereas indolent extranodal lymphomas are generally treated with RT alone as the primary treatment. The previously applied wide field and involved field techniques are no longer relevant, and have been replaced by defined volumes based on modern imaging and the ICRU concepts, the so-called involved site RT (ISRT). Moreover, there is increasing evidence that the RT doses used in the past are higher than necessary for disease control. Indolent lymphomas are highly radiosensitive, and the dose range is normally between 20 and 30 Gy. For aggressive lymphomas doses of 30 to 36 Gy are appropriate after a complete response to CT, whereas higher doses of 40-45 Gy are used for gross residual disease. The goal of modern smaller field RT is to reduce both treatment volume and dose whilst maintaining efficacy and minimising acute and late sequelae.

Target volumes, doses and radiation techniques depend on the type of lymphoma and the extent and location of disease. In extranodal lymphomas in general the same principles apply as for localized nodal lymphomas, but the extranodal location needs to be taken into consideration (e.g., CNS, ocular, orbital, head & neck, skin etc.). In many organs (e.g., stomach, salivary glands, thyroid gland, CNS) lymphoma is multifocal. Moreover, even with modern imaging it may be difficult to accurately define the exact extent of disease in many extranodal sites. Hence, the whole organ is usually treated even if apparently only partially involved. Some aggressive lymphoma types, notably the T-cell lymphomas, are less sensitive to CT than aggressive B-cell lymphomas, and suspected microscopic disease may have to be included in the target for RT even in the combined modality setting. Uninvolved nodes are not routinely included in the CTV even in indolent lymphomas. However, first

echelon nodes of uncertain status close to the primary organ may be included.

The International Lymphoma Radiation Oncology Group (ILROG) has published guidelines on modern RT for extranodal lymphomas (1,2). The guidelines provide general principles for RT of the different types of extranodal lymphomas, but they require the clinician to adapt the volume, the dose, and the technique to the individual clinical setting.

**Teaching Lecture: Strategies to increase safety in radiation oncology: how to make accidents less likely to occur**

**SP-0195 Strategies to increase safety in radiation oncology: how to make accidents less likely to occur**  
P. Scalliet<sup>1</sup>

<sup>1</sup>*UCL Cliniques Univ. St. Luc, Brussels, Belgium*

Although a universally accepted, specific definition of quality in radiotherapy is lacking, the provision of safe and quality treatment is the aspiration of the radiotherapy community. Safety is that part of the Quality Assurance Management system that ensures a faultless delivery of treatment. Actually, the entire purpose of QA management is to guarantee a safe radiotherapy. Two aspects can be identified within safety management : *proactive* safety and *reactive* safety. Proactive safety is that part of the quality system that specify what procedures are appropriate for a preventive assessment of risk. It consists of an elaborate deconvolution of the entire radiotherapy process, followed by an assessment of how, why and when can any part of the process fail. It is therefore an intellectual exercise, a test for the imagination facing a complex treatment or procedure, before the process is actually implemented in the practice. The most frequent methodology in proactive safety management is (H)FMAE or (human) failure mode and effect analysis. Other approaches exist, but they all come to the same point : describe the process and try to understand in what way it can fail (failure mode) and what effect it is likely to have on the patient (effect). When looking into possible failure modes, two scores are given : one for the frequency (is it likely to occur frequently or not) and one for the severity (will the consequence be severe or not). Combining the scores helps to rank the risk on a priority scale. But not all failure modes are preventable. Even with the best provisions, failures will still occur. A failure can reach the patient or not. In the first case it is called an incident or an accident depending on the severity of the consequence, else it is a near-miss. A second possible classification is whether the failure is recoverable or if it is not. Discovering during the course of radiotherapy that a small dose error occurred but that it can be recovered by altering the remaining treatment sessions is typically a "recoverable" mistake. Discovering the same at the end of the treatment is obviously "not recoverable". However, such distinctions are not universally accepted, and a lot of different definitions exist. The interesting part of it is that by analysing mistakes, a better or deeper knowledge of the actual safety is gained, and corrective actions on the quality

management system itself can be introduced. Therefore, registering and analysing errors is an efficient way to improve safety.

**Teaching Lecture: Automated planning, knowledge-based planning and other novel developments in treatment planning - how do they work and perform?**

---

**SP-0196 Automated planning, knowledge-based planning and other novelties in treatment planning - how do they work and perform?**

B. Heijmen<sup>1</sup>, P. Voet<sup>2</sup>, L. Rossi<sup>1</sup>, A. Sharfo<sup>1</sup>, Y. Wang<sup>1</sup>, S. Breedveld<sup>1</sup>

<sup>1</sup>Erasmus MC Cancer Institute, Radiation Oncology, Rotterdam, The Netherlands

<sup>2</sup>Elekta AB, Elekta AB, Stockholm, Sweden

This lecture will give an overview of latest developments in treatment planning, both including principles of novel approaches, and applications. More specifically, the following topics will be discussed:

- Treatment plan generation as a formal multi-criterial optimization problem - difference between Pareto-optimal plan and clinically optimal plan
- Overview of algorithms for automated and knowledge-based plan generation
- Validation of the quality of automatically generated plans: how + results
- Automated planning for bias-free treatment technique comparisons
- Automated planning for adaptive radiotherapy
- Future role of planners in the era of automated plan generation
- Real-time planning
- Beam angle optimization for non-coplanar treatment
- Individualized automated plan QA: is the generated plan optimal for the given patient anatomy?
- From PTV/PRV towards probabilistic or robust planning

---

**Teaching Lecture: Building of NTCP models that contain non-dosimetric parameters**

---

**SP-0197 Building of NTCP models that contain non-dosimetric parameters**

T. Rancati<sup>1</sup>

<sup>1</sup>Fondazione IRCCS Istituto Nazionale dei Tumori, Prostate Cancer Program, Milan, Italy

It is well known that the risk of radio-induced toxicity increases when higher doses and larger volumes are involved in the irradiation and, in the last years, some consistent results have been published on the possible estimation of normal tissue complication probability (NTCP) for a number of organs-at-risk.

The widespread method used for such calculations is based on a sigmoid dose-response curve coupled to reduction of the whole dose-volume histogram into one parameter (such as the equivalent uniform dose).

NTCP models with their prediction based only on dosimetric variables can be used in treatment planning and can act as a baseline reference. On the other hand, it is becoming clearer that radiation-related side effects are also correlated to a number of patient-related factors. With the advent of newer radiotherapy technologies, which allow steep gradients and minimization of doses to normal tissues, there is an increased interest in understanding clinical/genetic risk factors that might enhance patient radio-sensitivity and to develop NTCP models which might include these variables in order to achieve better normal tissue complication predictions. A number of published studies have shown that current

NTCP models can be improved by incorporating clinical risk factors into model formulation. Overview of published results will be presented.

A further important step is the inclusion of molecular/genetic predictors into NTCP models. This issue is still at a very primitive stage and should be elucidated because, given the same set of clinical/dosimetric factors, patient-to-patient variability in normal tissue response to radiation has been widely recognized in clinical practice, suggesting that this phenomenon might be, at least in part, genetically driven.

In this presentation data on molecular/genetic markers influencing radio-induced toxicity are presented, together with the first findings supporting the hypothesis that a genetically determined dose-response relationship is possible and could be used to predict the probability of side effects associated with radiotherapy and serve as a rational basis for individualized radiation dose prescriptions.

The future lies in these multi-factorial prediction models: a great effort has to be done to collect reliable detailed prospective data for the development of NTCP models with the inclusion of predisposing clinical/genetic features for normal tissues involved in radiotherapy.

**Teaching Lecture: Particle therapy - how to start up and carry out daily clinical practice**

---

**SP-0198 Particle therapy - how to start up and carry out daily clinical practice**

H. Hentschel<sup>1</sup>

<sup>1</sup>EBG MedAustron GmbH, Medical Department, Wiener Neustadt, Austria

The MedAustron Center for ionbeam radiotherapy and research started clinical operation, i.e. patient treatment in December 2016.

MedAustron does not use any turn-key solutions for beam acceleration, beam delivery, patient positioning and positioning-verification but refined existing products and teamed up with industrial and scientific partners to develop novel solutions. The decision to use non off-the-shelf technology and to CE-certify the Synchrotron and affiliated components as medical devices is an opportunity to maximize the usability of the given technical conditions as well as to optimize the efficiency of patient treatment. The team of RTTs which was already integrated in the project phase faced new challenges and demands off the beaten path of existing and settled structures of hospital based radiotherapy departments. The approach of sequentially taking individual beam lines and particle species in operation involves constant change and demands a team of flexible and innovative radiotherapists. MedAustron is an autonomous outpatient clinic which is not affiliated with a hospital. As a consequence RTTs are also involved in regulatory affairs, quality management, risk management, purchase, maintenance and documentation of inspections of medical products and supplies.

---

**Teaching Lecture: Three-dimensional cell culture systems**

---

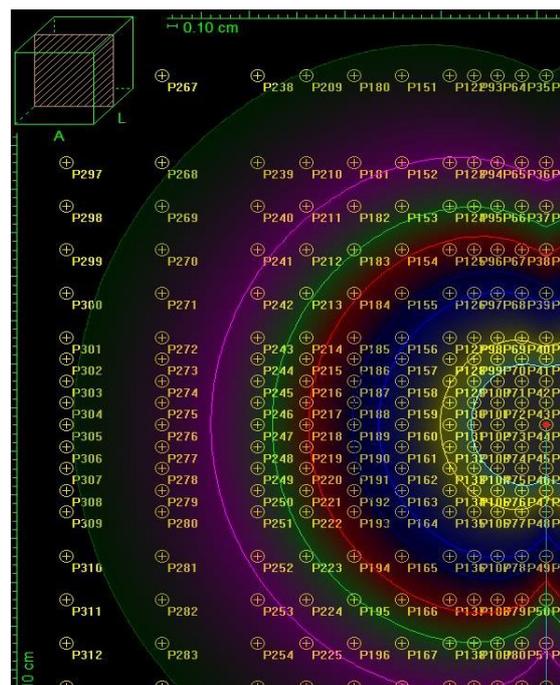

**SP-0199 Three-dimensional cell culture systems**

N. Cordes<sup>1</sup>

<sup>1</sup>OncoRay - Center for Radiation Research in Oncology, Dresden, Germany

3D cell cultures appear in many different self-made and commercially available facets. A common denominator for some of them is that they enable cell growth in a more

physiological environment than conventional 2D cell cultures. Unfortunately, validation of their suitability to do so and to fit to a particular scientific question is mostly missing. In this teaching lecture I will discuss validation strategies and data of comparative analyses between 2D, 3D and tumor xenografts of various processes such as signal transduction, DNA repair and others. Based on our long-standing experience, a large variety of endpoints can be determined and many methods can be conducted in 3D cell cultures. While this is sometimes not as easy as in 2D and also requires a bit more financial invest, the generated data reflect cell behavior in-vivo and thus have a higher clinically relevance. Further, we are able to address specific tumor features in detail. For example, malignant tumors show great genetic/epigenetic and morphological/cell biological heterogeneity. Another important point is the sparing of animal experiments based on our broad knowledge that human (patho)physiology is significantly different from mice (or other species). Many decades of in-vivo research have demonstrated that only a negligible proportion of therapeutic approaches could be translated from rodents to humans. In conclusion, 3D cell culture models can elegantly support our efforts to gain more knowledge for precision cancer medicine as they present powerful tools for generating more clinically relevant information. A broader implementation of the 3D methodology is likely to underscore our efforts to better understand tumor and normal cell radiation responses and foster identification of most critical cancer targets.

---

Teaching Lecture: Commissioning of dose calculations in brachytherapy TPS

---

**SP-0200 Commissioning of dose calculations in brachytherapy TPS**

J. Steenhuijsen<sup>1</sup>

<sup>1</sup>Catharina Ziekenhuis, Eindhoven, The Netherlands

When commissioning a Treatment Planning System for brachytherapy, most attention is given to the accurate calculation of the absolute dose and the dose distribution. The goal of the TPS however is to devise a treatment with an optimal dose distribution to both targets and organs at risk with the use of an applicator or needles. Thus, when commissioning the TPS, not only accurate calculation of the dose distribution has to be established. It is equally important to verify the correctness (size, rotation, order, reconstruction) of the images (CT, MR, US) used and to check the accuracy of (automatic) contouring, the resulting Regions Of Interest, ROI-mathematics and the Dose Volume Histograms based on these ROIs. The user should also be aware of specific behavior of the planning system (for instance with respect to extremely small volumes or volumes defined on one slice).

Also definitions of sources and applicators and accurate reconstruction of applicators have to be verified. On the other hand, the time available to spend on TPS-commissioning is limited, so an intelligent choice of tests to has to be made. A prospective risk analysis can help with this choice.

The teaching lecture gives an overview on literature on commissioning of TPS for brachytherapy and provides practical methods to check the various parts of the TPS.

Symposium: New developments in Personalised Radiation Oncology (PRO)

---

**SP-0201 E-health and Personalised Radiation Oncology: cloud technologies and advanced sensing**

S. Kyriazakos<sup>1</sup>

<sup>1</sup>Innovation Sprint, Brussels, Belgium

eHealth solutions have started in the past decade to attract the attention of several markets, as they support both healthy adults and patients of chronic diseases. However, the level of maturity of eHealth solutions targeting cancer patients is very low. Among the reasons is the highly regulated environment, the cost of the service and the technical challenges to offer accurate, intelligent, personalized applications, respecting the privacy of the patient.

In this talk, the best-of-breed of Internet technologies, such as cloud infrastructures, Big Data analytics, advanced sensing and smart applications will be presented and it will be demonstrated how integrated approaches can break the entry barriers, thus improving the daily life and the treatment of cancer patients.

**SP-0202 Integration and analysis of complex data for Personalised Radiation Oncology**

A. Dekker<sup>1</sup>

<sup>1</sup>Maastricht Radiation Oncology MAASTRO GROW - School for Oncology and Developmental Biology- University Maastricht, Maastricht, The Netherlands

Personalised radiation oncology requires a prediction of the outcome of an individual cancer patient treated with radiation oncology with or without additional treatment modalities. This outcome prediction should include prediction of tumour outcomes (e.g. survival, local control, distant metastasis), toxicity outcomes affecting quality of life (e.g. radiation induced and non-radiation induced toxicities, overall quality of life) and ideally should also predict expected cost, both for the treatment itself and additional societal costs during the lifetime of a patient.

Making accurate prediction for these outcomes requires data on many patients, preferably from many institutions using different treatment protocols. Also these data needs to be of high quality, rich in its content and will come from many data domains (clinical, imaging, omics, society, quantified self). Integration of data across these domains and across hospitals worldwide and analysis of such complex datasets is the topic of this seminar. With lung cancer as the running example, known prognostic and predictive factors for outcomes after radiotherapy will be summarized to show the domains from which data needs to be integrated and the challenges associated with each domain. The problem of dimensionality reduction, risk of over-fitting and need for robust validation will be detailed. Then the need and barriers for integration data across vertical data partitions (e.g. departments in a hospital having a 'slice' of data for a give patient) and across horizontal partitions (e.g. each hospital has a patient cohort with data) will be discussed. Finally, some example implementations and first results of efforts to integrate and analyse these complex data will be shown.

#### **SP-0203 Innovative clinical trial designs for Personalised Radiation Oncology**

S. Brown<sup>1</sup>

<sup>1</sup>University of Leeds, Institute of Clinical Trials Research, Leeds, United Kingdom

Radiation oncology research requires use of appropriate novel trial designs and robust statistical strategies to ensure reliable decision making. Phase I/II drug trials typically focus on identifying the maximum tolerated dose of a novel therapy. In the context of radiation oncology, this concept is not so clear cut. Various aims of phase I/II trials investigating radiotherapy-novel agent combinations include identifying optimum scheduling, determining the optimum biologic dose, and obtaining preliminary estimates of efficacy. Difficulties in attributing toxicities and evaluating longer-term toxicity also pose problems in designing early phase radiation oncology trials. Opportunities exist to apply novel clinical trial designs to the setting of phase I and II trials in radiation oncology, to overcome some of these difficulties, and to also enable investigation of a number of novel agent-radiotherapy combinations together. Several practical designs addressing this will be discussed in this session, as well as those taking into account known biomarkers in the evaluation of efficacy.

#### **SP-0204 Decision support systems and shared decision making**

M.A. Gambacorta<sup>1</sup>, G. Chiloire<sup>1</sup>, C. Masciocchi<sup>1</sup>, N. Dinapoli<sup>1</sup>, F. Cellini<sup>1</sup>, A. Re<sup>1</sup>, V. Valentini<sup>1</sup>

<sup>1</sup>Università Cattolica del Sacro Cuore -Policlinico A. Gemelli, Radiation Oncology, Rome, Italy

The personalized approach to cancer patient requires a shared decision which derives from the contribution of every single specialist involved in the cure of any single person affected by cancer. The tumor behaviour and patient outcomes are related to several factors. These factors and their interactions are sometimes poorly known by the doctors who will take the therapeutic decision for the patients. Different branches of medicine have developed their own lines of research which are sometimes difficult to be interpreted, difficult to be integrated with classical clinical factors and for these reasons, difficult to be applied in clinical practice. In the clinical prediction and decision making process, results provided by these researches are rarely included, whereas clinicians usually use few clinical and imaging data for understanding tumor behaviour, predicting patients' outcomes and thus for choosing the the most suitable treatment. In the last years, in the literature,

several studies based on the analysis of large data-base started to appear. These type of studies uses an advanced statistic aiming to find the connections between different covariates in predicting outcomes. The clinical decision is usually based on general guidelines which extrapolate information from randomized clinical trial (RCT). Moreover independent factors, derived from several RCT, are used by the Oncologists to make his prevision on tumor behaviour and consequently to choose the „right treatment“ for a specific patient. RCT enclose patients with characteristics chosen beforehand and usually the innovative information are never or rarely included. This lead to a potential miss of several information that could refine prediction and thus promote personalized treatments and to an erroneous outcomes prediction that can lead to un-appropriate treatment decision for a specific patient. Integrative data analysis has the potential to correlate data of different origins (genetic, radiology, clinic,...) with patient's outcomes and to create a consistent dataset useful to obtain a trustful analysis for the Decision Support System (DSS). The DSS can easily be applied in clinical practice helping the Oncologist to merge several information that otherwise would be excluded in the process of decision making. The possibility to predict the outcome for a certain patient in combination with a specific treatment with more accuracy, will lead to better identification of risk groups and thus better treatment decisions in individual patients, but it will also stimulate research focused on specific risk groups which try to find new treatment options or other combinations of treatment options for these subgroups. These treatments will be more personalized, which will not only save patients from unnecessary toxicity and inconvenience, but will also facilitate the choice of the most appropriate treatment. The resulting predictive models, based on patient features, enable a more patient specific selection from the treatment options menu and a possibility to share decisions with patients based on an objective evaluation of risks and benefits. Finally, considering the important role that predictive models could play in the clinical practice, clinicians must be aware of the limits of these prediction models. They need to be internally validated taking into account the quality of the collected data. An external validation of models is also essential to support general applicability of the prediction model. Therefore structural collaboration between different groups is crucial to generate enough anonymized large databases from patients included or not in clinical trials.

#### **Symposium: Safety and clinical and cost effectiveness of multi-modality IGRT and ART**

#### **SP-0205 What evidence is needed to assess cost-effectiveness of new technology and how can we get it (easily)?**

M. Johannesma<sup>1</sup>

<sup>1</sup>Health Insurance Company CZ, Department Innovation & Advice, Tilburg, The Netherlands

The incidence of cancer is increasing worldwide. By this, but also due to the rapid diffusion of new technologies, there is a continues rise in health care costs. For decision-making, primary studies of costs of health technology are gaining importance and cost-effectiveness analysis are increasingly used to estimate the incremental health gain for an incremental use of resources. Economic evaluation in health care, the comparative analysis of alternative interventions in terms of both their costs and consequences, are performed with the aim to determine the value for money of new treatments compared to the prevailing standard. In their aim to support decision making in health care, they represent one aspect within

the wider spectrum of Health Technology Assessment (HTA). Although more limited types of evaluations exist, only the formal comparison of costs and effects between two or more alternative interventions is considered to be a full economic evaluation. To date, economic evaluation has been mainly applied to pharmaceutical interventions. Less attention has been paid to other types of intervention, including those involving advanced health technologies in radiotherapy. Overall, the fundamental problem in determine the cost-effectiveness for new technologies is the lack of valid data on effects as well as costs. While randomized trials provide the most robust clinical evidence of comparative efficacy, it is widely recognized that high-level evidence is rarely achievable with new technology, due to methodological and ethical problems. Decision making in high technology areas is therefore more challenging since adequate data is often lacking. The number of published well performed economic evaluations of radiotherapy using appears quite low. As a consequence, there is limited robust evidence on the effectiveness and cost effectiveness of radiotherapy in cancer. Besides, it seems that results of apparently similar cost-effectiveness studies are often not comparable, since there is no uniformity on used input variables - e.g. patient and tumor characteristics, assumed impact of the treatment on outcome, treatment costs - which is essential for the final result of the analysis. Therefore, comparing results of for example Markov model analysis were different variables are used doesn't make sense. Let's take a closer look at the case of proton therapy. It seems hard, or even impossible, to estimate the cost-effectiveness of proton therapy based on the published literature, mainly due to a lack of data. This does not, however, relieve the many proton centers that have recently become operational from the moral duty to generate prospective evidence in terms of clinical outcome and value for money. Even if they do, this will take many years, whereas guidance in how to most optimally allocate resources to these novel treatments is urgently needed. Of course, more and better data, will result in better outcome and more robust conclusions, however this lack of data was already obvious ten years ago, we might wonder if an adequate dataset will ever be available. A model-based approach could be the solution based on subgroup or individual patients. Applying NTCP models forms the decisive link can generate evidence regarding the value of proton therapy, and helps to create enriched cohorts of patients who are likely to benefit from protons. Next, it is possible to quantitatively assess the effectiveness of proton therapy for individual patients, comparing photon and proton treatments on dose metric, toxicity and cost-effectiveness levels, retrieved from a decision support system. Gathering good clinical and cost data remains essential in defining the cost-effectiveness of new technologies, such as proton therapy. In the absence of level 1 evidence, well-performed modelling studies taking the uncertainties, available cost and outcome parameters into account, can help to tackle the problem. Because it is evident that protons will not be cost-effective for a total group of patients but for a subset of patients, we shouldn't look at the whole population anymore but at an individual patient level. Well-designed decision support systems will play an important role here. Whereas agreement on used input variables and primary endpoints remains still essential.

#### SP-0206 Tips and tricks for safe and effective routine clinical application

F. Duprez<sup>1</sup>

<sup>1</sup>Universitair Ziekenhuis Gent, Radiotherapie-Oncologie, Gent, Belgium

Since almost a decade, adaptive (ART) and multimodality image guided radiotherapy (IGRT) have been investigated with the aim of improving radiotherapy in many settings.

Several planning studies, observational studies and prospective trials have demonstrated the feasibility and theoretical advantages of ART and IGRT. However, the implementation of ART and IGRT also imply incremental work load, use of imaging techniques and extra or longer hospital visits for patients that can already be overwhelmed by standard procedures in their ill status. Unlike the fact that there is yet no large-scale evidence of the safety or cost effectiveness of these techniques in clinical routine, dedicated hardware and software for ART and IGRT are commercially available and implemented in an increasing number of centers.

This lecture will focus on the clinician-oriented point of view. ART might be planned before start of therapy, e.g. consecutive plannings at certain timepoints in the radiation course, while it might also be decided during the course of radiotherapy based on clinical findings or changing anatomy: both indications for ART will be discussed in the lecture. Unanswered questions and caveats will be covered, e.g. how to report and interpret final delivered doses, how to handle with volume shrinkage in targets/organs-at-risk and how to identify triggers to decide to adapt treatment. During the lecture, practical tips and tricks for implementation of ART and multimodality IGRT will be given.

#### SP-0207 Do we have the tools for safe application of adaptive radiotherapy?

L.B. Hysing<sup>1,2</sup>, S. Thörnqvist<sup>1,2</sup>

<sup>1</sup>Haukeland University Hospital, Oncology and Medical physics, Bergen, Norway

<sup>2</sup>University of Bergen, Physics and Technology, Bergen, Norway

Radiotherapy (RT) is traditionally administered as an 'open loop-process' of pre-treatment imaging, planning and fractionated treatment delivery. But why don't we just image the patient at each treatment fraction, make a plan on the fly and administer this plan to the patient while he/she is lying on the treatment table? In the context of adaptive radiotherapy (ART) this would be referred to as online re-planning. ART is the process where the original treatment plan can be modified if motivated by feedback from previous fractions during the course of RT (Yan et al. PMB 1997;42:123-32). Whereas feedback in the vast majority of the clinical ART workflows in pelvic RT are based on daily images acquired at each fraction, the type, timing and frequency of adaptations can vary greatly from daily online tracking and re-planning approaches, daily plan selection or updating of the plan once during the course of treatment (Thörnqvist S. Acta Oncol 2016;55:943-58). As of January 2015, the online re-planning scenario above had been applied to 1409 patients, all receiving brachytherapy for gynecological cancer. However, for external beam therapy online re-planning was common among in-silico simulation studies (36% of prostate studies, 56% of gyne studies and 22% of bladder studies as of Jan 2015), but it had not yet been applied clinically. Identified bottle necks for clinical application were limited in-room imaging quality (mostly CBCT) together with manual contouring which was a pre-requisite in 70% of the in-silico studies. For external photon therapy, MRI is becoming an alternative to CBCT with better soft tissue contrast thus also aiding contour propagation based on deformable image registration. However, for particle therapy where ART is expected to be needed more frequently as well as for a larger fraction of patients, in-room imaging will remain a big challenge. For photon therapy, tools are being developed by both research teams and vendors to allow for fast re-planning at each treatment fraction. Such solutions should include i) target generation ii) evaluation of the dose distribution iii) QA of the MU calculation of beam parameters. Is such a workflow feasible and realistic in clinical practice? Is it safe? How and which dose should be reported and

compared? Can the resources of ART be motivated by a clinical gain, or have we lost the clinical perspective during the technological development? These are points that will be further addressed in this talk.

**SP-0208 Development of procedures for safe clinical application of plan-of-the-day adaptive radiotherapy**

S. Quint<sup>1</sup>, J. Penninkhof<sup>1</sup>, J. Schiphof-Godart<sup>1</sup>, W. Hilst-van der<sup>1</sup>, B. Heijmen<sup>1</sup>, M. Hoogeman<sup>1</sup>

<sup>1</sup>Erasmus MC Cancer Institute, Radiation Oncology, Rotterdam, The Netherlands

Complex tissue variations during the course of a radiotherapy treatment combined with IMRT or VMAT require adaptive approaches using in-room verification of position and shape of the target volume for optimal dose avoidance in organs at risk. In Erasmus MC we have developed an on-line adaptive approach for cervical and bladder cancer patients. So far more than 200 patients have been treated with adaptive therapy [Heijkoop S., IJROBP 2014, Jun;90(3):673-9]. For each patient, an individualized library of treatment plans is pre-treatment established. Each plan in the library is optimally suited for a patient anatomy that can potentially occur during treatment. During each fraction, the plan that best matches the anatomy of the day is selected, based on an acquired CBCT.

In this presentation, we will discuss aspects for safe introduction and application of the novel technology, including formal risk analyses, multi-disciplinary involvement, education, and definition of tasks and responsibilities of technologists, physicists, and physicians.

**Symposium: Robust optimisation in protons and photons**

**SP-0209 What is the actual robustness of the plans we deliver in particle therapy and what measures do we take to obtain it**

S. Molinelli<sup>1</sup>, M. Ciocca<sup>1</sup>

<sup>1</sup>Fondazione CNAO, Medical Physics, Pavia, Italy

A prerequisite of high precision radiotherapy (RT) is high precision of dose planning and delivery. If all involved uncertainties are not accounted for, this will result in a reduced benefit of highly conformal techniques, such as particle therapy (PT). By definition, a plan is robust when treatment goals are met despite uncertainties in patient and beam models and the plan remains acceptable over a range of likely variation. PTV margins are a well-established strategy to guarantee target coverage in photon RT, but showed to be a suboptimal solution in PT. Deviations in particle range entail significant dose deformations, related to the single beam path and require beam specific margin expansions. Uncertainties, and robustness as a consequence, depend on multiple factors: plan optimization, dose calculation accuracy, immobilization systems, image guidance protocols and delivery techniques. First of all, robust beam selection is essential to reduce heterogeneities across the beam path and avoid regions subject to intra and inter-fraction variations in patient anatomy which could determine unexpected severe dose errors. Set up errors and inherent deviations in CT calibration values can be included in plan evaluation and in the optimization process itself. Several approaches have been proposed for robust plan optimization, showing that the cost of robustness is often a reduction of plan conformality and a consequent increase of OAR doses. Planned dose recalculation based on machine log files allows for evaluation of the impact of dose delivery errors, providing important information on plan sensitivity to beam energy or position deviations. The consistency between planned and delivered doses may

substantially deteriorate when approximation errors occur in the dose calculation algorithm. This influences particle range and causes improper modeling of the Bragg peak degradation and beam lateral spread in heterogeneous media. When comparing TPSs based on different beam models, substantial dose differences can be found, particularly if passive beam modulators are used. While for protons the well-known distal end RBE enhancement can be easily accounted for with a distal margin extension, a more complex issue concerns carbon ions RBE-weighted doses. The RBE dependence on depth, dose, energy, fractionation and cell type is strictly related to the biological model adopted in the TPS. Changing the model or model parameters, impacts on RBE-weighted dose values corresponding to the same absorbed (and delivered) dose, with a significant influence on clinical outcomes. Most clinical TPS in use do not provide any tool for management of plan robustness. Site specific, manual and cumbersome approaches are often required, based on beam geometry constraints and the use of avoidance structure to force and/or prevent radiation pathways. Recent commercial systems provide robust evaluation and optimization tools based on the inclusion of set up errors and CT-HU variation to account for random and systematic range uncertainties. Few attempts have been made in the direction of delivery pattern optimization, in terms of energy layers rescanning, redistribution and filtration and spot editing. Simultaneous plan optimization on multiple CT scans, representing different anatomical conditions involved in the dose delivery phase (e.g.: 4D CT scans, in case of gated treatments to mitigate plan sensitivity against residual organ motion) is, to our knowledge, still missing. A fast and accurate MC engine should be available for dosimetric accuracy assessment in challenging clinical cases, where the calculation algorithm is known to present significant limitations. For carbon ion therapy, TPSs should provide dose averaged LET and fragment spectra distributions, in addition to a flexible selection of different RBE biological models and model parameters. Common plan evaluation metrics, setting a threshold between plan robustness and conformality, are still not available in clinical routine. Retrospective analysis of delivered plans could help in the definition of reference robustness databases in centers with consolidated clinical results. Experimental systems for in-vivo monitoring of particles range provide a direct measure of the uncertainties involved. A new PET scanner able to operate during the actual treatment of H&N tumors has recently been tested, based on the measurement of the B+ activity induced by the interaction of the therapeutic beam with patient tissues. Optimal PT plans should preserve target dose conformity, healthy tissue sparing and robustness towards uncertainties. IGRT protocols to minimize inter-fraction deviations should be integrated with robust plan geometry, optimization and evaluation. Even in a robust dose distribution, due to the sensitivity of particle range to variations in volume, shape and filling of tissues along the beam path, the implementation of adaptive protocols is mandatory for a correct treatment.

**SP-0210 Minimax robust optimisation applied to IMPT for oropharyngeal tumours**

S. Van de Water<sup>1</sup>, M. Hoogeman<sup>2</sup>, B. Heijmen<sup>2</sup>

<sup>1</sup>Erasmus MC Cancer Institute, Department of Radiation Oncology, Rotterdam, The Netherlands

Robust optimization techniques increasingly receive attention, especially in the field of particle therapy, as they are considered more effective and more efficient in dealing with treatment uncertainties compared with the use of conventional safety margins. During robust optimization, treatment uncertainties are explicitly included in the mathematical optimization, thereby ensuring adequate irradiation when errors occur during treatment execution. Different approaches to robust

optimization have been described in literature. 'Minimax' robust optimization is a relatively straightforward implementation and is currently incorporated in several treatment planning systems that are commercially available. During minimax robust optimization, dose-influence matrices are typically calculated for the nominal scenario (without treatment errors) and for a number of user-defined error scenarios, and are subsequently used to optimize worst-case values. The user can generally specify the number of included error scenarios and the magnitude of the treatment errors accounted for. In this way, one can account for errors in patient setup and in particle range, and, in some implementations, for anatomical changes.

The characteristics and practicalities of minimax robust optimization in intensity-modulated proton therapy (IMPT) for oropharyngeal cancer patients will be addressed in this presentation:

1. Robustness recipes: Which robust optimization settings (i.e. error scenarios) should be used for given population-based distributions of setup and range errors (systematic/random), in order to obtain adequate clinical target volume (CTV) coverage in oropharyngeal cancer patients? Available robustness recipes differ between patients with unilateral or bilateral tumors and suggest that setup errors and range errors can be accounted for independently.

2. The price of robustness: What does robustness cost in terms of dose to organs-at-risk (OARs)? An investigation on the impact of the degree of robustness (i.e. magnitude of the included error scenarios) on OAR doses and resulting normal-tissue complication probabilities showed that setup robustness had a substantially larger impact than range robustness. This suggests that minimizing setup errors should be given a higher priority than minimizing range errors, in IMPT treatments for oropharyngeal cancer patients.

3. Minimax robust optimization to account for anatomical uncertainties. Anatomical robust optimization can effectively deal with changes in nasal cavity filling, providing substantially improved CTV and OAR doses compared with the conventional margin-based approach. Future investigations should reveal whether minimax robust optimization can also be used to account for other anatomical changes in oropharyngeal cancer patients.

#### SP-0211 Clinical implementation of coverage probability planning in cervix cancer

J.C. Lindegaard<sup>1</sup>, A. Ramlov<sup>1</sup>, M. Assenholt<sup>1</sup>, M. Jensen<sup>1</sup>, C. Grønberg<sup>1</sup>, R. Nout<sup>2</sup>, L. Fokdal<sup>1</sup>, K. Tanderup<sup>1</sup>, M. Alber<sup>3</sup>

<sup>1</sup>Aarhus University Hospital, Department of Oncology, Aarhus C, Denmark

<sup>2</sup>Leiden University Medical Center, Department of Radiation Oncology, Leiden, The Netherlands

<sup>3</sup>Heidelberg University Hospital and Heidelberg Institute for Radiation Oncology HIRO, Department of Radiation Oncology, Heidelberg, Germany

Definitive radiotherapy in locally advanced cervical cancer (LACC) often includes boosting of multiple pathological pelvic nodes. The simultaneous integrated boost (SIB) technique delivered by intensity modulated radiotherapy (IMRT) or volumetric arc therapy (VMAT) is increasingly being used as recent studies have shown excellent nodal control with a boost of 55-60 Gy. However, nodal boosting on top of elective whole pelvic radiotherapy at 45-50 Gy invariably causes collateral higher dose to especially bowel and pelvic bones, as metastatic regional nodes in LACC are most often situated in the retroperitoneal lymphatic space close to both bowel loops and the pelvic wall. This dilemma may be even worse in situations where para-aortic nodes are encountered and require irradiation.

At present no consensus exists on the required margin for nodal boosting by SIB, but margins of 5-10 mm from the

gross tumor volume of the node (GTV-N) to the nodal planning target volume (PTV-N) have been reported. Since the diameter of pathological nodes (GTV-N) most often is about 10-20 mm, SIB dose planning using a classical PTV concept of a dose plateau with full PTV-N coverage will entail a relatively large volume being treated to high doses compared to the actual GTV-N volume. In addition, the robustness of SIB being embedded in the 45-50 Gy irradiation of the whole pelvis is not fully utilized.

Coverage probability treatment planning (CovP) has previously been shown to provide robust dose escalation for IMRT of prostate cancer with overlapping PTV and rectum planning volume as well as superior patient specific small bowel planning volume allowing for tighter OAR margins with for instance para-aortic radiotherapy. Reduction of the dose at the perimeter of the PTV-N could therefore be considered by employing coverage probability dose planning (CovP) for SIB in LACC. With CovP local weights for each voxel are being used to create a dose gradient at the edges of PTV-N according to the presumed probability of finding the nodal target at this coordinate in the treatment room. The shape of the fall-off is based on assumptions about the position error of the GTV-N. CovP has recently been implemented in the prospective international multicentre EMBRACE II study for SIB planning of nodal boosting in LACC ([www.embracestudy.dk](http://www.embracestudy.dk)).

Clinical validation and implementation of CovP treatment planning in LACC was performed at Aarhus University Hospital in 2015 as a preparation for the Embrace II study. Until then CovP had only been explored by use of experimental treatment planning systems. A first step was therefore to obtain a set of dose constraints based on a number of CovP dummy runs performed in the research dose planning software Hyperion. Based on assumptions regarding the position of GTV-N over time, the dose optimizer created a dose gradient around the CTV-N which was allowed to lie partially inside PTV-N. From these experimental CovP plans, dose constraints for use with the clinical treatment planning system Eclipse were chosen that captured the dose peak and dose gradient of the CovP dose distribution for this particular setting of SIB boosting in LACC: PTV-N D98 >90%, CTV-N D98 > 100% and a soft constraint of CTV-N D50 > 101.5% of the prescribed dose. The next step was then to analyze a number of previously treated patients with LACC. In total 25 patients with 47 boosted nodes treated with SIB delivered by IMRT or VMAT from 2012-2015 were investigated (Figure 1). Dose of EBRT was 45 Gy/25 fx with a SIB of 55-57.5 Gy depending on the expected dose from brachytherapy (BT). The planning aim was to reach D98 > 57 GyEQD2. Nodes were contoured on cone beam CT (CBCT) and the accumulated dose in GTV-N<sub>CBCT</sub> and volume of body, pelvic bones and bowel receiving >50 Gy (V50) were determined. Nearly all nodes (89%) were visible on CBCT and showed considerable regression. Total EBRT and BT D98 was >57 GyEQD2 in 98% of the visible nodes. Compared to conventional planning, CovP significantly reduced V50 of body, bones and bowel. With CovP a new tool is available for nodal SIB in LACC allowing for controlled underdosing at the edge of the PTV. As this study is mainly based on pelvic nodes along the major vessels it is still unclear how margin reduction and CovP will perform for SIB of para-aortic nodes or nodes in the groins. Nodes in the vicinity of organs which may be displaced e.g. by the bladder or rectum may also need monitoring in terms of delivered dose and eventually plan adaptation during EBRT. However, CovP could be of interest for nodal SIB in anal, rectal, vulvar, penile, vaginal, prostate and bladder cancer. In EMBRACE II the patients are treated with a reduced PTV-N margin (5 mm), daily IGRT, IMRT/VMAT and CovP planning for SIB with planning aims presented above. With an estimated accrual of 800 patients, of which 50% will node positive disease, a

comprehensive study regarding follow-up after CovP based nodal boosting can be expected.

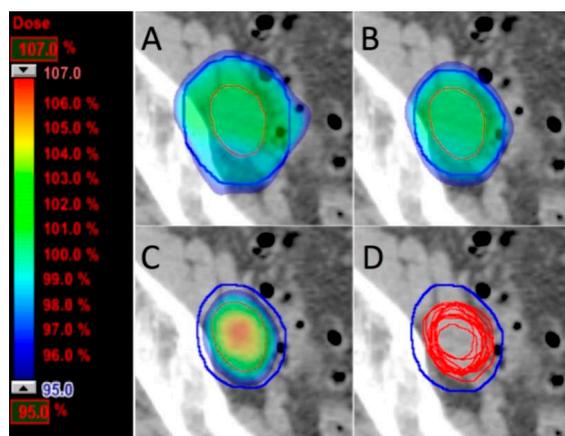

Figure 1. Pathological node (red contour) from locally advanced cervical cancer positioned at the external iliac vessels treated with a simultaneous integrated boost of 55 Gy/25 fx on top of whole pelvis 45 Gy/25 fx: A) Conventional planning 10 mm PTV margin (blue contour), B) Conventional planning 5 mm PTV margin, C) Coverage probability planning 5 mm PTV margin, D) Cone beam CT contours of the node obtained during treatment demonstrating regression towards the centre of the node.

#### Symposium: Ultra fast online therapy adaptation (replanning, dose accumulation QA)

##### SP-0212 Automatic image segmentation and structure evaluation for on-line adaptive RT

S. Mucic<sup>1</sup>

<sup>1</sup>Washington University School of Medicine, Department of Radiation Oncology, St. Louis, USA

The online adaptive radiotherapy (OART) has become a practical reality in recent years. Through experience, we have learned that the conventional radiotherapy planning (RTP) practices are not directly translatable to OART. With the OART, the entire planning process needs to be performed very quickly and generally can take no longer than 20-30 minutes for imaging, segmentation, planning, and quality assurance. The efficiency requirements of OART mean that each of the treatment planning steps needs to be performed in minutes rather than in hours or days, which can be afforded with the conventional RTP processes. This rate of efficiency demands a fundamental revisiting of the paradigms used in conventional RTP. One of the major differences between the OART and conventional RTP is image segmentation and processing of the segmented structures. For image segmentation, the OART efficiency needs mean that 1) there will be a significantly higher degree of reliance on auto-segmentation, 2) that few structures may be used/delineated, 3) that the conventional paradigms for structure creation will not be followed and that some structure will be contoured only to a limited extent, or 4) a combination of all three of these approaches. Unfortunate reality is that even the most sophisticated modern auto-contouring algorithms still have an unacceptably high degree of failure and inaccuracy and that these algorithms are almost always guaranteed to need some degree of manual editing. Additionally, many practical clinical cases are proving themselves to be not very good candidates for auto-contouring and that manual segmentation may be the best/most practical approach. The suboptimal performance of auto-contouring algorithms and use of a significant amount of available time on manual contouring or contour editing means that typically there is not much time left for contour validation. This lack of time for contour validation means that there is an increasing need for automatic evaluation of the segmented structures. It

is well understood that suboptimal structure delineation (target or normal organs) can lead to suboptimal or unsafe treatment plans. Inaccuracies in structure delineation can translate to errors in treatment planning with OART more likely than with conventional RTP due the limited time available for quality assurance of segmented structures with OART. Many bodies have recommended that peer review process should be used as the second check of accuracy of organ delineation. With OART, prospective peer review will likely never be practical and the accuracy of auto-segmentation as well as the robustness of automatic evaluation of segmented structures will have to be able to compensate for limited ability for independent human checks. This presentation includes discussion of current practices in OART image segmentation with review of disease sites which are leading in the initial use of OART. Also discussed will be the image segmentation approaches for OART. Finally, efforts for development of automatic methods for verification of accuracy of segmented structures will be discussed. Now that OART is a practical reality, it is obvious that additional work is needed in development of image segmentation algorithms as well as development of automatic methods for verification of segmented structures.

##### SP-0213 Ultra-fast treatment planning and dose reconstruction

P. Ziegenhein<sup>1</sup>

<sup>1</sup>The Institute of Cancer Research and The Royal Marsden NHS Foundation Trust, Joint Department of Physics, Sutton, United Kingdom

A new generation of hybrid MRI and linear accelerator machines, such as the MR-linac, is currently brought into practice which allows monitoring the changing patient anatomy during radiation delivery. The newly acquired images cannot only be used for real-time position verification but also to inform a re-planning strategy which adapts the treatment to the latest geometries. This new technique demands for a more interactive therapy workflow than it is used today. Treatment planning and dose verification steps need to be carried out more frequently and faster in order to make use of the continuously updated patient images.

In this talk we will address two vital aspects of realizing an online therapy adaptation workflow: ultrafast treatment planning and dose reconstruction. Nowadays, with the help of modern computational hardware both operations can be performed in real-time. We will present state-of-the-art techniques designed especially for multi/many-core CPUs and discuss opportunities and challenges of their application. A proof of concept study on realistic patient data will be presented while alternative techniques and methods are analyzed and critically evaluated.

##### SP-0214 Online tumour tracking - technology and quality assurance

E. Colvill<sup>1</sup>

<sup>1</sup>Aarhus University Hospital, Radiation Oncology, Aarhus C, Denmark

Intrafraction motion during radiotherapy delivery causes a blurring of the delivered dose distribution. For treatment sites affected by respiratory motion, including lung, liver and pancreas this effect can result in substantial deviations between planned and delivered dose, potentially compromising clinical goals. Treatment delivery accuracy may be increased through the implementation of adaptive delivery techniques. Online tumour tracking adapts the treatment to anatomical changes which may occur on the scale of seconds or minutes. It combines monitoring of the target motion and adaptation to that motion in real-time. In this talk a review of motion monitoring and treatment adaptation

techniques for online tumour tracking will be presented and a discussion on the required quality assurance for application in patient treatments. Many motion monitoring techniques may be utilised for online tumour tracking including various internal and external tracking techniques or combinations of the two. Online tumour tracking includes simple adaptation methods such as gating and breathhold techniques which minimise the motion present during the time that the treatment beam is on. However, the main focus in this talk will be on techniques leveraging treatment units specifically designed for intrafraction motion compensation. These include online tumour tracking with robotic (CyberKnife) and gimbaled (Vero) linacs, as well as with standard linacs utilising a multi-leaf collimator (MLC) or a robotic couch. The talk will conclude with a discussion of important factors to be considered in the design of quality assurance programmes for online tumour tracking.

**Symposium: Particle therapy: how to start up and carry out daily clinical practice**

---

**SP-0215 RTTs skills for proton therapy - how and what to include in a learning programme**

A. Boejen<sup>1</sup>, T. Trans<sup>1</sup>, M. Madsen<sup>1</sup>, D. Mortensen<sup>2</sup>  
<sup>1</sup>Aarhus University Hospital, Department of Oncology, 8000 Aarhus C, Denmark  
<sup>2</sup>Aarhus University Hospital, The Danish Centre for Particle Therapy, 8000 Aarhus C, Denmark

Treatments with particle therapy (PT) will be common daily practice in more clinics and countries in Europe in the coming years. At Aarhus University Hospital, the Danish Centre for Particle Therapy is currently under construction, and installing and monitoring of equipment for dose delivery will start June 2017. All clinical procedures, such as CT-scanning, dose planning and immobilisation, must be ready for practice, as well as guidelines e.g. for patient pathway, correct dose delivery, image guidance, patient care and management. Interdisciplinary groups are starting to build up a new field. All professions must be qualified in their field to secure patients receive a correct treatment, and all centres are organising education and learning programmes.

This presentation will share our experiences concerning development of skills, learning objects and education programmes for experienced radiation therapists (RTTs) at a centre under establishment, which is expected to be in operation autumn 2018. The presentation will also cover experiences on establishing learning programmes in an interdisciplinary group with no clinical experience in proton therapy and no available online education programmes or documentation of the competencies for RTTs on PT.

To secure an international perspective ESTRO's Core Curricula[1] were used as inspiration to build up learning levels and expected outcomes concerning knowledge, skills and attitudes using Bloom's taxonomy[2]. The taxonomy should be used in the field of clinicians, physicists and RTTs, while harmonisation was expected to be useful in the development of interdisciplinary programmes. Hiring of RTTs will start in spring 2018 and is estimated to be expanded with opening of additional gantries every six to twelve months until full employment in 2023. The final learning programme has to consider the progressive increase in employed RTTs and ensure the right competencies for RTTs within treatment preparation, dose delivery and patient care.

The preliminary tasks for RTTs were described first and followed by a long list defining specific competencies regarding e.g. management of positioning, fixation, ProBeam, IGRT and side effects. There has to be a

constant focus on the differences between conventional radiotherapy and PT. The systematic plan with learning levels in all contexts has helped to visualize learning methods in each competence. A 3D virtual ProBeam (VERTUAL Ltd, UK) is being developed and will be integrated together with an IT-laboratory (Varian VMS) as part of the learning features. Interdisciplinary education, supervision and collaboration with physicists and clinicians are important. Observer ships at experienced particle centres and weekly conferences with evaluation of proton plans aimed at learning have contributed to the learning process.

**SP-0216 How to start up a proton therapy department - the point of view of a RTT**

M. Furberg<sup>1</sup>  
<sup>1</sup>Skandionkliniken, Uppsala, Sweden

**Short history, organization and distributed competence.**

The Swedish proton project started in 2003 with a formation of SPTC (Swedish proton therapy center), which consisted of members of the medical profession. They advocated for a national proton clinic in Sweden, and in 2005 all 21 county politicians agreed that we should have a proton therapy clinic in Sweden. In 2006 the seven counties that have university hospitals formed a municipal federation for advanced radiotherapy and decided that they would build a proton clinic that would be located in Uppsala, in the middle of Sweden. They also decided that the clinic would be based on a distributed competence concept, which means that all expertise available in the country at university clinics will be used and that all preparation for the patient fixation, CT scanning, target delineation and treatment planning would be conducted at university clinics, while the treatment will be delivered at the proton facility. In practice, this means that the university hospitals would make a photon and a proton plan for each of the patients to see whether there is an advantage for protons for the diagnoses that had clinical proton protocols. These plans are presented on a national multidisciplinary video conference where the plans are compared and the clinicians jointly take the decision whether the patient should receive proton therapy. In this case the patient is called to the clinic while fixation devices and the proton plans are sent to the facility. The clinic uses permanent staff, including all RTT/nurses, two permanent physicians and three permanent medical physicists, as well as rotating radiation oncologists and medical physicists from the university hospitals.

**Process description and risk analysis.**

The first RTT/nurse was hired a year and a half before the start of treatments, who along with a national multidisciplinary working group devised a process description and a risk analysis based on the proposed patient course from the university clinics to the Skandion Clinic and back. Two RTT/nurses employed one year before the start of treatments worked together in various national working groups to develop procedures, workflows, train in and configure the systems to be used in the process such as the Mosaiq OIS (oncology information system), patient information system and fixation procedures. Three RTT/nurses joined six months before the start of treatments with responsibility to work up procedures and guidelines for the coordinator, the procedures and guidelines for pediatric treatments and for nursing care at the facility. An important part was dedicated to writing all the required documents for new processes that has to be developed from scratch, so a group of RTT/nurses and

medical physicists built a document management system that follows the patient process from university clinics to the Skandion Clinic. It contains all guiding and supporting documents, procedures and instructions. An essential experience acquired was that it is very important to write the required documents on so many procedures, guidelines and instructions as much as possible before the first patient treatment. Thus it was found that once the clinic was up and running with patient treatments, it was much easier to revise an existing procedure than to get time to write entirely new ones.

**Acceptance and measurement, education and training.** It was decided early on that the RTT/nurses would work in team with the medical physicists on measurement and acceptance of IBA's equipment so there was at least one RTT/nurse during the daytime. Then we continued during the first half of the year with a medical physicist and a RTT/nurse to work together on the morning checks. The clinical training included the IBA Web training from UPenn in Philadelphia as well as study visits for two weeks in the proton clinic in Philadelphia. To this the IBA on site clinical training at the Skandion Clinic was added. We were given training on all new systems including trolley transport, CT scanning, journal system, fire and safety, CPR, etc. Another valuable experience was gathered from end-to-end testing, when a mock patient went through all phases of the process from each university clinic to the Skandion Clinic and back.

**An empty House to a functioning clinic.**

RTT/nurses had responsibility for equipping the premises with all that may be needed in order to start up a functioning clinic. This included practically everything from staff clothing to consumables and medicines, the toys for the children and even the special requirements of the anesthesia personnel.

In summary, it has been hard work, frustrating at times, but extremely educational and stimulating most of the time, and above all a fun time to start up a clinic.

**SP-0217 Workflow in a proton therapy department - real difference from photon therapy?**

**F. Fellin<sup>1</sup>**

<sup>1</sup>*Ospedale Santa Chiara di Trento, U.O. Protonterapia, Trento, Italy*

In Europe, there was a significantly increase in proton therapy (PT) facilities in the last few years. In PT, Radiation Therapy Technologists (RTTs) have a key role throughout the patient's therapeutic course, such as in photon therapy. The physical characteristics of protons are an advantage for saving the organs at risk (OARs) and/or for increasing the dose to the target, but they imply some important criticalities during the patient workflow. Pencil Beam Scanning (PBS) is the most advanced technique for PT but this is the proton technique with more criticality. RTTs, should know these critical issues and be aware of the impact that they have in the patient workflow and in their working activities. RTTs are involved in several steps of the patient workflow in PT; in general, they are the same as in photon therapy: simulation CT, diagnostic imaging, treatment planning, delivery of therapy. However, in each single step, there are important differences compared to photon therapy. Starting from the simulation, the main differences relate to the choice of the immobilization devices, both for their purchase that for each specific patient, and the definition with tattoo of the treatment isocenter that, especially with PBS, it can be defined directly during the acquisition of simulation CT. In addition, since the dose delivery is very accurate, the definition of target volumes and OARs must be very strict. For this reason, the PT facilities are usually equipped with MR and PET-CT systems; RTTs must be able to use this equipment and to acquire the necessary images.

In the treatment planning step, the Medical Dosimetrists

(MDs) work with the Medical Physicists in the plans optimization; they will use all the experience to get the best plan for each patient. In addition to all the attention that MDs must have during treatment planning, which are common in photon therapy, in PT there are other situations in which they must be careful. For example, it is very important to set the correct direction of the fields based on the tissues that the beams must pass through before reaching the target and it is recommended to avoid that all fields have the distal fall-off in the same area (in particular near OARs); it is important to limit the use of the range shifter and to select the most appropriate irradiation technique based on the specific case (SFO, MFO); MDs must know and evaluate all possible uncertainties (range, RBE, ...); they must adopt robust optimization techniques and field specific PTV. Even for the delivery of therapy sessions, there are some important differences between photon and proton therapy. First, the equipment is quite different: RTTs must know in detail the PT equipment operation. Proton therapy equipment is much larger and more complex compared to photon therapy system. In PT, the patient setup is checked every day; generally, RTTs use flat panels with x-ray tubes system (for 2D images) or CBCT (for 3D images). In some facilities, a CT on-rails is installed in the treatment room and RTTs use this one for monitoring the patient position before the therapy. The advantage of CT on-rails is that, in principle, you can use the daily images for checking the dose distribution every day. In PT, tattoos performed during the simulation CT are important especially in the first treatment session. They are used to align the patient and move manually the treatment couch on the isocenter, for defined the setup position. Afterwards, RTTs capture the couch coordinate for setup position and, during subsequent sessions, the table will be aligned automatically. In all sessions except the first one, tattoos are important only in treatments with immobilization devices that are not perfectly indexed on the couch, e.g. in the case of treatments in pelvic area. RTTs must be very careful during the proton dose delivery with PBS. There isn't a proper ratio between dose and monitor units delivered; the number of monitor units depend on the field size: the greater the size of the target, the greater the number of MU and the beam-on time. Given the precision of proton dose delivery, small anatomical changes can lead to important variations of dose distribution in the patient. For this reason, RTTs must observe and communicate any anatomical variations that they see during the patient setup. In this way, it is possible to perform any dosimetrical checks in the course of therapy. In these cases, it is very useful to have a CT on-rails. In PT, RTTs will have to acquire a weekly control CT for treatments of areas prone to anatomical changes. It will be used by Physicists or MDs to perform dose assessments during the treatment and, if necessary, they will organize a replanning.

These are some of the most significant differences observed in proton therapy compared to photon therapy; they change the work of RTTs in patient workflow. PT is an advanced, complex and precise radiation therapy technique and it requires very high skills for RTTs.

**Symposium with Proffered Papers: Combining tumour and normal tissue models**

**SP-0218 Novel approaches in the study of bladder cancer**

**A. Kiltie<sup>1</sup>**

<sup>1</sup>*Oxford, United Kingdom,*

Patients with muscle-invasive bladder cancer can be treated by removal of their bladder (cystectomy) or by bladder preserving strategies, which include the use of

radiotherapy and chemotherapeutic agents which act as radiosensitisers. In assessing the efficacy of drugs as radiosensitising agents, it is important to determine their effects on normal tissues as well as tumours. We have developed a modified crypt assay to assess acute toxicity on bowel surrounding the bladder *in vivo*. Furthermore, as murine small intestine is exquisitely sensitive to the doses of radiation used, we have developed an irradiation method which avoids the small intestine, using a small animal radiation research platform (SARRP), to assess late bowel toxicity associated with bladder cancer radiotherapy. Our methods should help identify those agents which may be suitable to take forward to clinical trials.

**SP-0219 Optimising the output of preclinical lung models to optimize the chances of success into the clinic.**

E. Deutsch<sup>1</sup>

<sup>1</sup>*Institut Gustave Roussy, Villejuif, France*

Despite the numerous promising preclinical data, increasing the therapeutic efficacy of chest radiotherapy using novel drugs-radiotherapy combinations has often failed to show promise in the frame of clinical trials. In some cases, these novel approaches failed to increase the anti-tumor efficacy of standard radiotherapy suggesting that preclinical models were not appropriate enough to recapitulate the complexity and the most recent advances in our understanding of tumor biology (i.e. the spectrum of mutational events, the tumor/immune host interactions...). In other cases, new drugs- radiotherapy combinations induced severe toxicities that justified the discontinuation of clinical development plans. This underscores the fact that in many circumstances, preclinical models have been overlooking normal tissue response to radiotherapy. As an illustration of this, major monoclonal antibodies used in the clinic such as anti EGFR or anti VEGF were developed in the clinic on the basis of preclinical rationale that were not able to detect any impact on normal tissue response. Another reason for these limited effects is the fact that many preclinical experiments fail to associate and to combine with chemoradiation and use radiation alone as a comparator. The development of orthotopic, syngenic tumor models offers the opportunity to evaluate within the same series of experiments both the normal tissue and the tumor response. The rising interest in the field of immuno oncology is also increasing our need for such models since the immune / stromal component which is not only an emerging player during tumor response to radiotherapy. As an illustration of this, we will present data from our group underscoring the fact that modulating the immune stroma affects normal response of the normal lung to radiotherapy. We make the assumption that such models could be a mean to minimize the early discontinuation of new drugs radiotherapy clinical trials and eventually to increase the patients' clinical benefit as the results of a better selection of novel therapeutic that would not impair, and if possible enhance, the tumor versus normal tissue clinical ratio.

**OC-0220 Exploiting novel combined-modality approaches for treatment of highly aggressive pancreas carcinomas**

M. Orth<sup>1</sup>, L. Posselt<sup>2</sup>, S. Kirchleitner<sup>2</sup>, J. Schuster<sup>1</sup>, C. Belka<sup>1</sup>, M. Schnurr<sup>2</sup>, K. Lauber<sup>1</sup>

<sup>1</sup>*LMU Munich, Department of Radiation Oncology, Munich, Germany*

<sup>2</sup>*LMU Munich, Department of Clinical Pharmacology, Munich, Germany*

**Purpose or Objective**

Pancreatic ductal adenocarcinoma (PDAC) is a cancer entity with growing prevalence and very poor prognosis.

The survival rates are limited to approximately 25% of patients after one year and only 5% after five years, respectively. Standard treatment encompasses surgical resection (if possible) accompanied by radiotherapy, chemotherapy and/or palliative care. However, treatment failure is frequent, and inherent resistance towards radio- and/or chemotherapy is considered as one major reason. Accordingly, novel treatment approaches are needed, which can address this resistance and which are able to create synergisms with the classic therapy modalities.

**Material and Methods**

A panel of human PDAC cell lines was subjected to clonogenic survival assays, and scores of radioresistance were extracted by principal component analysis. Next, the relative expression levels of DNA damage response (DDR) genes were analyzed by qRT-PCR, and correlation analyses were employed in order to identify potential drivers of radioresistance. Specific inhibitors targeting the respective candidates were examined in terms of their potential to sensitize PDAC cell lines towards radiotherapy. The obtained results were confirmed by RNA interference. The clinical relevance of the identified target genes was evaluated in the TCGA PDAC data set. Finally, an orthotopic PDAC model with fractionated CT-based irradiation was established in order to evaluate the therapeutic potential of our approach *in vivo*.

**Results**

Using a cohort of nine human PDAC cell lines, we identified several crucial components of the DNA damage response (DDR) machinery to be upregulated in the radioresistant cell lines, including ATM and DNA-PKcs. The impact of both kinases on clonogenicity was examined both by pharmacological inhibition and RNA interference. We found that inhibition and siRNA-mediated knockdown of DNA-PKcs significantly diminished the clonogenic potential of radioresistant PDAC cell lines. Using the TCGA PDAC collective, we found that expression of DNA-PKcs is elevated in about 11% of all samples and that this upregulation is associated with a striking decrease in overall survival. Currently, the *in vivo* efficacy of DNA-PKcs inhibition in combination with fractionated radiotherapy is tested in an orthotopic mouse PDAC model.

**Conclusion**

The poor prognosis of pancreatic ductal adenocarcinoma urgently demands for the development of novel treatment approaches. We show that pharmacological inhibition of the DDR-related kinase DNA-PKcs gives rise to a novel, highly promising treatment approach which should be further explored in the future.

**OC-0221 High-performance radiosensitivity assay to predict post radiation overreactions**

G. Vogin<sup>1</sup>, L. Bodgi<sup>2</sup>, A. Canet<sup>2</sup>, S. Pereira<sup>2</sup>, J. Gillet-Daubin<sup>2</sup>, N. Foray<sup>3</sup>

<sup>1</sup>*Institut de Cancérologie de Lorraine & UMR 7365 CNRS-UL, Academic Department of Radiation Oncology, VANDOEUVRE-LES-NANCY Cedex, France*

<sup>2</sup>*Neolys Diagnostics, R&D, Lyon, France*

<sup>3</sup>*Cancer Center of Lyon- UMR Inserm 1052 CNRS 5286 CLB, Radiobiology, Lyon, France*

**Purpose or Objective**

Between 5 and 15% of patients treated with radiation experience toxicity considered "unusual" that can lead to serious sequelae. Identifying those patients prior treatment would therefore have sound positive clinical implications. Retrospective analysis on skin biopsies from patients treated by radiotherapy to define a radiobiological parameter with the highest predictive performance that can be used as a reliable predictor of post-treatment toxicity.

**Material and Methods**

Immunofluorescence experiments were performed on the COPERNIC collection of 116 skin fibroblasts irradiated at 2

Gy. Biomarkers of DNA double-strand breaks (DSB) recognition and repair were assessed from 10 minutes to 24 hours after irradiation, including the relocalization of phosphorylated ATM Protein (pATM) as nuclear foci. These biological results were plotted against the CTCAE grades. A ROC curve analysis was then performed on patients after they were merged in two groups: radioresistant (grade <2) and radiosensitive (grade  $\geq 2$ ).

#### Results

This study showed that a delay in the nucleoshuttling of the ATM protein, which is involved in the recognition of the DSB, was a common feature to patients with overreaction (OR). The maximal number of pATM foci between 10 min and 1h post irradiation (pATMmax) was found to be the parameter with the best correlation with each OR severity grade, independently of tumor localization and of the early or late nature of reactions. When taken as a binary predictive assay with the optimal cut-off value of 35 pATM foci, pATMmax foci showed promising predictive performances, with an AUC of 0.97, a PPV of 99%, a specificity of 92% and a sensitivity of 100%.

#### Conclusion

The results of these experiments allowed us to identify pATMmax as a high performance predictive parameter of post-radiotherapy OR. Additional studies are in progress to confirm that this radiosensitivity assay reaches the same performances in any radiotherapy condition to change our daily clinical practice.

#### OC-0222 GnRH receptor blockade reduces radiation-induced bladder toxicity: first evidence in a rat model.

<sup>2</sup>Ospedale San Raffaele, Radiotherapy, Milan, Italy

<sup>3</sup>Ospedale San Raffaele, Medical Physics, Milan, Italy

<sup>4</sup>Ospedale San Raffaele, Experimental Imaging Center, Milan, Italy

#### Purpose or Objective

Genitourinary toxicity represents a major side effect in patients treated with primary, adjuvant or salvage radiotherapy for prostate cancer (PCa). Many clinical trials aimed at finding predictive factors of radiation-induced toxicity analyzed the impact of androgen deprivation therapy (ADT) with controversial results. However, recent data on large groups of patients support the hypothesis that short-term ADT is protective towards radiation cystitis. Our pilot study is aimed at supporting the putative beneficial role of a GnRH antagonist (degarelix) by means of an animal model that recapitulates many features of the human pathology.

#### Material and Methods

Male rats were surgically catheterized and randomly divided into three groups: radio-treated only (RT, n=4), radio-treated+degarelix (RT+DGX, n=4) and control (CTRL, n=2). Rats from RT and RT+DGX group were irradiated with a single fraction of 20 Gy to the bladder. The RT+DGX group received the drug (150  $\mu\text{g}/\text{kg}$ , sub-cute) once a week for 3 weeks, starting 1 week prior to irradiation. Each rat underwent pelvic ultrasound, before and after (day 6) irradiation, to evaluate bladder wall thickness. At day 21, cystometry was performed to evaluate bladder function. Then the animals were sacrificed and their bladder analysed in H&E and Azan-Mallory trichrome staining (day 21). One-way ANOVA with Tukey post test and t-Student were used to assess the statistical differences.

#### Results

Our data show that, in RT group, compared to pre-irradiation baseline, bladder wall thickness increased 1.8-fold after radiations ( $0.5\pm 0.2$  vs  $0.9\pm 0.4$  mm,  $p<0.05$ ),

while no significant differences were found in RT+DGX group ( $0.6\pm 0.2$  mm). Bladder basal (BP), threshold (TP), flow (FP), and maximal (MP) pressures as well as AUC/MI increased significantly in RT group compared to RT+DGX (BP:  $21\pm 6$  vs  $9.8\pm 0.5$ ; TP:  $41\pm 16$  vs  $15\pm 4$ ; FP:  $53\pm 19$  vs  $24\pm 4$ ; MP:  $83\pm 25$  vs  $41\pm 3$ ; AUC/MI:  $30\pm 10$  vs  $13\pm 2$ , cmH<sub>2</sub>O, all  $p<0.01$ ). Also, both micturition volume (MV) and intervals (MI) were reduced in RT animals and improved after DGX (MV:  $0.4\pm 0.1$  vs  $1.1\pm 0.3$  mL; MI:  $174\pm 45$  vs  $349\pm 116$  sec, all  $p<0.01$ ). The non-voiding bladder contractions in each micturition cycle were significantly higher in RT than RT+DGX group ( $5.5\pm 2$  vs  $0.6\pm 0.5$ ,  $p<0.05$ ). Compared to CTRL, histopathological analysis confirmed in RT group an increased mucosal layer ( $81\pm 25$  vs  $40\pm 16$   $\mu\text{m}$ ,  $p<0.05$ ), which was instead less pronounced in RT+DGX ( $63\pm 23$   $\mu\text{m}$ ). Finally, the bladder muscle/collagen ratio decreased in RT rats ( $0.8\pm 0.1$ ,  $p<0.01$ ) compared to CTRL ( $1.3\pm 0.2$ ) and almost normalized by DGX ( $1.1\pm 0.2$ ).

#### Conclusion

In irradiated rats, DGX prevented the urinary functional impairment and histological subversion of bladder wall. The differences in terms of both mucosa thickness and reduced collagen deposition suggest a possible effect by DGX on inflammation-mediated tissue remodeling. The presence of GnRH receptors in the bladder urothelium advocates a local effect with potential applications as radioprotectors, firstly in high-dose RT for PCa.

#### Symposium: Paediatric brachytherapy

#### SP-0223 The AMORE concept and late effects outcome for paediatric brachytherapy

B. Pieters<sup>1</sup>

<sup>1</sup>Academic Medical Center P.O. Box, Radiation Oncology, Amsterdam, The Netherlands

Childhood head and neck rhabdomyosarcomas are often large tumors at diagnosis. These tumors are usually located in areas with many vital structures. Radiotherapy to these tumors will have a high probability for serious late sequelae because of the sensitivity of normal tissue for radiation at young age. For these reasons the AMORE concept was developed in the nineties of last century for local treatment after the standard chemotherapy courses. AMORE is the acronym for Ablative surgery, MOld brachytherapy, and REconstruction. After a macroscopic radical excision, pulsed-dose rate brachytherapy (32-36 x 1.25 Gy at 2.1hour interval) is applied with a mold technique. The dose is prescribed on 5 mm from the mold surface. After brachytherapy the mold is surgically removed and the defect reconstructed with a free vascularized flap or a transpositional muscle flap. The Amsterdam cohort, with AMORE treated patients, was compared to a similar group of patients from London treated with only external beam radiotherapy (EBRT) as the radiation modality. Failure-free survival and overall survival were 58% and 76%, respectively and not statistically significant different between the two groups. Both groups were identically analyzed in a Late Effects Outpatient Clinic and all possible late effects scored according to the Common Terminology Criteria for Adverse Events version 4. The most seen late effect was musculoskeletal deformities; 60% any grade. The EBRT-based cohort therapy resulted in more adverse effects than the AMORE-based cohort. Also grade 3-4 adverse events were significantly more pronounced in the EBRT-based cohort. The largest difference in late effects was found for growth hormone deficiency. The odds ratio was 2.1 for EBRT-based therapy compared to AMORE-based therapy. In conclusion AMORE, with brachytherapy as radiation modality, is proven to be equivalent to EBRT with less late effects.

**SP-0224 Brachytherapy for bladder/prostate rhabdomyosarcoma: clinical outcome and functional results**

C. Chargari<sup>1</sup>, H. Martelli<sup>2</sup>, F. Guérin<sup>2</sup>, R. Mazon<sup>1</sup>, V. Minard-Colin<sup>3</sup>, E. Deutsch<sup>1</sup>, C. Haie-Meder<sup>4</sup>

<sup>1</sup>Institut Gustave Roussy, Brachytherapy Unit, Villejuif, France

<sup>2</sup>Kremlin Bicêtre University Hospital, Pediatric Surgery, Kremlin Bicêtre, France

<sup>3</sup>Institut Gustave Roussy, Pediatric oncology, Villejuif, France

<sup>4</sup>Institut Gustave Roussy, Radiotherapy Department, Villejuif, France

Historically, the standard treatment of children with bladder and/or prostate rhabdomyosarcoma (BP RMS) was based on total cystectomy or cysto-prostatectomy. The severe urinary and sexual sequelae of this radical surgical approach have prompted collaborative groups to look at alternative strategies, based on a multimodal conservative approach combining chemotherapeutic agents with radiation therapy. Although the probability of long-term survival with bladder preservation has improved with multimodal approaches, the risk of late gastrointestinal and genitourinary toxicities remains a major issue in children undergoing pelvic external beam radiotherapy (EBRT). Brachytherapy has been used in our center as part of the multimodal treatment of patients with BP RMS, in an effort to minimize sequelae. We report the results of an original conservative strategy based on surgery combined with brachytherapy. The outcome of children treated in our department between 1991 and 2015 for a BP RMS and undergoing a multimodal approach combining a conservative surgery (partial cystectomy and/or partial prostatectomy) and a perioperative interstitial low-dose rate or pulse-dose rate brachytherapy was prospectively documented. Prior to brachytherapy, children had received chemotherapy with modalities depending on their risk group of treatment. A total of 100 patients were treated, median age of 28 months (5.6 months-14 years). According to the Intergroup Rhabdomyosarcoma Study (IRS) Group group, 84 were IRS-III and 12 were IRS-IV tumors. Four patients were treated at relapse. Median number of chemotherapy cycles before local therapy was 6 (4-13). After surgery, 63 patients had a macroscopical tumor residuum. Five patients underwent a brachytherapy boost before pelvic external beam radiotherapy (EBRT) because of nodal involvement and 95 had exclusive brachytherapy. Median follow-up was 64 months (6 months-24.5 years). Five year disease-free and overall survival rates were 84% (95%CI: 80-88%) and 91% (95%CI: 87-95%), respectively. At last follow-up, most survivors presented with only mild to moderate genitourinary sequelae and a normal diurnal urinary continence. Five patients required a secondary total cystectomy: 3 for a nonfunctional bladder and 2 for relapse. A specific analysis of the urinary outcome of patients treated according to this strategy showed that 75% of long-term male survivors considered they had a normal quality of life after the combined conservative local treatment of their BP RMS. Therefore, brachytherapy is effective as part of a conservative strategy on BP RMS, with a relatively low delayed toxicity as compared with previously published studies using EBRT. Longer follow-up is required to ensure that the functional results are maintained over time.

**SP-0225 Intraoperative HDR brachytherapy for pediatric cancers**

S. Wolden<sup>1</sup>

<sup>1</sup>Memorial Sloan Kettering Cancer Center, New York- NY, USA

Brachytherapy remains the most conformal technique for delivering therapeutic radiation, making it an ideal option for pediatric patients. The normal tissue sparing is even

superior to proton therapy. I will discuss high dose rate (HDR) intraoperative brachytherapy (IORT) as a specific technique for the treatment of pediatric tumors. IORT may be used as an adjunct or even in place of external beam radiotherapy to maximize local control while minimizing normal tissue complications. We will review various IORT techniques as well as specific indications. Long term outcomes of relatively large series of children with neuroblastoma and pediatric sarcomas will be reviewed. A brief overview of other unique forms of brachytherapy for rare childhood tumors will also be presented.

**OC-0226 Towards consistency of TPS dose calculations: converting dose to medium to dose to water**

N. Reynaert<sup>1</sup>, F. Crop<sup>1</sup>, E. Sterpin<sup>2</sup>, H. Palmans<sup>3</sup>

<sup>1</sup>Centre Oscar Lambret, PHYSIQUE MEDICALE, Lille, France

<sup>2</sup>Katholieke Universiteit Leuven, Department of Oncology- Laboratory of Experimental Radiotherapy, Leuven, Belgium

<sup>3</sup>National Physical Laboratory, Radiation Dosimetry, Teddington, United Kingdom

**Purpose or Objective**

The aim of the current work is to demonstrate that conversion factors between dose to medium and dose to water calculated by different treatment planning systems for photon beams should be based on mass energy attenuation coefficients and that stopping power ratios should not be considered.

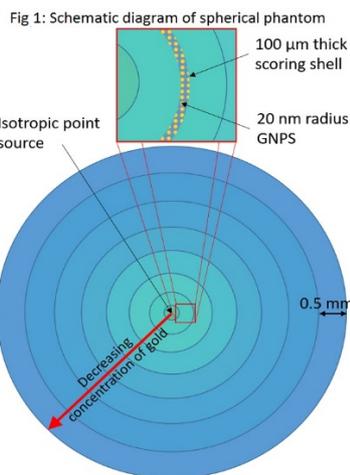

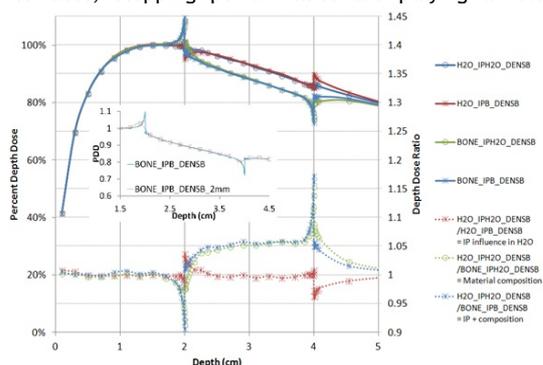

**Material and Methods**

A theoretical explanation is introduced establishing the inadequacy of stopping power values when converting dose to medium to dose to water (when considering TPS dose calculations). Monte Carlo calculations (EGSnrc) are performed in a simple bone phantom, validating the theoretical model. A bone slab is modeled and calculations are performed in bone and in water having the same electron density as bone. Special attention was paid on the importance and the range of the interface effects. Calculations were performed for 6 and 20 MV photon beams and 6-18 MeV electron beams are also considered.

**Results**

The Monte Carlo simulations clearly confirm the theoretical model. In the framework of TPS reporting/prescription, the dose to medium to dose to water conversion problem cannot be considered as a cavity problem as the composition of all voxels is modified simultaneously, leading to large electron fluence differences. For photon beams, the secondary electron fluence is modified by two effects. On one hand, fewer electrons are generated in bone because of the lower attenuation coefficients compared to water with the same electron density, which tends to increase the secondary electron fluence in water compared to bone. On the other hand, the range of these secondary electrons is larger in bone than in water with bone density which leads to an inverse effect. The first effect is defined by the ratio of mass attenuation coefficients; while the second by the ratio of stopping powers which is compensating the stopping power ratio present in the formal equation of the ratio of dose to water to dose to medium. Only at

interfaces, stopping power ratios are playing a role.

## Conclusion

As the range of the interface effects is less than commonly used voxel sizes for MV photon beams, one can in general use the ratio of attenuation coefficients to convert dose to medium to dose to water. As a direct consequence, uncertainties on stopping powers (due to uncertainties on the ionization potential of tissues) have negligible impact on the dose to medium to dose to water conversion. Dose to water obtained by multiplying dose to medium with stopping power ratios is another concept not consistent with how dose to water is calculated by conventional TPSSs.

## OC-0227 The heterogeneous multiscale model for efficient computation of microscopic dose metrics

M. Martinov<sup>1</sup>, R. Thomson<sup>1</sup>

<sup>1</sup>Carleton University, Physics, Ottawa, Canada

### Purpose or Objective

In the field of radiation therapy, there is increasing interest in the effects of ionizing radiation on short (micrometre, nanometre) length scales within macroscopic (~centimetre) volumes of interest. A common technique for studying radiation transport and energy deposition is via Monte Carlo (MC) simulations, requiring complex simulation geometries that are both reliable and efficient, two traits often in contention. This work introduces a general MC framework, the Heterogeneous MultiScale (HetMS) model, to address these challenges.

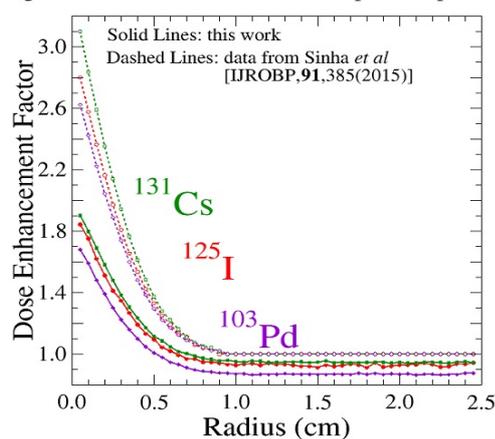

### Material and Methods

The HetMS model involves combining distinct models of varying level of detail on different length scales into a single simulation. We implement and present the HetMS model using EGSnrc for the context of gold nanoparticle (GNP) radiation therapy. Our model is verified via comparison with recently-published results of other MC GNP simulations. We then consider two scenarios: (A) 20 keV to 1 MeV photon beams incident on a 1 cm radius and 3 cm long cylindrical phantom; (B) low-dose rate brachytherapy sources at the centre of a 2.5 cm radius sphere with GNPs diffusing outwards from the centre (Fig. 1). In each simulation, homogenized tissue/gold mixtures are employed in larger volumes, with distinct subvolumes containing GNPs discretely modelled in pure tissue. Dose scored in pure tissue within the subvolumes is compared to dose scored in homogeneous tissue/gold mixtures and dose to pure tissue (to compute Dose Enhancement Factors (DEFs)).

## Results

HetMS simulations are able to efficiently account for important macroscopic and microscopic effects, successfully modelling the competing effects of photon fluence perturbation (due to modelling of gold/tissue mixtures in macroscopic volumes) coupled with enhanced local energy deposition (due to discrete modelling of GNPs within subvolumes). Energy deposition is most sensitive to these competing effects for lower energy sources, with considerable variations in DEFs for different source energies, depths in phantom, gold concentrations, and GNP sizes. For the cylinder phantom with 20 mg Au/g tissue, DEFs near 3.1 are observed near the phantom surface and decrease to less than one by 7 mm depth (i.e. dose decreases, not enhancements). Within the spherical phantom, DEFs vary with time for diffusion, radionuclide, and radius; DEFs differ considerably compared to those computed using a widely-applied analytic approach (Fig. 2). Compared with discrete modelling of GNPs within entire macroscopic geometry, HetMS simulations offer efficiency enhancements of up to a factor of 120.

Fig 2: Dose enhancement factor for spherical phantom

## Conclusion

The HetMS framework enables efficient simulation of both macroscopic and microscopic effects that must both be considered for accurate simulation of radiation transport and energy deposition. The HetMS model allows for MC simulations, typically prohibited by dense parameter spaces, to be employed in diverse radiotherapy and radiation protection scenarios.

### OC-0228 DVH criteria for prostate *in vivo* EPID dosimetry

R.F.M. Van Oers<sup>1</sup>, E. Van der Bijl<sup>1</sup>, I. Olaciregui-Ruiz<sup>1</sup>, A. Mans<sup>1</sup>

<sup>1</sup>Netherlands Cancer Institute, Radiation Oncology, Amsterdam, The Netherlands

#### Purpose or Objective

In our department *in vivo* EPID dosimetry is used for dose verification of all treatment plans. The algorithm uses EPID images acquired behind the patient to reconstruct the *in vivo* 3D dose distribution. This is then automatically compared to the planned dose distribution and alerts are generated when deviations are detected.

These alerts are based on  $\gamma$ -analysis. Gamma values combine dose-difference and distance-to-agreement in a single metric, but this metric contains no information on the clinical relevance of deviations. Furthermore,  $\gamma$ -analysis can be insensitive to systematic under- or overdoses in plans with inhomogeneous dose distributions. Dose-volume histograms (DVHs) are widely used for evaluation of treatment plans, and readily understood by clinicians. Moreover, differences in DVH parameters can be linked more straightforwardly to clinical relevance. This makes DVH-based criteria an attractive alternative to  $\gamma$ -criteria for *in vivo* EPID dosimetry alerts.

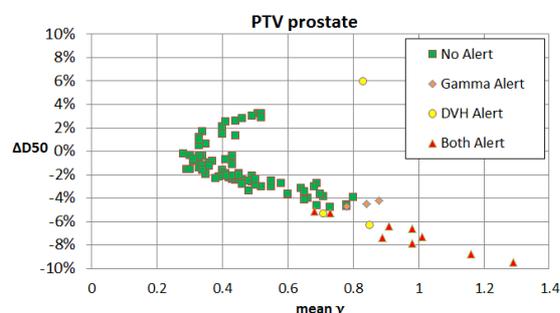

In this study we investigated the correlation between  $\gamma$ - and DVH-parameters of the PTV for prostate treatments, and compared the alert rates for different criteria in order to propose a suitable set of DVH-criteria for clinical implementation.

#### Material and Methods

*In vivo* 3D dose distributions were reconstructed for the first three fractions of 95 prostate VMAT treatments, and then averaged for the evaluation of each treatment. The  $\gamma$ -analysis was done with global 3%/3mm settings. DVHs were obtained for the PTV (prostate + seminal vesicles). Calculated  $\gamma$ -parameters were mean  $\gamma$ , the near-maximum  $\gamma$  ( $\gamma_1$ ), and the  $\gamma$ -passrate ( $\gamma\% < 1$ ); our current criteria also include the isocenter dose difference ( $\Delta D_{\text{isoc}}$ ). Calculated DVH-parameters were the difference in near-maximum dose ( $\Delta D_2$ ), median dose ( $\Delta D_{50}$ ), and near-minimum dose ( $\Delta D_{98}$ ). We obtained alert rates for different sets of criteria on these DVH-parameters. These were compared to alert rates for the current  $\gamma$ -based criteria. There are two alert levels, higher-priority "error" and lower-priority "warning".

#### Results

The strongest correlation was found between  $\gamma$ -mean and  $|\Delta D_{50}|$ , Pearson's  $r=0.95$ . All other  $\gamma$ - and DVH parameters were also strongly correlated, with  $r$  values around 0.85.

**Figure 1:** Relation between  $\gamma$ -mean and  $\Delta D_{50}$  for the analyzed prostate VMAT plans. The indicated alerts are generated by the "error level" sets of  $\gamma$ - and DVH-criteria.

Table 1 shows alert rates for different sets of  $\gamma$ - and DVH-criteria. The two highlighted sets of  $\gamma$ -criteria are the ones currently used in our clinic to generate alerts for prostate

treatments, juxtaposed with sets of DVH-criteria of similar alert rate.

ΔDVH				γ (3%/3mm)				
ΔD <sub>2</sub>	ΔD <sub>50</sub>	ΔD <sub>98</sub>	Alerts	mean γ	γ <sub>1</sub> %	γ-passrate	ΔD <sub>isoc</sub>	Alerts
4.0%	2.0%	4.0%	75%					
5.0%	2.5%	5.0%	56%	0.5	2	85%	3%	51%
6.0%	3.0%	6.0%	38%					
7.0%	3.5%	7.0%	29%					
8.0%	4.0%	8.0%	23%					
9.0%	4.5%	9.0%	19%					
10.0%	5.0%	10.0%	13%	1	4	70%	5%	13%
11.0%	5.5%	11.0%	10%					

**Table 1:** Alert rates (% of treatments) for different sets of  $\gamma$ - and DVH-criteria. The top set of  $\gamma$ -criteria corresponds to "warning level" alerts, the bottom set corresponds to "error level" alerts.

#### Conclusion

A strong correlation was found between  $\gamma$ - and DVH-parameters of the PTV; a set of DVH-criteria that performs comparably to the current  $\gamma$ -criteria can easily be chosen.

### OC-0229 EPID dose response in the MR-Linac with and without presence of a magnetic field

J. Torres Xirau<sup>1</sup>, I. Olaciregui-Ruiz<sup>1</sup>, B. J. Mijnheer<sup>1</sup>, U. A. van der Heide<sup>1</sup>, A. Mans<sup>1</sup>

<sup>1</sup>Netherlands Cancer Institute Antoni van Leeuwenhoek Hospital, Department of Radiation Oncology, Amsterdam, The Netherlands

#### Purpose or Objective

Image-guided radiotherapy systems are being investigated and clinically implemented aiming for online and real-time adaptation of the treatment plan. The use of Electronic Portal Imaging Devices (EPIDs) for independent *in vivo* dose verification in the Elekta MR-Linac is being developed. One of the challenges for MR-Linac portal dosimetry is the presence of a small magnetic field at the EPID level. In the presence of a magnetic field, the secondary electrons that actually deposit the dose in the scintillator of the EPID will be affected by the Lorentz force possibly leading to a B-field induced dose redistribution. The aim of this study was to analyze and quantify the effects of the B-field on the EPID images acquired on the Elekta MR-Linac.

#### Material and Methods

The Elekta/Philips MR-Linac combines a 1.5T magnetic resonance imaging scanner with a linear accelerator and is equipped with an on-board EPID. A magnetometer (MetroLab THM1176) was used to measure the strength of the magnetic B-field at the surface of the EPID. To assess the reproducibility of the panel readouts, a 10x10 cm<sup>2</sup> field was irradiated 10 times in two consecutive days and the value of the on-axis region (averaged 5x5 pixels) of EPID images was recorded. During the installation of the MR-Linac in our institute, EPID images were acquired before the B-field was ramped up and repeated with B-field one month later. To study the on-axis response of the EPID as function of field size with and without the magnetic B-field, square fields were irradiated with field sizes varying from 2 to 20 cm. Furthermore, EPID images acquired with and without B-field were compared by means of a 2-D  $\gamma$ -analysis (local 2%, 1mm, 20% isodose) and X-Y EPID lateral profiles were compared by visual inspection.

#### Results

The magnetic field measured on top of the panel did not exceed 2.5 mT, yielding an electron trajectory radius of approximately 1.20 m. The reproducibility of EPID central axis values for ten irradiated 10x10 cm<sup>2</sup> fields was 0.3% (1 SD).

The normalized on-axis EPID response as function of field size with and without the presence of the magnetic field is shown in Figure 1 together with their ratio.

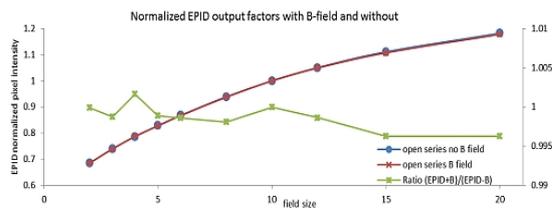

Figure 1: Normalized EPID central axis values for increasing field sizes (2x2-20x20 cm<sup>2</sup>) with (red) and without (blue) the presence of the magnetic field (left axis). In green, the ratio between the red and blue curves (right axis).

Figure 2 shows the comparison between the normalized lateral X and Y profiles of EPID images acquired with and without the B-field (3x3,5x5,8x8,10x10,12x12,15x15,20x20 cm<sup>2</sup>). More than 99% of the points showed local deviations smaller than 2% for the X and Y profiles.

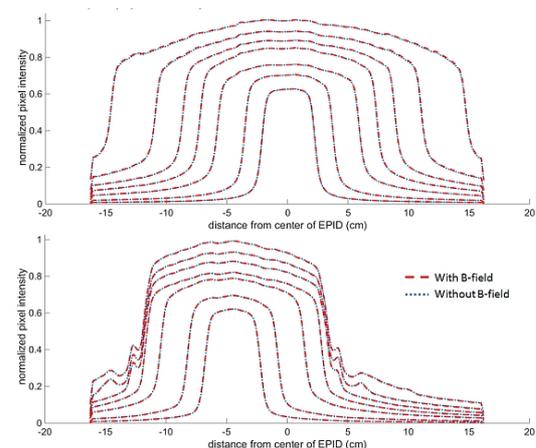

Figure 2: (top) and (bottom) EPID lateral profiles are shown for EPID images acquired with (red) the magnetic field, and (blue) without. Note the shift of the Y profiles due to a not centered position of the EPID.

The 2-D  $\gamma$ -analysis showed that the averaged  $\gamma_{\text{mean}}$  was  $0.42 \pm 0.16$  and the  $\%_{\gamma \leq 1}$  was  $96.6 \pm 4.5$ .

### Conclusion

EPID images acquired with and without B-field are virtually identical, indicating that the presence of a small (2.5 mT) magnetic field at the EPID level in the MR-Linac should not become an impediment for the implementation of EPID dosimetry in the MR-Linac.

### Acknowledgements

This research was partly sponsored by Elekta AB, Stockholm, Sweden. The authors would like to thank Robert Spaninks (Elekta) for assistance with the measurements.

### OC-0230 Treatment log files as a tool to identify inaccuracies in scanned proton beam delivery and planning

M. Belosi<sup>1</sup>, R. Van der Meer<sup>1</sup>, P. Garcia de Acilu Laa<sup>2</sup>, A. Bolsi<sup>1</sup>, D. Weber<sup>1</sup>, A. Lomax<sup>1</sup>

<sup>1</sup>Paul Scherrer Institute, Centre for Proton Therapy, Villigen PSI, Switzerland

<sup>2</sup>Hospital Universitario Puerta del Sur Hospitales de Madrid, Radiofísica Hospitalitaria, Madrid, Spain

### Purpose or Objective

Dose distributions delivered at Gantry2 (G2) at the Paul Scherrer Institut (PSI) can be reconstructed on the patient anatomy based on machine log files. These dose reconstructions are a powerful tool in identifying potential issues related to the integrity of the patients' dose delivery, as has already been demonstrated for a first series of patients treated in G2 for skull base chordomas (Scandurra et al. 2016). Here, such calculations have been extended by investigating their dependency on planning technique (e.g. SFUD vs IMPT, field direction etc) and on couch position. The latter is crucial for quality assurance of the delivery of patched fields (different sub-fields

combined to treat large areas) necessary for large H&N and pelvic treatments.

### Material and Methods

As of November 2015, 43 patients were treated on G2 for a total of 74 plans (21 SFUD, 51 IMPT and 3 SIB) and 248 fields (average of 4 fields per plan), of which 26 fields were patched. Parameters recorded during the treatment delivery of these patients (spot positions, MU's per pencil beam, couch and gantry position) are stored into a log file and used to reconstruct the 3D dose distribution by an in-house developed Independent Dose Calculation software (Meier et al. 2015). A MATLAB script calculates the dose metrics by comparing the reconstructed to the nominal dose distribution. These metrics include the maximum, minimum and mean dose differences as well as the percentage of voxels within +/- 1% of the nominal dose (pass rate).

### Results

Table 1 shows the results of the log file analysis. Interestingly, and despite the typically higher modulation for IMPT, the average pass rate for both SFUD and IMPT is similar, with the 95% percentile actually being a little better for IMPT. In addition, complex plans with steep in-field dose gradients, such as SIB treatments, also had pass rates >99%. Nevertheless, highly modulated plans can have larger local dose differences as seen by the larger max dose deviation in Table 1 and demonstrated for a specific case in Figure 1. Hence, attention should be paid to the location of isolated, highly weighted spots.

	Total Plans	SFUD Plans	IMPT Plans	SIB Plans	Fields	Patched Fields
Max Dose Diff [%]	3.4	2.7	3.4	1.2	10.3	2.5
Min Dose Diff [%]	-3.3	-3.3	-3.3	-1	-9	-3.3
Mean Pass Rate [%]	99.3	98.9	99.4	99.9	92.2	98
95th Percentile	97.5	93.7	97.6	100	74.9	93.8
Lowest Pass Rate [%]	90.6	90.6	91.4	99.9	58.3	93.1

Table 1. Max, Min Dose Differences (%) log file – nominal dose; average, 95th percentile and lowest values for the +/-1% pass rate (percentage of voxels with log file – nominal dose difference within +/-1%). For each plan, only one random fraction was chosen for the log file dose reconstruction

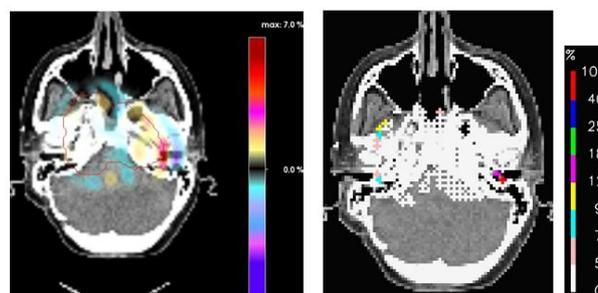

Figure 1. Left hand-side: voxel by voxel dose difference log file – nominal dose for one highly modulated field. A hot-spot of +7% is clearly visible at the target border on the left side of the patient, close to the cochlea; this is immediately followed by a cold-spot of -7%.

Right hand-side: optimized spot list for the same field, revealing 2 very highly weighted spots exactly in correspondence of the dose discrepancy on the left hand-side picture.

Finally, the results of the first patched field treatments (2 to 4 patches per field) did not show any evidence of dose deviations at the interface between patches.

### Conclusion

3D dose reconstruction using treatment log files is a powerful tool to identify delivery problems and trends, and to improve planning robustness. Further effort should be invested in order to predict field robustness to delivery fluctuations before the clinical delivery of the plan as part of the plan's specific QA.

### OC-0231 The suitability of radiochromic film in 0.35T magnetic field CO-60 compared with conventional 6MV D.L.J. Barten<sup>1</sup>, L.J. Van Battum<sup>1</sup>, D. Hoffmans<sup>1</sup>, S. Heukelom<sup>1</sup>

<sup>1</sup>VUMC, Radiotherapie, Amsterdam, The Netherlands

### Purpose or Objective

Recently the 0.35T CO<sup>60</sup> MRIdian system (Viewray Inc., Cleveland) is clinically implemented at our institution. IMRT online adaptive patient treatment is daily routine. Quality assurance (QA) on dose delivery (both absolute and position), and end to end test (per fraction and overall) are prerequisites for safety and quality. Hereto, a reliable dosimeter is required. EBT GafChromic film might appropriate. However, a magnetic field can cause perturbations to absolute and relative dosimetry measurements. In addition, the amount of radiation induced dipole polymers might be influenced by the orientation of the film in the B<sub>0</sub>-field, i.e. an angular dependency in absolute dose response might be present. The purpose of this study is to investigate suitability of EBT3 GafChromic film for MRIdian QA purposes.

### Material and Methods

GafChromic film sheets were irradiated in a water phantom using the MRIdian and a Linac (Varian 2300C/D, 6MV) as comparison system. The film sheets are placed in a rotatable device positioned in the water phantom such that the B<sub>0</sub> field is frontal or sagittal to the film surface in initial position (figure 1). The film was rotated over 7 angles from 0° to 90° and irradiated with 3Gy. On each machine 4 measurements were performed for each orientation. The irradiation setup is 5cm depth, 100cm SSD and 10.5x10.5cm<sup>2</sup>/10x10cm<sup>2</sup> (MRIdian/Linac) field size. Optical density (OD) to dose (D) calibration measurements (4x) were performed up to 8Gy both on MRIdian and Linac, with the film perpendicular to the beam axis. The film sheets were scanned in portrait mode with the A4 Epson 1680 Expression Pro flatbed scanner and at the film rotation point OD and D values were analyzed for the red, green and blue channel.

The following comparisons were made:

- Reproducibility of MRIdian and Linac film measurements
- Angle dependent film response with (MRIdian) and without B<sub>0</sub> (Linac) influence
- Angle dependent film response in frontal or sagittal setting

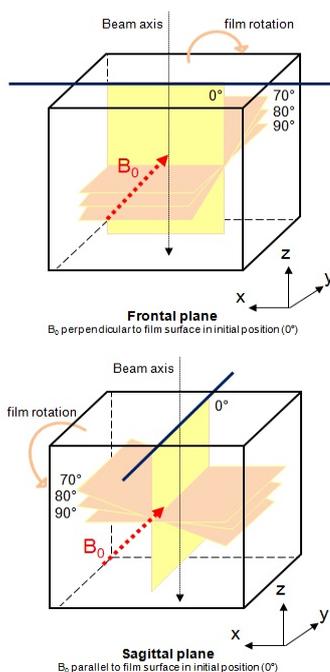

Figure 1 Schematic representation of experimental setup

### Results

Table 1 represents (a) the reproducibility of film OD values for both machines, (b) the influence of B<sub>0</sub> on film dose response over all angles and (c) the mean dose values

averaged over all angles for frontal and sagittal planes. The blue channel shows the widest range, which is i.a. due to the fact that the blue channel is barely dependent on dose and is sensitive to the dye homogeneity in the film. Using triple color correction on the results in (c) gives better mutual correspondence.

Table 1. Results are shown for each comparison made (a, b and c). Each part shows the discussed parameters per color channel (R,G,B) with it's minimal and maximal value (min/max) or 1SD (SD). B<sub>F</sub>F and B<sub>S</sub>S represent measurements in frontal and sagittal plane, respectively.

a. Calibration curve reproducibility						
Mean SD% for OD values averaged over all calibration dose points						
	R	G	B	Min/Max_R	Min/Max_G	Min/Max_B
Linac	0,53%	0,81%	0,57%	0,04/1,34%	0,31/1,66%	0,06/1,26%
MRIdian	0,37%	0,31%	0,58%	0,04/0,91%	0,01/1,04%	0,15/1,07%
b. B <sub>0</sub> influence on film response						
Mean dose difference (ΔD = MRIdian - Linac) [cGy] averaged over all angles						
	R	G	B	Min/Max_R	Min/Max_G	Min/Max_B
ΔD B <sub>F</sub> F	0,19	-3,28	-0,28	-2,81/3,46	-7,07/0,77	-14,25/13,51
ΔD B <sub>S</sub> S	2,51	0,33	4,86	-2,60/7,62	-4,78/6,08	-19,56/29,56
c. Film response in frontal and sagittal setting						
Mean dose values [cGy] averaged over all angles and its 1SD						
	R	G	B	SD_R	SD_G	SD_B
MRIdian B <sub>F</sub> F	297,19	298,88	303,87	0,52%	0,68%	2,56%
MRIdian B <sub>S</sub> S	299,74	301,78	309,06	0,36%	0,35%	1,61%
Linac B <sub>F</sub> F	297,00	302,16	304,15	0,62%	0,65%	1,98%
Linac B <sub>S</sub> S	297,23	301,44	304,19	0,89%	0,99%	4,69%

### Conclusion

All data indicates that there is no dose deviation between MRIdian and Linac measurements neither in frontal or sagittal setting. In addition, within experimental uncertainty there is no B<sub>0</sub> influence on absolute film dose response. This means that EBT3 GafChromic film can be used for absolute dosimetry regardless its orientation in the field. This makes it a suitable dosimeter for QA measurements and end to end testing in a 0.35T CO<sup>60</sup> machine.

### OC-0232 Development of a novel 'end to end' dosimetry audit of motion management in radiotherapy

A.L. Palmer<sup>1</sup>, D. Nash<sup>1</sup>, S. Jafari<sup>1</sup>, S. Muscat<sup>1</sup>  
<sup>1</sup>Portsmouth Hospital NHS trust, Medical Physics  
 Department, Portsmouth Hampshire, United Kingdom

### Purpose or Objective

External dosimetry audit is valuable to assure quality, safety, and enable improvements. However, motion management in radiotherapy has not previously been subject to rigorous audit. 4DCT allows assessment of motion at treatment planning, but verifying the accuracy of mitigation strategies at treatment planning and delivery is poorly reported. This includes any detrimental effect of MLC, gantry and target motion interplay. We have developed an end-to-end dosimetry audit system to objectively assess the success of motion management strategies. The audit system may be used for interdepartmental dosimetry audit as well as to provide improved understanding and accuracy of motion managed radiotherapy.

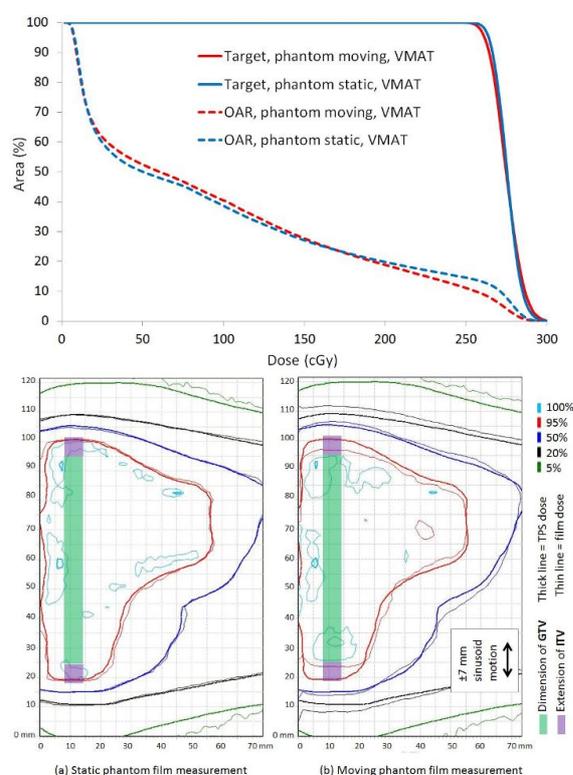

### Material and Methods

The system uses a respiratory motion lung g-phantom (Quasar), custom designed insert with target t (~40 mm diameter irregular structure) and lung OAR. Dose plane measurement is made using triple-channel film dosimetry (EBT3 and FilmQAPro) with uncertainty reduction strategies. Measurements are performed with the phantom static to provide a conventional end-to-end evaluation of accuracy and then moving (+/- 7 mm sinusoid) to add separately the effect of motion. A novel dose-area-histogram, via Matlab, was used to assess dose coverage of the moving target (GTV and ITV) in the film plane. Agreement between treatment planning system (TPS) calculation and measured dose was performed using

isodose overlay and gamma analysis. Pilot audits were conducted at two radiotherapy centres.

### Results

The end-to-end audit was performed for both IMRT and VMAT treatments. Figure 1 shows the dose-area-histogram for the film measurement plane, for the target and lung OAR, for VMAT delivery at one centre, with and without phantom motion. Dose received by 95% of the GTV area was 263 cGy with the phantom static, 260 cGy with the phantom moving, confirming an appropriate ITV planning margin. Gamma analysis (3% global, 2mm, 20% cut-off) between planned and measured dose had mean passing rates of 98.3% with static phantom, 87.6% with moving phantom. There was no significant difference between IMRT and VMAT modes. Figure 2 shows an isodose comparison between planned and measured doses for a VMAT treatment. Motion blurring reduces the dose gradient around the target in the direction of motion. The 95% isodose of the TPS plan covers the ITV, while the film measured 95% isodose covers the GTV of the moving phantom.

### Conclusion

A novel, practical method for the dosimetric assessment of motion management strategies in radiotherapy planning and delivery has been designed and successfully piloted at two radiotherapy centres using IMRT and VMAT, enabling independent end-to-end dosimetry audit for mobile RT targets. The results showed the local 4DCT treatment planning approach was sufficient to deliver the required dose to the moving target structure at treatment delivery, and any adverse effects of MLC/gantry motion and target motion interplay were not detrimental. Initially 12 centres in the UK are being audited.

### Purpose or Objective

Radiosensitivity gene signature including 31 genes was identified using microarray data of NCI-60 cancer cells, however, has not been validated in independent datasets for breast cancer patients. We investigated the link between the radiosensitivity gene signature & PD-L1 and clinical outcome in order to identify a group of intensifying clinical benefit of radiotherapy (RT) combined with anti-PD1/PD-L1 therapy.

### Material and Methods

We validated an identified gene signature alleged to radiosensitivity and analyzed PD-L1 status of invasive breast cancer in The Cancer Genome Atlas (TCGA) dataset using bioinformatic tools. First, we downloaded TCGA breast carcinoma (BRCA) gene expression data sets of 1,215 samples achieved from the Illumina HiSeq 2000 RNA Sequencing platform using UCSC Cancer Genomics Browser. To validate gene signature of our interest, 1,065 patients (or samples) were divided into two clusters using consensus clustering algorithm, then assigned radiosensitive (RS) or radioresistant (RR) group according to their prognosis. Patients were also stratified PD-L1 high or PD-L1 low group by median value of CD274 mRNA expression level as surrogates of PD-L1. Relationship between RS/RR groups and PD-L1 status was also assessed, visualized with heat maps, and their prognostic value was evaluated by Kaplan-Meier analysis and Cox proportional hazard models.

### Results

Patients assigned to RS group had better 5-year recurrence-free survival (RFS) rate compared with RR group on univariate (89 % vs. 75 %, p-value = 0.017) only when treated with radiotherapy. RS group was independently associated with PD-L1 high group compared with RR group, as well as CD274 expression was significantly higher in RS group (p-value < 0.001). In a PD-L1 high group, RS group had better 5-year RFS rate over RR group (89 % vs. 72 %, p-value = 0.015), which was also significant on multivariate analysis. The level of PD-L1 expression could represent immunogenicity of tumors, we speculated that the PD-L1 high group had more immunogenic tumors which should be more sensitive to radiation-induced immunologic cell death.

### Conclusion

We first validated the predictive value of radiosensitivity gene signature following adjuvant RT in TCGA data set for invasive breast cancer and also found a relationship with this radiosensitivity gene signature and PD-L1. Radiosensitivity gene signature and PD-L1 status were important factors to predict a clinical outcome of RT in patients with invasive breast cancer and could be used for selecting patients who benefit from radiation therapy combined with anti-PD1/PDL1 therapy.

### PV-0234 SPECT-CT visualization of axillary lymph nodes in breast cancer: the guide for radiotherapy planning

S. Novikov<sup>1</sup>, P. Krzhivitskiy<sup>2</sup>, S. Kanaev<sup>1</sup>, P. Krivorotko<sup>3</sup>, A. Artemeva<sup>4</sup>, E. Turkevich<sup>4</sup>

<sup>1</sup>Prof. N.N. Petrov Research Institute of Oncology, Radiation Oncology, St. Petersburg, Russian Federation

<sup>2</sup>Prof. N.N. Petrov Research Institute of Oncology, Nuclear Medicine, St. Petersburg, Russian Federation

<sup>3</sup>Prof. N.N. Petrov Research Institute of Oncology, Breast Surgery, St. Petersburg, Russian Federation

<sup>4</sup>Prof. N.N. Petrov Research Institute of Oncology, Pathology, St. Petersburg, Russian Federation

### Purpose or Objective

It was proposed that in some patients with early breast cancer (BC) breast-conserving surgery with subsequent irradiation of remaining breast tissue and sentinel lymph nodes (SLN) should provide sustained control over BC and achieving high rates of disease-free survival.

**Purpose:** to evaluate diagnostic accuracy of SPECT-CT with <sup>99m</sup>Tc-MIBI in predicting non-SLN invasion by BC. To determine efficacy of SPECT-CT (with <sup>99m</sup>Tc-radiocolloids) visualization of axillary SLN for radiotherapy planning. To determine treatment algorithms based on SPECT-CT examinations with <sup>99m</sup>Tc-MIBI and <sup>99m</sup>Tc-radiocolloids in patients with early BC.

### Material and Methods

Accuracy of SPECT-CT in diagnosis of axillary non-SLN invasion (metastases in 2 and more lymph nodes) was prospectively evaluated in 186 primary women with cT1-3NxM0 BC. Diagnostic results were evaluated by histological examination of removed axillary LN: in 84 cases - by sentinel LN biopsy, in 102 - by standard axillary LN dissection.

In 153 BC patients we determined topography of axillary SLN and their relation within standard tangential radiotherapy fields used for breast irradiation after conservative surgery. Distribution of axillary SLN was allocated to following subregions: central(C), anterior pectoral(AP), sub-(SP) intrapectoral (IP), lateral (L), subscapular (SSc), pectoral nodes lying close to thorax wall (Th).

Finally, on routine 3D treatment plans of 10 consecutive patients we examined radiation doses absorbed by SLN localized in various axillary subregions and analyzed dose distribution with different fields set up.

### Results

In the first study histological signs of axillary lymph nodes involvement were detected in 66 of 186 evaluated patients, 43 of them had invasion of non-SLN. Sensitivity of hybrid SPECT-CT imaging with <sup>99m</sup>Tc-MIBI in diagnosis of axillary non-SLN invasion was 93%. This high sensitivity help us to determine women that can be treated by irradiation of SLN without axillary surgery.

In 153 women of the second group we used SPECT-CT with radiocolloids to determine topography of SLN. We mentioned following distribution of axillary SLN: C-64(50.5%), AP-34(26.8%), Th-19(14.9%), L or SSc-10(7.8%). In 17(13.4%) cases SLN were localized both on the I and II(IP, SP) levels.

Evaluation of 3D treatment plans demonstrated that standard tangential radiation fields does not cover SLN in 80% cases. In 20% they encompass C, AP, IP, SP nodes. Modification of tangential fields permit effective irradiation of C, AP, IP, SP, L, SSc nodes in all cases. Th LN can be covered only by IMRT technique.

### Conclusion

SPECT-CT with <sup>99m</sup>Tc-MIBI can effectively diagnose non-SLN invasion by BC and subsequent SPECT-CT with radiocolloids permit accurate planning and irradiation of SLN by extended tangential radiation fields. This strategy can be considered as alternative to treatment with surgical axillary staging.

### Purpose or Objective

This study was performed to identify a subset of patients who may benefit from post-mastectomy radiotherapy (PMRT) among node-negative patients.

### Material and Methods

We retrospectively reviewed 1,828 patients with pT1-2N0 breast cancer, treated with mastectomy without PMRT from 2005 to 2010 at 10 institutions. Univariate and multivariate analyses for locoregional recurrence (LRR) and any first recurrence (AFR) were performed according to clinicopathologic factors and biologic subtypes.

### Results

During a median follow-up period of 5.9 years (range: 0.7-10.4 years), 98 patients developed AFR (39 cases of isolated LRR, 13 of LRR with synchronous distant metastasis, and 46 of isolated distant metastasis), and 52 patients developed LRR (31 cases of local recurrence, 28 of regional recurrence, and 7 of local and regional recurrence). The 10-year LRR and AFR rates were 3.8% and 7.9%, respectively. Multivariate analysis revealed that an age of  $\leq 40$  years (hazard ratio [HR], 3.3;  $p < 0.001$ ) and stage T2 cancer (HR, 1.3;  $p = 0.013$ ) were independent risk factors for LRR. The 10-year LRR rates were 2.5% with no risk factors, 4.5% with one risk factor, and 12.4% with two risk factors. Multivariate analysis for AFR revealed that an age of  $\leq 40$  years (HR, 2.6;  $p < 0.001$ ), stage T2 cancer (HR, 1.3;  $p < 0.001$ ), and the triple-negative biological subtype (HR, 1.6;  $p = 0.045$ ) were independent risk factors for AFR. The 10-year AFR rates were 3.9% with no risk factors, 10.6% with one risk factor, and 18.1% with two to three risk factors.

### Conclusion

Mastectomy without PMRT is a sufficient local treatment for pT1-2N0M0 breast cancer. Nevertheless, PMRT might be considered for patients with two or three risk factors, among those of young age, with T2 tumors, and with the triple-negative biological subtype based on LRR and AFR.

### PV-0236 Impact of radiation therapy delay in patients underwent neoadjuvant chemotherapy and breast surgery

S. Silva<sup>1</sup>, A. Pereira<sup>1</sup>, M. Kenya<sup>2</sup>, M. Gustavo<sup>2</sup>, M. Mano<sup>1</sup>

<sup>1</sup>Instituto do Cancer do Estado de São Paulo Universidade de São Paulo-, Clinical Oncology, São Paulo, Brazil

<sup>2</sup>Instituto do Cancer do Estado de São Paulo Universidade de São Paulo-, Radiotherapy, Sao Paulo, Brazil

### Purpose or Objective

Post-operative radiation therapy (PORT) is often used for breast cancer patients who received neoadjuvant chemotherapy (CT) followed by surgery. Nevertheless, the optimal time to initiation of PORT is unclear.

### Material and Methods

Between 2008 to 2014, data from non metastatic breast cancer patients who underwent PORT after neoadjuvant CT and surgery were assessed retrospectively. Patients were categorized into three groups according to the time between surgery and PORT: <8 weeks, 8-16 weeks and >16 weeks. The primary endpoint was disease free survival (DFS). Multivariate Cox regression adjusted for molecular profile, histological grade (HG), age, clinical stage and complete pathologic response (pCR) was used to estimate survival outcomes. Binary logistic regression model was used to calculate the adjusted odds ratios for recurrence.

### Results

Among the 581 patients included, the vast majority had clinical stage III (75%) and received anthracycline-taxane based neoadjuvant CT (95%). Forty-three patients received PORT within 8 weeks, 354 in 8-16 weeks and 184 after 16 weeks from surgery. With a median follow-up of 32 months, beginning radiation therapy up to 8 weeks after surgery was associated with better DFS (HR 0.36; 95%CI 0.146-0.914; p=0.03) and a trend in better OS (HR 0.223; 95%CI 0.07-1.14; p=0.08). The factors associated with less recurrence rate were: PORT at 8 weeks (OR=0.33; 95% CI 0.12-0.90; p=0.03), stage I-II (OR=0.41; 95%CI 0.25-0.69; p=0.001) and pCR (OR=0.15; 95%CI 0.07-0.32; p<0.001).

### Conclusion

PORT started up to 8 weeks after surgery was associated with better DFS and a trend in better OS in a predominantly stage III population of breast cancer patients submitted to neoadjuvant CT. Our findings suggest that early initiation of radiation therapy should be granted for these patients.

<sup>12</sup>Associazione Italiana Radioterapia Oncologica, intraoperative radiotherapy working group, -, Italy'

### Purpose or Objective

To assess the outcome and the patterns of failure in patients (pts) who develop an ipsilateral in breast

recurrence (IBTR) after breast conservative surgery (BCS) partial breast irradiation (PBI) with intraoperative radiotherapy with electrons (IORT).

### Material and Methods

The Italian IORT Working Group promoted collection of information regarding clinical management and outcome of pts who experienced a failure of breast conservative treatment after being given IORT as sole radiotherapy (full dose at 21 Gy). Data from 8 Italian radiation centers were recorded in a central dedicated database for a total of 228 pts. Pts gave informed consent for the use of anonymized data for research and training purposes. Clinical outcomes included IBTR, nodal failure, distant metastases, disease-free survival and overall survival. Treatment options were recorded.

### Results

Median time from BCS with IORT full dose (21 Gy) to IBTR was of 3.9 years (range 0.4-15 years). 128/228 pts (56.1%) experienced a true/marginal miss IBTR, 51/228 (22.3%) presented local relapse in a breast site far from the index quadrant, 8/228 (3.5%) relapsed with lymphangitis features. In about 15% of cases, local relapse was combined with nodal regional or distant metastases. Axillary failure alone was observed in 4 pts (1.7%), while bone metastases without locoregional recurrence in only 1 case (0.4%). Surgical salvage therapy was carried out with different modalities. Mastectomy was performed in 129/228 patients (56.5%), 7.4% of them received also postmastectomy radiotherapy. Second conservative surgery with or without axillary investigation was given to 88 patients (38.5%). Interestingly, patients re-operated on conservatively received additional radiotherapy: 44 (19.2%) were treated with whole breast irradiation (WBRT), using conventional or hypofractionated schemes, while 22 (9.5%) were treated with PBI, using either intraoperative radiotherapy with electrons or conformal external beam radiotherapy. Only 8 pts didn't undergo reoperation due to disease progression. Median follow-up after salvage surgery was 3.5 years (0-12 years). In this time frame, 3.3% of pts developed a second isolated local relapse, while in other 3.3% of cases the second local relapsed combined with another event (nodal, distant, contralateral tumor reappearance). Distant metastases as first site of failure after salvage treatment occurred in 12.2% of pts. Status at last follow-up was: 70% alive without disease, 16% alive with disease, 12% died of disease.

### Conclusion

Treatment failure mostly consisted of local in breast reappearance at or near the irradiated site. While most of pts received salvage mastectomy, second BCS with additional radiotherapy, either WBRT or PBI, is feasible. Overall survival was lower than that reported by the randomized ELIOT trial and therefore a multivariate analysis is being performed to identify predictor and prognostic factors.

### PV-0238 Use of Stereotactic Ablative Radiotherapy in Non-Small Cell Lung Cancer Measuring 5 cm or More

H. Tekatli<sup>1</sup>, S. Van 't Hof<sup>1</sup>, E.J. Nossent<sup>2</sup>, M. Dahele<sup>1</sup>, W.F.A.R. Verbakel<sup>1</sup>, B.J. Slotman<sup>1</sup>, S. Senan<sup>1</sup>

<sup>1</sup>VU University Medical Center, Radiation Oncology, Amsterdam, The Netherlands

<sup>2</sup>VU University Medical Center, Pulmonology, Amsterdam, The Netherlands

### Purpose or Objective

Stereotactic ablative radiotherapy (SABR) is currently not the guideline recommended treatment for lung tumors measuring 5 cm or more. However, improvements in treatment planning and delivery have enabled better sparing of normal organs, leading to an increased use of SABR for these tumors.

### Material and Methods

We retrospectively analyzed outcomes in patients with a primary or recurrent non-small cell lung cancer measuring  $\geq 5$  cm, who were treated with 5 or 8 fractions of SABR at a single center, between 2003-2014. Patients who had prior thoracic radiotherapy were excluded. The maximum tumor diameter in the axial, transversal, or sagittal planes was measured on lung window-level settings in the end-inspiratory phase of the 10-phase free-breathing four-dimensional planning CT scan. Between 2003-2008, SABR was delivered using 8-12 non-coplanar static conformal beams and stereoscopic X-ray image-guidance, and after 2008, Volumetric Modulated Arc Therapy was used with online cone-beam CT based positioning on the tumor. All cases with potential severe toxicity (i.e. grade 3 or higher,  $\geq G3$ ) were evaluated by a clinical panel consisting of three clinicians using the Common Terminology Criteria for Adverse Events version 4.03, and was consensus based.

### Results

63 consecutive patients with a median tumor diameter of 5.8 cm (range 5.1-10.4) were identified; 81% had T2N0 disease, and 18% T3N0. Median Charlson Comorbidity Index was 2 (range 0-6). After a median follow-up of 54.7 months, median survival was 28.3 months (95% CI 18.3-38.2). For T2b tumors, median OS was 28.7 months (95% CI 12.2-45.3), and for T3 tumors this was 21.5 months (95% CI 16.4-26.6). Disease free survival at 2 years was 82.1%, and local, regional, and distant control rates at 2 years were 95.8%, 93.7%, and 83.6%, respectively. Distant metastases only were the commonest pattern of failure (10%).  $\geq G3$  toxicity was recorded in 30% of patients, with radiation pneumonitis the most common toxicity (19%). A likely ( $n = 4$ ) or possible ( $n = 8$ ) treatment-related death was scored in 19% of patients. Retrospective review of CT scans revealed pre-existing interstitial lung disease in 8 patients (13%), with fatal toxicity developing in 5 of them (63%).

### Conclusion

Lung SABR in tumors  $\geq 5$  cm resulted in high local control rates and acceptable survival outcomes, except in patients with co-existing interstitial lung disease. Our findings indicate that a more systematic screening for interstitial lung disease should take place prior to referral for SABR.

### PV-0239 Validation of lung cancer survival models in a clinical routine SBRT population

J. Van Soest<sup>1</sup>, T. Purdie<sup>2</sup>, M. Giuliani<sup>2</sup>, P. Lindsay<sup>2</sup>, A. Hope<sup>2</sup>, D. Jaffray<sup>2</sup>, A. Dekker<sup>1</sup>

<sup>1</sup>Maastricht University Medical Centre+, Department of Radiotherapy MAASTRO - GROW School for Oncology & Developmental Biology, Maastricht, The Netherlands

<sup>2</sup>University Health Network, Radiation Medicine Program, Toronto, Canada

### Purpose or Objective

In recent years, many different prediction models have been developed based on clinical trial data. Although some of these models have been validated in external datasets, most of these validations did not report whether this validation tested reproducibility (same cohort characteristics for training and validation set), or transferability (different cohort characteristics). In this work, we performed an external validation of a survival prediction model learned on Stage III NSCLC patients in a routine clinical dataset of lung SBRT patients.

### Material and Methods

Inclusion criteria were all patients with clinical T1-2N0M0 treated with SBRT from January 2005 to March 2014. The survival prediction model under validation was published before (PMID 25936599), including its dataset. Cohorts (original training and current validation) were compared using a KM curve and by calculating the cohort differences AUC (PMID 25179855). This cohort differences model predicts whether patients belong to the training or

validation dataset. If this model has a high AUC, it means that the model is able to predict whether a patient belongs to the training/validation cohort; indicating large cohort differences and testing for transferability of the model. If the AUC is low (close to 0.5), the cohort differences are small, and therefore validation tests reproducibility in a similar patient cohort.

For validation, we applied the model to predict survival at several endpoints (6 months, 1, 2 and 3 years), and put the results into context with the cohort differences AUC. Finally, we learned a new logistic regression model for 2-year survival, using stepwise AIC as variable selection method.

### Results

When investigating cohort differences, the KM curve in figure 1 already shows a difference between the Stage III training cohort, and the current clinical routine validation cohort of SBRT patients. Both in terms of survival and follow-up. The cohort differences AUC was 0.97; indicating an almost perfect prediction whether a patient belonged to the training or validation cohort. This indicates a large difference between patients in the training and validation cohort.

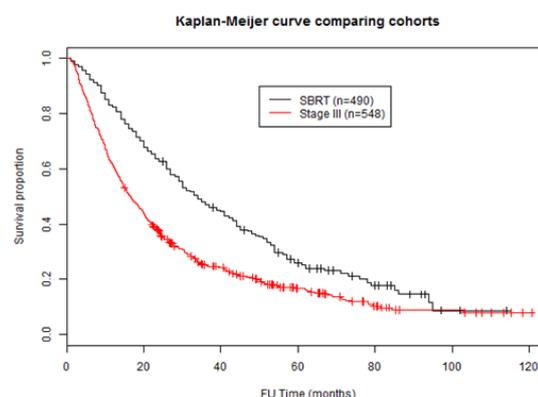

Table 1 shows the model performance on the validation dataset, indicating a decline in the current validation dataset (original model training & validation AUC: 0.64 and 0.58-0.60, respectively). Learning a model for 2-year survival on this SBRT cohort increased the AUC (0.73,  $n=267$ , events=97).

Timepoint (months)	AUC	Survival percentage	Lost in FU
6	0.63	92%	44 (8.8%)
12	0.60	81%	77 (15.4%)
24	0.62	59%	126 (25.2%)
36	0.61	41%	158 (31.6%)

### Conclusion

Our current validation shows that the prediction model under investigation, learned using Stage III NSCLC patients, shows an equal performance in a routine clinical cohort of SBRT patients. Based on the cohort differences AUC, we conclude that the previous model is transferable to another patient population. Preliminary investigations show that a specific model for SBRT patients could increase model performance. Therefore future work is to further refine training, and externally validate a new model for NSCLC patients treated with SBRT.

### PV-0240 A logistic regression model to predict 30-day mortality: difference between routine and trial data

A. Jochems<sup>1</sup>, I. El-Naqa<sup>2</sup>, M. Kessler<sup>2</sup>, C. Mayo<sup>2</sup>, J. Reeves<sup>2</sup>, J. Shruti<sup>2</sup>, M. Matuszak<sup>2</sup>, R. Ten Haken<sup>2</sup>, C. <sup>4</sup>Ingham Institute and Liverpool and Macarthur Cancer Therapy Centres, School of Physics, Liverpool, Australia

<sup>5</sup>Ingham Institute and Liverpool and Macarthur Cancer Therapy Centres, School of medicine, Liverpool, Australia

<sup>6</sup>University of Sydney, School of Physics, Sydney, Australia

### Purpose or Objective

Early death after a treatment can be seen as a therapeutic failure. Wallington and colleagues reported that 8% of all non-small cell lung cancer (NSCLC) patients die within thirty days of systemic treatment initiation[1]. Identification of patient at risk for early mortality is crucial to avoid unnecessary harm and avoid costs. In this work, we validate the logistic regression model proposed by Wallington and colleagues in 2 independent datasets. Additionally, we develop our own model and validate it on the same datasets.

### Material and Methods

Patients with NSCLC treated with concurrent chemoradiation were included in this study. The Institute 1 cohort consists of 411 patients treated in routine clinical practice. The Institute 3 cohort consists of 121 patients, treated in clinical trials. The Institute 4 cohort consists of 57 patients, treated in a clinical trial. The Institute 2 cohort consists of 355 patients, treated in routine clinical practice. A logistic regression model was learned on the Institute 1 cohort. This model used WHO performance status, age, nodal stage and prescribed tumor dose to make predictions.

### Results

11 out of 411 (3%) patients died within 30 day of start of treatment in the Institute 1 cohort and 22 out of 355 (6%) patients in the Institute 2 cohort. In both the Institute 4 and Institute 3 clinical trials, no patients died within 30 days. Death rates for the Institute 1 and Institute 2 cohorts combined are significantly higher than the death rates of the Institute 4 cohort and Institute 3 cohort combined ( $P < 0.01$ ) Survival curves for these cohorts are reported in figure 1. Based on the Institute 1 cohort, the AUC for the Wallington model was 0.69 (95% CI: 0.53-0.85) and 0.72 (95% CI: 0.49-0.94) with our own model. The AUCs were not significantly different ( $P = 0.64$ ) Based on the Institute 2 cohort, the AUC for the Wallington model was 0.58 (95% CI: 0.48-0.7), whereas it was 0.72 (95% CI: 0.64-0.81) with our own model. The difference was significant ( $P < 0.001$ ).

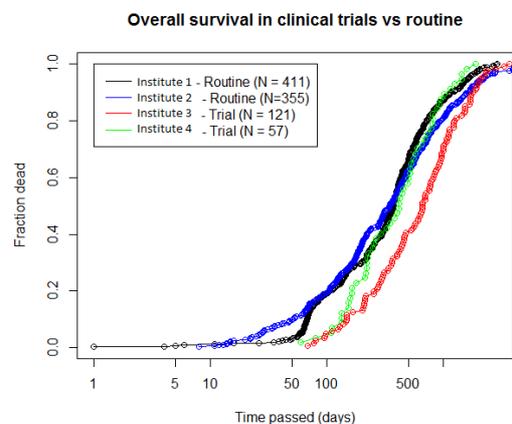

Figure 1: Survival curves for each cohort investigated.

Circles identify deceased patients.

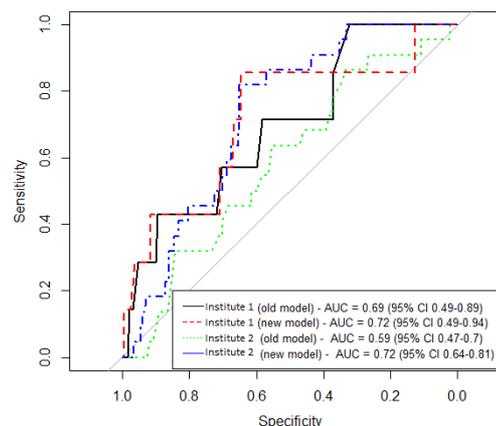

Figure 2: ROC curves of the models.

### Conclusion

Early mortality is more common in cohorts originating from routine clinical practice compared to clinical trials, indicating a selection bias for the trial patients. Development of accurate predictive tools for early mortality is important to inform patients about treatment options and optimize care.

### PV-0241 Comparing endpoints of radiation induced lung injury for NSCLC: radiology vs. clinical symptoms

U. Bernchou<sup>1</sup>, R.L. Christiansen<sup>1</sup>, J.T. Asmussen<sup>2</sup>, T. Schytte<sup>2</sup>, O. Hansen<sup>2</sup>, C. Brink<sup>1</sup>

<sup>1</sup>Odense University Hospital, Laboratory of Radiation physics, Odense, Denmark

<sup>2</sup>Odense University Hospital, Department of Radiology, Odense, Denmark

### Purpose or Objective

Clinical symptoms is the gold standard endpoint in most studies of radiation induced lung injury for non-small cell lung cancer (NSCLC) patients even though the scoring often is challenged by confounding medical conditions. However, lung injuries frequently manifest radiologically; and radiologic injury could potentially be used in outcome modelling to disentangle effects of confounding factors. The purpose of the present study was to investigate the relation between clinically scored dyspnea and the extent and appearance of radiologic injury in the lung after radiotherapy for NSCLC patients.

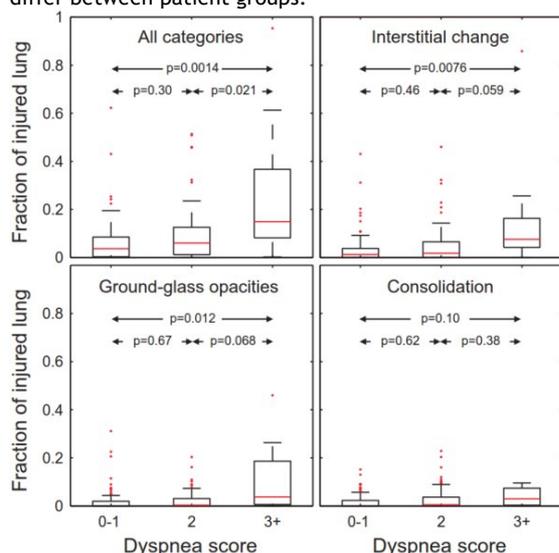

### Material and Methods

Eligible follow-up CT scans acquired within 6 months after commencement of radiotherapy were retrospectively evaluated in a cohort of 220 NSCLC patients treated to 60-66 Gy in 30-33 fractions. The volume fraction of lung with radiologic injuries was estimated in each scan and was divided in three categories based on appearance: Interstitial changes, ground-glass opacities, or consolidation in the lung. Clinical symptoms of dyspnea was recorded retrospectively and scored according to the Common Terminology for Adverse Events scale. The scores were divided into the following groups: No (grade 0-1), mild (grade 2), or severe (grade 3+) symptoms. Differences in the fraction of injured lung between groups were analyzed using Mann-Whitney U tests with a Bonferroni correction used to adjust P-values to compensate for multiple comparisons.

### Results

Of the patients included in the study, 127 (58%) did not develop symptoms, 82 (37%) developed mild symptoms, while 11 (5%) developed severe symptoms. Patients with severe dyspnea had a statistically significant higher fraction of injured lung (median fraction of injured lung =

0.15) as compared with patients with mild (median fraction of injured lung = 0.06) or no dyspnea (median fraction of injured lung = 0.04) as seen in the top left panel of the figure showing boxplots of the overall fraction of injured lung in the three groups of patients. Similar results were found when dividing the radiological injuries in categories based on appearance (see the last three panels in the figure). Patients with severe dyspnea had a significant higher fraction of interstitial changes or ground-glass opacities in the lung as compared with patients with no dyspnea, while the severe and mild groups only were borderline different. The fraction of lung with consolidation injury was low and did not significantly differ between patient groups.

#### Conclusion

The fraction of lung with radiological injuries after radiotherapy was higher in patients with severe dyspnea as compared to mild or no dyspnea. Dividing the radiological injury based on appearance did not increase the association with clinical symptoms. The radiologic endpoint provides supplementary information in patient outcome assessment and could be attractive for radiobiological response modelling as an objective endpoint disentangled from medical commodities.

<sup>3</sup>German Cancer Research Center, Department of Medical Physics in Radiotherapy, Heidelberg, Germany

<sup>4</sup>German Cancer Research Center, Clinical Cooperation Unit Molecular Radiooncology, Heidelberg, Germany

<sup>5</sup>Heidelberg Ion Beam Therapy Center, Heidelberg Ion Beam Therapy Center, Heidelberg, Germany

#### Purpose or Objective

Carbon ions (<sup>12</sup>C-ions) show an increased relative biological effectiveness (RBE) relative to photons and cell culture experiments exhibit a higher RBE especially in

hypoxic tumors. The underlying reason for this is that the oxygen enhancement ratio (OER) is smaller for <sup>12</sup>C-ions than for photons. However, there is a lack of *in vivo* evidence for a decreased OER of <sup>12</sup>C-ions relative to photons. To investigate the impact of hypoxia, dose-response curves for photons and <sup>12</sup>C-ions were determined for R3327-HI rat prostate adenocarcinomas under ambient and acute hypoxic conditions.

#### Material and Methods

Tumor fragments of a Dunning prostate tumor R3327-HI were transplanted s.c. into the distal thigh of male Copenhagen rats. Tumors were treated with increasing doses of either <sup>12</sup>C-ions or 6 MeV photons under ambient or acute hypoxic conditions. Acute hypoxia was induced by clamping the feeding artery 10 min before and during treatment. Primary endpoint was local tumor control within 300 days. OER-values for ambient vs. hypoxic conditions for both irradiation modalities as well as RBE-values were calculated based on TCD<sub>50</sub>-values (dose at 50% tumor control probability) of photons and <sup>12</sup>C-ions, respectively.

#### Results

Local tumor control was achieved with <sup>12</sup>C-ions and photons under normoxic as well as hypoxic conditions, however, a higher effectiveness was obtained for <sup>12</sup>C-ions. The RBE for local tumor control after single dose irradiation increased from ambient conditions (2.08±0.13) to hypoxic conditions (≈2.5). The OER was significantly smaller for <sup>12</sup>C-ions than for photons, but both values were lower than the OER-values measured under cell culture conditions. Since some animals are within their 300 days follow-up, precise OER-values are still pending.

#### Conclusion

The RBE of <sup>12</sup>C-ions increases under hypoxic conditions, since the OER of <sup>12</sup>C-ions is significantly lower than for photons. Interestingly, the OER for both radiation qualities was much lower than measured *in vitro*. This supports the need of *in vivo* experiments to assess the impact of hypoxia in patients treated in heavy ion radiotherapy.

#### OC-0243 Submicron focused proton irradiation - understanding the RBE of heavy ion irradiation

T.E. Schmid<sup>1,2</sup>, C. Greubel<sup>3</sup>, K. Ilicic<sup>2</sup>, D. Walsh<sup>3</sup>, J. Reindl<sup>3</sup>, C. Siebenwirth<sup>2</sup>, J.J. Wilkens<sup>2</sup>, G. Multhoff<sup>2</sup>, E. Schmid<sup>4</sup>, G. Dollinger<sup>3</sup>, S.E. Combs<sup>1,2</sup>

<sup>1</sup>Helmholtz Zentrum München, Institute of innovative Radiotherapy, Neuherberg, Germany

<sup>2</sup>Klinikum rechts der Isar, Radiooncology, München, Germany

<sup>3</sup>Universität der Bundeswehr München, Applied Physics, Neubiberg, Germany

<sup>4</sup>University of Munich, Department for Anatomy and Cell Biolog, München, Germany

#### Purpose or Objective

High LET radiation like heavy ions is well known to induce a higher relative biological effectiveness (RBE) than low LET radiation. The dependence of RBE with LET is of special interest for heavy ion tumor therapy and for radiation safety issues. Irradiations with low and high LET particles differ in the spatial dose distribution. Only a few high LET particles hit a cell nucleus and deposit doses of a few gray where the dose deposition and thus the DNA damage concentrates around the few ion trajectories. In contrast several hundred low LET particle hits are needed to achieve the same dose resulting in a quasi-homogeneous damage distribution. The influence of different spot sizes is studied on the induction of dicentric chromosomes.

#### Material and Methods

Human-hamster hybrid (AL) cells were irradiated with focused 20 MeV protons in a quadratic matrix pattern with point distances of 5.4×5.4 μm<sup>2</sup> and 117 protons per matrix point at the ion microbeam SNAKE using different spot-sizes between 0.8 and 2.7 μm (full width at half

maximum). All irradiation modes deposit a mean dose of 1.7 Gy. For RBE determination dose response curves of reference radiation were used.

#### Results

The RBE values, as determined by measuring dicentric in human-hamster hybrid (AL) cells, are significantly higher when 117 protons were focused to a 0.78  $\mu\text{m}$  spot within a  $5.4 \times 5.4 \mu\text{m}^2$  matrix compared to homogenous applied protons (RBE =  $1.96 \pm 0.16$  vs. RBE =  $1.30 \pm 0.16$ ). By doubling the spot size to 1.6  $\mu\text{m}$  the RBE decreased to  $1.52 \pm 0.16$ . By further increasing the spot size to 2.7  $\mu\text{m}$  the RBE was not longer different (RBE =  $1.36 \pm 0.14$ ) to the homogenous radiation.

#### Conclusion

Our experiments demonstrate evidence that low LET radiation focused to sub-micrometer diameters results in an increase in RBE for the induction of dicentric depending on the spot size. The local density of DSB is increased at the irradiated spots enhancing also the probability for the interaction of the DSB and thus raising the probability of connecting the wrong ends. We hypothesize that a tighter beam spot of protons might further enhance the RBE value.

Supported by the DFG-Cluster of Excellence 'Munich-Centre for Advanced Photonics', by the BMBF-project 02NUK031A and 02NUK031B "LET-Verbund".

#### OC-0244 Does the RBE depend on ion type?

A. Lühr<sup>1,2,3</sup>, C. Von Neubeck<sup>2,3</sup>, M. Baumann<sup>1,2,3,4</sup>, M. Krause<sup>1,2,3,4</sup>, W. Enghardt<sup>1,2,3,4</sup>

<sup>2</sup>OncoRay-National Center for Radiation Research in Oncology, Faculty of Medicine and University Hospital Carl Gustav Carus - Technische Universität Dresden - Helmholtz-Zentrum Dresden - Rossendorf, Dresden, Germany

<sup>3</sup>German Cancer Consortium DKTK, Partner Site Dresden, Dresden, Germany

<sup>4</sup>University Hospital Carl Gustav Carus at the Technische Universität Dresden, Department of Radiation Oncology, Dresden, Germany

#### Purpose or Objective

Currently, modeling of RBE as a simple function of linear energy transfer (LET) receives much attention in the proton therapy community. However, such LET-RBE parametrizations are purely empirical and ion type specific. Additionally, their applicability is restricted by large uncertainties associated with the biological input parameters from proton experiments. In contrast, long term clinical experience on RBE modeling as well as treatment outcome data exist for carbon ion therapy. The aim is to establish a clinically relevant RBE modeling for proton therapy that is directly based on available clinical and pre-clinical experience from carbon ion therapy.

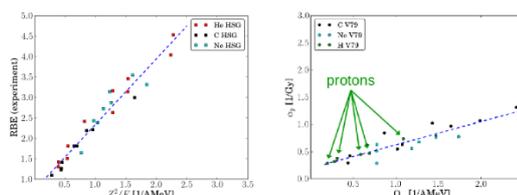

#### Material and Methods

The RBE dependence on the radiation field - i.e., on physics - was mathematically derived in a convenient way using assumptions also applied by the local effect model (LEM) and the micro kinetic model (MKM); both used in patient treatment. A large set of in vitro literature data (several hundred data points, including six different ion types) on RBE and the linear-quadratic model parameter  $\alpha_p$  for particles was used to validate the derived model. Pre-clinical RBE data of the rat spinal cord (one and two fractions) at six different depth positions in a carbon ion treatment field were used to demonstrate the transfer of carbon ion RBE data to proton therapy. Physical properties of the applied carbon treatment field as a function of depth were obtained by Monte Carlo simulation considering the full particle spectrum: dose, LET, beam quality  $Q = Z^2/E$  ( $Z =$  ion charge;  $E =$  kinetic energy).

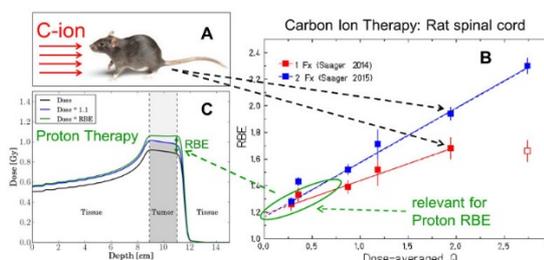

#### Results

The derivation revealed for  $\alpha_p$  and RBE a linear increase with beam quality  $Q$  but no dependence on ion type. These findings were well confirmed by the experimental in vitro data for different ions (Fig. 1). Specifically, the independence of ion type holds true for different cell types and irradiation under normoxic and hypoxic conditions.

The pre-clinical spinal cord RBE data increased linearly with  $Q$  (Fig. 2). The linear slope depends in the same way on fractionation dose as described by the derived model. Due to the apparent independence of RBE on ion type, the experimentally obtained RBE for carbon ions as function of  $Q$  could also be used to estimate the RBE in a proton SOBPs where  $Q$  can be determined at any depth (Fig. 2).

**Fig.1 Beam quality dependence:** In vitro RBE and  $\alpha_p$  as function of beam quality  $Q$  ( $Z^2/E$ ) for HSG and V79 cell lines. H: proton, He: helium, C: carbon, Ne: neon.

**Fig.2 Concept of RBE translation:** (A) Obtain (pre-) clinical RBE from carbon ion therapy as (B) function of beam quality and (C) use it to optimize dose prescription in proton therapy. Spinal cord RBE; 1 and 2 fractions (Fx). **Conclusion**

The RBE seems to depend on the beam quality  $Q$  but not on ion type for clinically relevant treatment situations. This opens up the possibility to directly transfer clinically and pre-clinically obtained parameters from carbon ion to proton therapy. Currently, RBE experiments and Monte Carlo simulations of patient treatments are performed as a next step to translate this approach to proton therapy.

#### OC-0245 Clinical evidence that end-of-range proton RBE exceeds 1.1: lung density changes following chest RT

T. Underwood<sup>1,2</sup>, C. Grassberger<sup>1</sup>, R. Bass<sup>1</sup>, R. Jimenez<sup>1</sup>, N. Meyersohn<sup>3</sup>, B. Yeap<sup>1</sup>, S. MacDonald<sup>1</sup>, H. Paganetti<sup>1</sup>  
<sup>1</sup>Massachusetts General Hospital & Harvard Medical School, Department of Radiation Oncology, Boston MA, USA

<sup>2</sup>University College London, Department of Medical Physics and Bioengineering, London, United Kingdom

<sup>3</sup>Massachusetts General Hospital & Harvard Medical School, Department of Radiology, Boston MA, USA

#### Purpose or Objective

Clinical practice assumes a fixed proton relative biological effectiveness (RBE) of 1.1, but it has been postulated that higher RBEs occur at the distal edge of proton spread out Bragg peaks, i.e. within the lung for chest wall patients. We performed retrospective qualitative & quantitative analyses of late-phase lung-density changes (indicative of asymptomatic fibrosis) for chest wall patients treated using protons & X-rays. Our null hypothesis (H0) was that, assuming a fixed proton RBE of 1.1, these changes would

be the same for the two cohorts, supporting current RBE practice. Our alternative hypothesis (H1) was that the radiographic abnormalities would be greater for the proton cohort, suggesting an end-of-range RBE > 1.1.

#### Material and Methods

We analyzed follow-up CTs for 10 proton/X-ray patient pairs matched for age, chemotherapy regimen, disease laterality & implant status. 5 patients had a smoking history (4 X-ray, 1 proton), all 20 were prescribed 50.4 Gy in 28 fractions. For brevity, we write 'Gy' throughout, but for protons 'Gy' should be taken as 'GyRBE assuming a fixed RBE of 1.1'. Proton TPS doses were recalculated using TOPAS Monte Carlo simulations. Deformable registrations enabled us to calculate changes in median HU value between pre- & post-treatment CTs for dose bins of 2-30 in 2 Gy increments. For each patient's final (modality-blinded) CT, qualitative abnormality grading was performed by a radiologist.

#### Results

Quantitative datasets for a matched pair are included in Fig 1, with the linear regression fits used to calculate our endpoint:  $\Delta\text{HU}/\text{Gy}$ . For all scans, Fig 2 plots this endpoint as a function of follow-up time: separation between the proton and X-ray cohorts is clear with proton scans exhibiting higher  $\Delta\text{HU}/\text{Gy}$  values. To assess the effect of 'modality' on the Fig 2 data, we used the lme4 package in R to perform a linear mixed effects analysis of log transformed  $\Delta\text{HU}/\text{Gy}$ . As fixed effects, we considered 'modality', 'mean lung dose', 'change in IV contrast', 'change in breathhold' plus 'follow-up interval' (without interaction terms). Subject was added as a random effect. A p-value of 0.0007 was obtained for a likelihood ratio test of the full model against the model without modality. Similar results were obtained for analysis of the non-smoker sub-population. A significant difference between the two modalities also arose from our qualitative radiological scoring (Wilcoxon signed rank test,  $p=0.018$ , median abnormality score=3/9, for protons, 1.5/9 for X-rays).

#### Conclusion

Our data indicate that we should reject H0 in favor of H1, to conclude that the end-of-range proton RBE for lung-density changes >1.1. Experiments have demonstrated that, in-vitro, RBE=1.1 underestimates the capacity of end-of-range protons to kill cells. We studied asymptomatic radiographic changes rather than cell kill, but our work nonetheless supports the thesis that end-of-range variations in proton RBE prove important in-vivo as well as in-vitro.

Fig 1: Example of single-timepoint data processing for follow-up scans for a matched pair of proton and X-ray patients

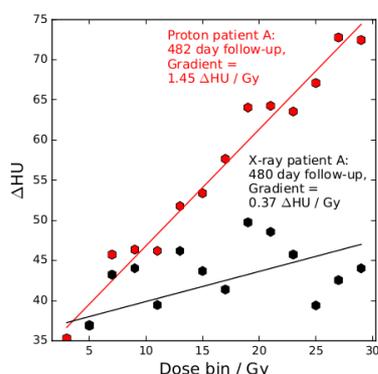

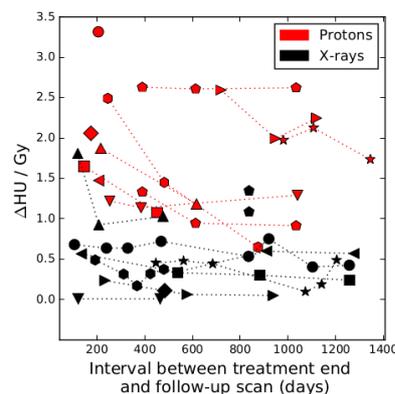

Fig 2:  $\Delta\text{HU} / \text{Gy}$  vs follow-up timepoint for all scans (each symbol type corresponds to one patient ID, matched proton / X-ray symbols correspond to matched pairs)

#### OC-0246 Proton minibeam radiation therapy spares normal rat brain

<sup>2</sup>Institut Pasteur, HUMAN HISTOPATHOLOGY AND ANIMAL MODELS, PARIS, France

<sup>3</sup>Institut Curie, Orsay Proton Therapy Center, Orsay, France

<sup>4</sup>Institut Curie, Experimental radiotherapy platform, Orsay, France

<sup>5</sup>University Paris Sud, Imagerie par Résonance Magnétique Médicale et Multi-Modalités, Orsay, France

#### Purpose or Objective

The morbidity of normal tissues continues being the main limitation in radiotherapy. To overcome it, we recently proposed a novel concept: proton minibeam radiation therapy (pMBRT) [1]. It allies the physical advantages of protons with the normal tissue preservation observed when irradiated with submillimetric spatially fractionated beams (minibeam radiation therapy) [2]. We have recently implemented the technique [3] at a clinical center (Proton therapy center in Orsay). The main objective of this work was to confirm the gain in tissue sparing thanks to pMBRT.

#### Material and Methods

The whole brain of 7 week-old male Fischer 344 rats ( $n=16$ ) was irradiated with 100 MeV protons. Half of the animals received conventional seamless proton irradiation (25 Gy in one fraction). The other rats were irradiated with pMBRT (58 Gy peak dose in one fraction). The average dose deposited in the same target volume was in both cases 25 Gy. The animals were followed up for 7 months. A magnetic resonance imaging (MRI) follow up (10 days, 3 months and 6 months) at a 7T small animal MRI scanner as well as histological analysis were performed.

#### Results

Rats treated with conventional proton irradiation exhibited severe moist desquamation and permanent epilation. The MRI and histology analysis showed important brain damage (extensive blood-brain barrier breakdown (BBB), hematomas, necrosis, microglial activation, etc.). See figure 1. In contrast, the pMBRT group presented no skin damage, a reversible epilation and no significant brain damage observed by MRI or histological analysis.

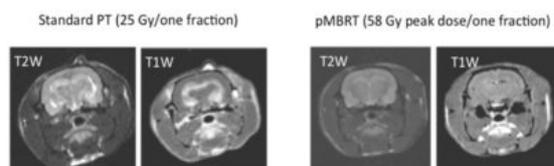

Figure 1. Comparison of  $T2_w$  and  $T1_w$  after Gd injection MRI sequences in the case of standard PT (left) and in pMBRT (right). The images were acquired 7 months after irradiation. Important lesions (hematomas, edemas) are observed in the  $T2_w$  images, as well as an extensive BBB breakdown in the standard PT case. The images corresponding to the pMBRT irradiation showed no significant damage.

#### Conclusion

Conclusion: pMBRT leads to an increase in normal tissue resistance. This net gain in normal tissue sparing can foster one of the main applications of proton therapy, paediatric oncology, as well as open the door to an efficient treatment of very radioresistant tumors, which are currently mostly treated palliatively. The next step will be to perform studies to unravel the biological mechanisms involved in normal tissue sparing.

##### SP-0247 Driving Radiotherapy Quality Improvement: The Canadian Experience

M. Milosevic<sup>1,2</sup>

<sup>1</sup>Princess Margaret Cancer Centre and University Health Network, Radiation Medicine Program, Toronto, Canada

<sup>2</sup>University of Toronto,

Department of Radiation Oncology, Toronto, Canada

The success of radiotherapy as an indispensable part of a cancer control strategy depends on a wide range of programmatic and system-level factors, including effective quality management. Treatment delivered in a suboptimal manner without appropriate oversight can lead to poor clinical outcomes or, in extreme cases, severe patient injury and death. In Canada, radiation treatment quality and safety activities have largely evolved independently in programs across the country with no over-arching coordination. The Canadian Partnership for Quality in Radiotherapy (CPQR) was formed in 2000 as a catalyst to harmonize quality and safety on a national scale.

CPQR utilized a bottom-up and top-down engagement model to motivate pan-Canadian harmonization of radiation treatment quality and safety. Guiding principles included involvement of the three primary disciplines involved in the delivery of radiation treatment, equal representations from all regions of Canada, impactful objectives aligned with the needs of the radiation treatment community, broad engagement of front-line practitioners and a person-centered focus with meaningful patient involvement. As well, CPQR engaged key stakeholder groups including Accreditation Canada, the Canadian Institute for Health Information (CIHI) and the provincial cancer agencies.

CPQR developed and validated practice guidelines and quality/safety indicators relating to program performance, equipment performance and patients engagement, as well as pan-Canadian radiation treatment accreditation standards and a national system for radiation treatment incident reporting. An independent review found that CPQR initiatives produced substantial and measurable improvements in the quality and safety performance of Canadian radiation treatment programs,

largely attributable to the methods used to motivate change and promote a culture of sharing and trust. CPQR was described as: ‘... the first successful example in the Canadian health care system where professionals from different disciplines work together as a team to improve the quality and safety of their practice’.

Looking forward, CPQR will capitalize on these successes and the momentum within the Canadian radiation treatment community to advance new quality and safety initiatives, working with ESTRO and other international partners. This will include a renewed focus on equitable access to radiation treatment in Canada and the collection and sharing of radiation treatment patient reported outcomes, integrating improvements in the care of individual patients with higher-level improvements in pan-Canadian health system performance.

##### SP-0248 Radiotherapy Quality Management and Improvement across Europe: variable approaches, united view

N. Jornet<sup>1</sup>

<sup>1</sup>Hospital de la Santa Creu i Sant Pau, Medical Physics, Barcelona, Spain

ESTRO vision states that “ Every cancer patient in Europe will have access to State of Art Radiotherapy as part of a multidisciplinary approach where treatment is individualized for the specific patient’s cancer, taking into account the particular patients’ circumstances”. Different studies show that access to radiotherapy in European Countries is far from being homogeneous and also the quality management strategies and initiatives at national level are not aligned. Quality and Safety are key elements to demonstrate that Radiotherapy is a key player in cancer cure. Therefore, to fulfill the vision, ESTRO, as an overarching organization, has to find a way to align European quality management strategies and quality indicators and standards- guiding and supporting- without overruling. This is challenging due to the diversity on cultural and economic backgrounds of European Countries. But this diversity is also an opportunity as we can learn from different countries experiences. The results of a survey on the actions being developed at a national level in Quality Management and Patient Safety show that the approaches differ. Some National Radiation Oncology Societies are active in the definition of quality indicators and standards while others focus on incident and accident reporting and analysis or in the implementation of clinical audits. On ESTRO side, ACROP committee is publishing consensus guidelines which together with ESTRO School are pillars to promote that good practice in RT departments across Europe and beyond. Furthermore, ESTRO is in a unique position to put together existing initiatives and propose a set of quality indicators and standards that could be used by the different countries. In addition, whether ESTRO should embark on accreditation of departments through Clinical Audits has been discussed in the Physics Committee strategy meeting in 2015, it is now under discussion at ESTRO board.

Wrapping up, while the approaches differ, the vision is unique “Equal access, high quality and safe radiation therapy”. However, there is still a long way to harmonize Quality Management practice through Europe and ESTRO can play an important role to facilitate this harmonization.

##### SP-0249 An Overview of Two Radiotherapy Quality Initiatives in Canada

M.D. Brundage<sup>1</sup>

<sup>1</sup>Cancer Centre of Southeastern Ontario, Kingston, Canada

This presentation will review two specific quality improvement initiatives for the practice of radiation

oncology in Canada, namely, reduction in waiting times for radiotherapy, and peer-review of radiation oncology treatment planning. Both are highly relevant to the overall strategy for quality improvement in Canada. Health care system performance on both wait times and peer-review are key quality indicators for radiotherapy treatment programs in Canada. Wait times for radiotherapy - known to be associated with treatment outcomes - have improved in some dimensions, but remain a problem in others, particularly when overall wait times from diagnosis to first treatment are considered. Trends in wait times and current strategies to reduce wait times will be discussed. Peer review of treatment planning consists of a radiation plan being reviewed by at least one independent radiation oncologist (preferably in a multi-disciplinary setting). Radiation planning peer review is endorsed as a critical component of a radiation oncology quality assurance program. The presentation will describe a pan-Canadian initiative that was launched in 2012 with the intent to disseminate the uptake and to improve the conduct of peer review activities. The components of the initiative include a national base-line survey of current practice and attitudes, strategies to promote the uptake of peer review, quantitative evaluations of peer review findings, qualitative assessments of peer review activities in radiation oncology programs, and development of "best practice" guidelines for practitioners and radiation programs for selected common radiotherapy treatment scenarios.

#### OC-0251 Late toxicity in HYPRO randomized trial analyzed by automated planning and intrinsic NTCP-modelling

A.W.M. Sharfo<sup>1</sup>, M.L.P. Dirkx<sup>1</sup>, R.G. Bijman<sup>1</sup>, W. Schillemans<sup>1</sup>, S. Breedveld<sup>1</sup>, S. Aluwini<sup>1</sup>, F. Pos<sup>2</sup>, L. Incrocci<sup>1</sup>, B.J.M. Heijmen<sup>1</sup>

<sup>1</sup>Erasmus MC Cancer Institute, Radiation Oncology, Rotterdam, The Netherlands

<sup>2</sup>Netherlands Cancer Institute-Antoni van Leeuwenhoek Hospital, Radiation Oncology, Amsterdam, The Netherlands

#### Purpose or Objective

To analyze delivered OAR doses and NTCPs in the HYPRO multicenter randomized hypofractionation trial for prostate cancer patients (Lancet Oncology 2015, 2016) using automated VMAT planning (autoVMAT). The applied multivariate NTCP models were derived by correlating clinically observed complications in the HYPRO trial with clinical and dosimetric parameters.

#### Material and Methods

820 prostate cancer patients were included in the HYPRO trial, randomly assigned to standard fractionation (39x2 Gy, 5 fr/wk) or hypofractionation (19x3.4 Gy, 3 fr/wk). Our platform for fully automated multi-criterial treatment planning was used to generate for each patient an autoVMAT plan. Achieving adequate PTV coverage had the highest priority, followed by minimization of the dose to the rectum, anus, bladder and hips. Plans were compared with respect to PTV dose coverage, rectum  $D_{mean}$ ,  $V_{65Gy}$  and  $V_{75Gy}$ , mean doses in anus and bladder, and maximum doses in the femoral heads. Moreover, comparisons were

performed using NTCP models derived from the HYPRO database for grade  $\geq 2$  late Gastro Intestinal (GI) toxicity, stool incontinence, stool frequency, rectal bleeding, and proctitis. For a subgroup of patients, autoIMRT plans with the clinically used beam angles were generated as well. For the analyses, all OAR doses in both fractionation schemes were converted to EQD<sub>2Gy</sub> assuming  $\alpha/\beta=3$  Gy.

#### Results

So far, 430 patients (215 in each arm) were analyzed. Compared to the clinically applied plans, autoVMAT plans had similar or higher PTV coverage. Large and highly significant enhanced OAR sparing was observed with autoVMAT for both treatment arms (see figure 1). Compared to the clinical plans, the autoVMAT plans showed reductions in mean doses in the rectum, anus and bladder of  $6.9\pm 4.4$  Gy,  $7.2\pm 6.2$  Gy and  $4.1\pm 2.7$  Gy ( $p<0.001$ ), respectively. Rectum  $V_{65Gy}$  and  $V_{75Gy}$  were reduced by 3.3% (relative difference  $23.4\pm 19.7\%$ ) and 1.3% (relative difference  $27.5\pm 51.9\%$ ) ( $p<0.001$ ), respectively. Maximum doses in the left and right femoral heads were also reduced by 29% and 32% on average. Figure 2 compares clinical and autoVMAT plans regarding NTCPs for the studied GI symptoms. Significant reductions in rectal NTCPs with autoVMAT were observed with a relative reduction of 10.5% in late GI grade  $\geq 2$ , 16.8% in stool incontinence, and 18.7% in rectal bleeding ( $p<0.001$ ). Plan quality improvements with autoIMRT relative to clinical plans were similar as those observed for autoVMAT, showing that enhanced plan quality was not related to the use of VMAT instead of IMRT.

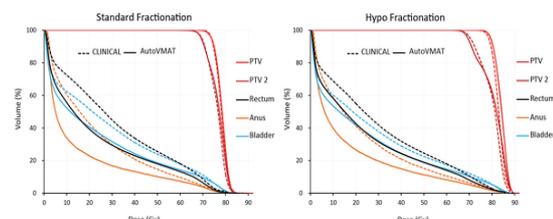

Figure 1. Average DVHs of prostate patients in the standard fractionation arm, and the hypofractionation arm.

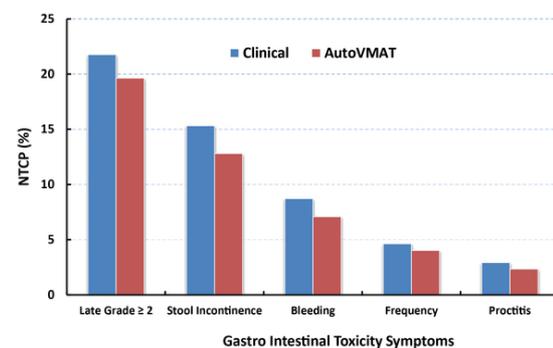

Figure 2. Reductions in NTCPs for GI toxicity symptoms with automated planning.

#### Conclusion

Automatically generated VMAT and IMRT plans resulted in large plan quality improvements compared to the clinically applied IMRT plans with significant NTCP reductions. The enhanced plan quality results from improved planning, possibly related to improvements in the treatment planning system (TPS) and/or automation of planning.

#### OC-0252 Acceptance rates of automatically generated treatment plans for breast cancer

G. van der Veen<sup>1</sup>, A. Duijn<sup>1</sup>, J. Trinks<sup>1</sup>, A. Scholten<sup>1</sup>, R. Harmsen<sup>1</sup>, G. Wortel<sup>1</sup>, R. De Graaf<sup>1</sup>, D. Den Boer<sup>1</sup>, E. Damen<sup>1</sup>

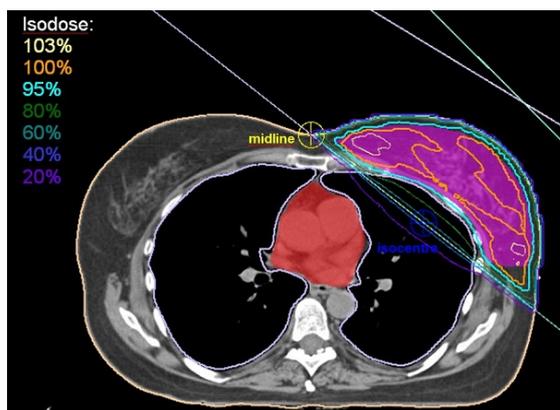

<sup>1</sup>Netherlands Cancer Institute Antoni van Leeuwenhoek Hospital, Radiation Oncology, Amsterdam, The Netherlands

### Purpose or Objective

In order to develop a more efficient workflow and to achieve RTT-independent plans for a portion of breast cancer treatments (whole breast radiotherapy with optional boost irradiation), a fully automated planning process has been clinically introduced. The process offers a number of alternative treatment plans to the RTT, who can choose to either select the optimal clinical plan, or improve one of the candidate plans to a clinically acceptable level. We investigated the acceptance rate of automatically created plans and the motivations for rejection and/or adaptation of these plans.

### Material and Methods

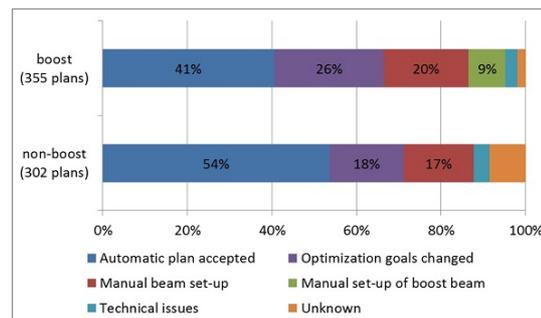

From November 2015 to September 2016 657 treatments have been planned using the automatic procedure. The plans consist of medial and lateral tangential beams, with an optional IMRT beam to deliver a boost dose to the primary tumour (bed) (Fig.1). The tangential beams consist of an open segment, delivering 75% of the dose, and a limited number of IMRT segments, delivering 25% of the dose. The open segments target the PTV (blocks on the heart when applicable), but are open outside the patient contour to allow for anatomical changes. 6MV and 10MV medial and lateral beams are offered. A heart clearance choice of 0 mm or 5 mm is also offered. This results in a total of 4 (right-sided breasts) or 8 (left-sided breasts) candidate plans. The in-house automatic planning software (FAST), controlling the Pinnacle<sup>3</sup> TPS, generates the plans and corresponding dose distributions automatically without any intervention from the RTT. This procedure commences as soon as the radiation oncologist has delineated the target volume.

**Fig. 1:** Example dose distribution of an automatically generated left breast treatment plan with a prescribed dose of 4256 cGy. The heart margin is 5 mm, beam energies are 6 MV. The V95% coverage is 98.8%,  $D_{max}$  is 105.5%.

### Results

Automatically generated plans were selected by the RTT without any adaptation in 54% of non-boost treatments and in 41% of boost treatments (Fig.2). For both classes, reasons for not selecting an automatically generated plan were very similar: in 45% of the cases, optimization goals were modified in order to change trade-offs between PTV coverage and OAR doses (at the discretion of the RTT). Our study found that in most of these cases the plan only marginally differed from the automatic plan. In another 40% of the cases a new plan was manually created, e.g. to replace the automatic tangential beam set-up with a more favourable set-up. The final 15% comprised cases in which automatic delineation was erroneous or other technical issues. In the majority of left-sided cases, the 5mm heart clearance plan was preferred. The variety in chosen beam energies is related to patient geometry.

**Fig. 2:** Acceptance of automatic boost and non-boost plans and reasons for rejecting/modifying automatic plans

### Conclusion

Considering that in close to 50% of all cases one of these plans was accepted for clinical use, a significant time saving is apparent (pre-clinical evaluation predicted an acceptance rate of 60%). This saving is estimated to be 1000 hours/year based on the projected 800 patients/year. In 45% of the cases in which an automatic plan was not chosen, only minor modifications were made to the plan, still resulting in a time reduction close to 450 hours/year.

### OC-0253 Machine Learning-Based Enables Data-driven Radiotherapy Treatment Planning Decision Support.

G. Valdes<sup>1</sup>, L. Wojtowicz<sup>2</sup>, A.J. Pattison<sup>3</sup>, C. Carpenter<sup>4</sup>, C. Simone<sup>2</sup>, A. Lin<sup>2</sup>, T. Solberg<sup>1</sup>

<sup>1</sup>University of California UCSF, Radiation Oncology, San Francisco CA, USA

<sup>2</sup>University of Pennsylvania, Radiation Oncology, Philadelphia, USA

<sup>3</sup>Siris Medical, CTO, Mountain View, USA

<sup>4</sup>Siris Medical, CEO, Mountain View, USA

### Purpose or Objective

Due to the complexity of dose deposition and variety of treatment delivery technology, plan outcomes remain non-intuitive. The ability to predict radiotherapy treatment discrete plan outcomes before planning enables the clinician to more accurately guide therapy decisions before engaging in the time-consuming plan creation process. We demonstrate the ability to accurately predict plans for lung photon and for head and neck proton and photon therapy using machine learning.

### Material and Methods

100 patients with early stage lung cancer who received stereotactic body radiation therapy (SBRT) and 36 patients with head and neck cancer who received postoperative proton radiotherapy were identified. Each head and neck patient also had corresponding photon-based volumetric modulated arc therapy plan (VMAT). DICOM-RT datasets were processed using commercial plan-prediction software (QuickMatch™, Siris Medical Inc.) to predict dose to Planning Target Volumes (PTVs) and Organs at Risk (OARs). For lung SBRT plans, we predicted doses to the lung, cord, brachial plexus, skin, esophagus, heart, great vessels, trachea, rib, chestwall, and PTV. For H&N plans, we predicted doses to the: parotid, submandibular[AL1], brain stem, cord, optic nerve, mandible, constrictors, esophagus, oral cavity, and larynx. We computed error metrics and established guidelines for dataset size. In addition, several deliverable plans were created to demonstrate the advantages of predictive modeling.

### Results

We were able to effectively predict dose distributions and dataset sizes required for desired accuracy errors for the OARs and PTVs for both photon and proton treatments. For lung SBRT plans, a dataset size of at least 69 plans resulted in all mean errors below 2.5Gy. For photon H&N plans, a dataset size of at least 121 plans resulted in all mean

errors below 2.5Gy. For proton H&N plans, a dataset size of at least 173 plans resulted in all mean errors below 2.5Gy. Dataset sizes are shown in Table 1. Shown visually in Figure 1, using predictive modeling of the plan outcome, re-planning a lung SBRT case resulted in improved dose to critical structures while maintaining coverage to the PTV, compared to the clinically-developed and treated plans.

Error Target (Gy)	5	4	3	2.5	2
Lung dataset size	16	46	61	69	74
HN Proton size	169	130	153	173	192
HN Photon size	68	136	145	121	136

Table 1: Plan datasets required for desired dose accuracy.

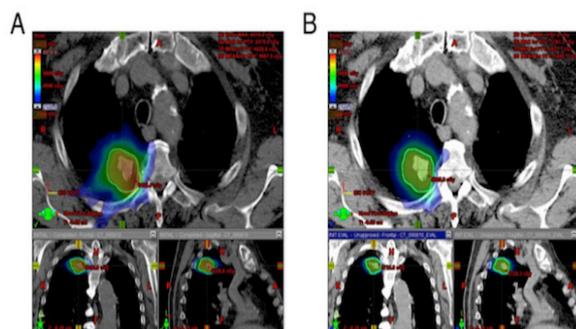

Figure 1 Comparison of clinical plan developed without (A) and with (B) predictive modeling.

#### Conclusion

We have demonstrated the ability to predict dosimetric indices. These results have clinical implications that extend from decision making to planning workflow improvement to quality improvement.

#### OC-0254 Prospective validation of independent DVH prediction for QA of automatic treatment planning

Y. Wang<sup>1</sup>, B.J.M. Heijmen<sup>1</sup>, S.F. Petit<sup>1</sup>

<sup>1</sup>Erasmus MC - Cancer Institute, Radiation Oncology, Rotterdam, The Netherlands

#### Purpose or Objective

In our institute, fully automated, knowledge-based treatment planning is used in routine clinical practice. For the majority of patients, this is expected to result in high quality treatment plans. However, technical and procedural issues might result in suboptimal plans for some patients that might go undetected. In this study, we prospectively investigated the clinical usefulness of an independent DVH prediction tool to detect outliers in treatment plan quality for prostate cancer patients.

#### Material and Methods

All prostate cancer patients treated from January 2015 till half September 2016 with the full prescribed dose delivered to the prostate only or to the prostate+seminal vesicles were included in the study. They were treated with an automatically generated VMAT or dMLC plan. The QA method was based on overlap volume histogram and principal component analysis and is fully independent of the planning method. The model was trained with 50% of the patients treated in 2015 (N=22) and validated on the other 50% (N=21). We focused on 5 different dose metrics: rectum  $D_{mean}$ ,  $V_{65}$ ,  $V_{75}$ ; anus  $D_{mean}$  and bladder  $D_{mean}$ .

Next, to study the clinical usefulness of treatment planning QA, the QA model was applied prospectively for the patients treated in 2016 (N=50). Patients for which at least one of the five dose metrics fell outside the 90% prediction confidence interval (CI) were further improved by manual plan adjustments ('re-planning'). The re-planning goals were to keep or improve *all* dose metrics of interest within or lower than the 90% CI, and anyway not

deteriorate them by more than 1Gy/1% compared to the original plan. Given the 5 parameters of interest and the 90% criteria,  $(1 - (0.9)^5) = 40\%$  patients were expected to fall outside the prediction range.

#### Results

Figure 1 shows the results of the model validation.

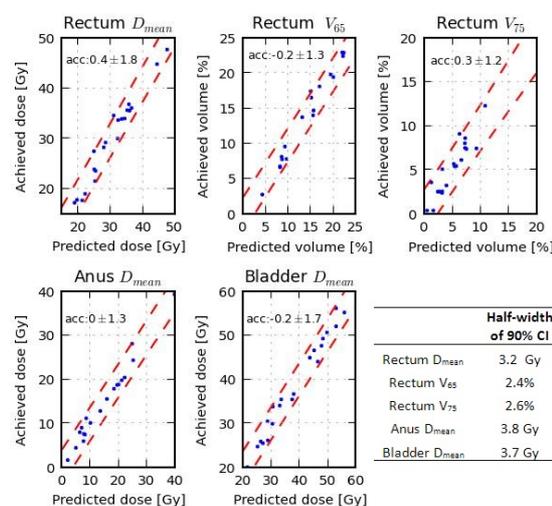

Figure 1. Comparisons of predicted and achieved rectum  $D_{mean}$ ,  $V_{65}$ ,  $V_{75}$ , anus  $D_{mean}$  and bladder  $D_{mean}$  (markers) with 90% confidence intervals (dashed lines), for the 21 patients that were used to validate the model. The prediction accuracy (acc, i.e., predicted dose - achieved dose) is shown in each subplot, and the average half-width of the 90% confidence intervals is shown in the lower right corner.

17 Patients from the prospective cohort were classified as outliers, including all four patients with metal hips, which were excluded from further analysis. The remaining outliers 13/46 (28.3%) were re-planned and for all the re-planning requirements (above) were met. As shown in Figure 2, the new plans were moderately superior to the clinical plans for rectum  $D_{mean}$  (average improvement 0.9Gy, max. improvement 3.0Gy,  $p=0.009$ ),  $V_{65}$  (2.4%, max 4.2%,  $p=0.001$ ), anus  $D_{mean}$  (1.5Gy, max 6.8Gy,  $p=0.004$ ), and bladder  $D_{mean}$  (1.7Gy, max 5.1Gy,  $p=0.001$ ). The rectum  $V_{75}$  of the new plans was slightly higher than with the original plan (0.2%,  $p=0.028$ ). No significant differences were found in PTV conformity or the femoral head  $D_{max}$ .

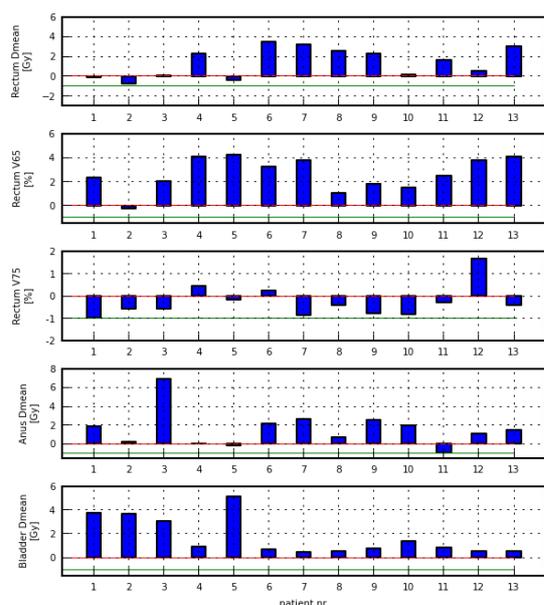

Figure 2. Comparing the clinical and re-planned plans for the 13 patients with one or more dosimetric parameters outside the 90% confidence interval. The y-axes represent differences in the dose metrics. If the difference is positive (above the red line), the re-planned plan is better than the clinical plan. The re-planned plans should not deteriorate other dose metrics by more than 1Gy or 1% (should be above the green line).

## Conclusion

The proposed plan QA tool can detect outliers with an accuracy of 3-4Gy and 2%-3% (90% CI). Totally 13/46 (28%) of the automatically generated plans were outliers. Indeed, for all of them re-planning resulted in an improved plan. This emphasizes the need for treatment planning QA, also for automated treatment planning. For manual treatment planning, the percentage of outliers is expected to be higher and therefore treatment planning QA is even more important.

## OC-0255 Practical use of principal component analysis in radiotherapy planning

D. Christophides<sup>1</sup>, A. Gilbert<sup>2</sup>, A.L. Appelt<sup>2</sup>, J. Fenwick<sup>3</sup>, J. Lilley<sup>4</sup>, D. Sebag-Montefiore<sup>2</sup>

<sup>1</sup>Leeds CRUK Centre and Leeds Institute of Cancer and Pathology, University of Leeds, Leeds, United Kingdom

<sup>2</sup>Leeds Institute of Cancer and Pathology - University of Leeds and Leeds Cancer Centre, St James's University Hospital, Leeds, United Kingdom

<sup>3</sup>Institute of Translational Medicine, University of Liverpool, Liverpool, United Kingdom

<sup>4</sup>Leeds Cancer Centre, St James's University Hospital, Leeds, United Kingdom

## Purpose or Objective

Principal component analysis (PCA) is a promising technique for handling DVH data in NTCP modelling. However it is challenging to interpret its results clinically and use them to make informed decisions for specific patients. A method is developed that uses PCA-based NTCP modelling to produce treatment optimisation objectives which can be used for treatment plan improvement. The utility of the method is demonstrated in a treatment planning case as well as in a simulation study, for reducing predicted patient reported outcome (PRO) scores of vaginal stenosis.

## Material and Methods

Data from 221 female patients treated with pelvic radiotherapy were made available from a larger study (DRF-2012-05-201) on optimising patient outcomes. Vaginal stenosis PRO scores ("Has your vagina felt tight?": "Not at all" (0), "A little" (1), "Quite a bit" (2) and "Very much" (3)) were completed by 74 (29%) patients. The

principal components (PCs) extracted from the available external genitalia DVHs, along with clinical factors, were used to construct an ordinal logistic regression model that predicted the probability of patients having vaginal stenosis symptoms.

The model identified age, hormone replacement therapy and the first PC (PC1) as important predictors of vaginal stenosis PRO scores. Based on the model, the probability of grade 2 or greater PRO score could be calculated; as well as a PC1 that could theoretically reduce that probability by 50% (PC1'). PC1' was used to derive a PCA-modified DVH' using the following method: i) the modified principal components were inversely transformed into the DVH domain to obtain a new DVH', ii) DVH' was cropped so the volumes were always greater than 0% and lower than the original DVH, and iii) DVH' was made monotonically decreasing.

An anal cancer patient case was planned using VMAT and the PCA-based model information, as a demonstration of the clinical applicability of PCA-based modelling. The method was then used to modify the DVHs of all available patients (N=221). The probability of having grade 2 ≥ PRO scores using the un-modified patient DVH and the PCA-modified DVH' were compared using a paired t-test.

## Results

The treatment planning case demonstrated the clinical relevance of PCA-based modelling by using PCA information to formulate cost functions to reduce the dose to the genitalia (Fig.1), which resulted in a reduction of the predicted probability of vaginal stenosis symptoms (Fig.2). The simulation results showed a statistically significant decrease in the probability of having grade 2 ≥ PRO scores (Reduction in mean = 33%, p<0.001).

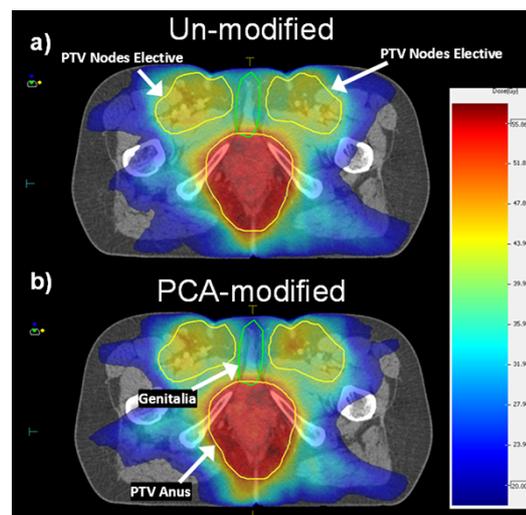

Fig. 1. a) Axial CT slice of the 'Un-modified' plan without any optimisation of the genitalia DVH showing the dose distribution near the genitalia contour, the elective nodes PTV and the anus PTV. b) The dose distribution of the 'PCA-modified' plan demonstrating the dose reduction in the genitalia to reduce the probability of having vaginal stenosis symptoms. The genitalia dose reduction optimisation was based on cost functions constructed using information from the PCA-based modelling (Fig.2).

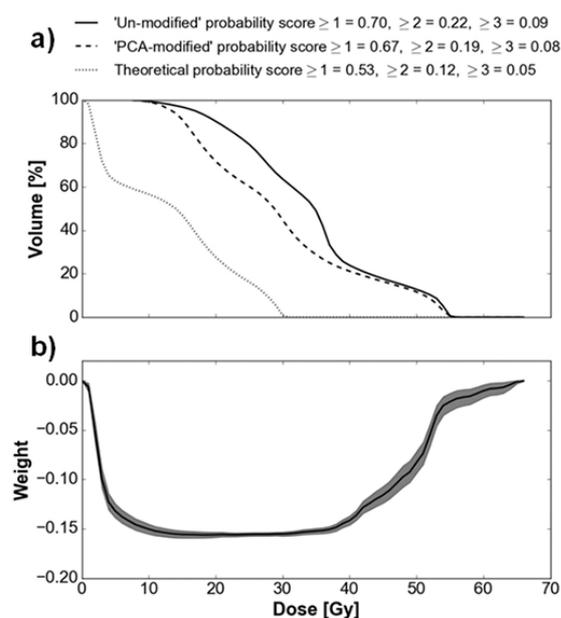

Fig. 2. a) The original genitalia DVH of the 'Un-modified' plan (Fig.1), along with the DVH from the 'PCA-modified' plan (Fig.1) optimised to reduce the dose to the genitalia and a theoretical DVH derived using the proposed method. b) Eigenvector 1 (solid line) was used to set DVH cost functions in the treatment planning system at 20 Gy, 30 Gy and 40 Gy to reduce the dose to the genitalia DVH. The cost functions dose points were chosen to coincide with the higher magnitudes of eigenvector 1. (95% confidence interval is shown, grey shaded area).

### Conclusion

The method presented allows for the use of PCA-based NTCP modelling to optimize patient DVHs to improve treatment plans. The clinical applicability of the method was tested on a treatment planning case, with a reduction of the predicted probability of vaginal stenosis symptoms. Furthermore simulation results showed a potential significant reduction of grade  $\geq 2$  vaginal stenosis PRO scores.

### OC-0256 Using a knowledge-based planning solution to select patients for proton therapy

A. Delaney<sup>1</sup>, M. Dahele<sup>1</sup>, J. Tol<sup>1</sup>, I. Kuijper<sup>1</sup>, B. Slotman<sup>1</sup>, W. Verbakel<sup>1</sup>

<sup>1</sup>VUMC, Radiotherapy, Amsterdam, The Netherlands

### Purpose or Objective

The decision to treat a patient with protons or photons is currently based upon the dosimetry of both plans and, for example, whether proton plans reduce dose to organs at risk (OAR) or the estimated toxicity by a pre-determined threshold. However, creation of two treatment plans (TPs) is time intensive, and plans can vary in quality due to patient-specific choices, planning experience and institutional-protocols. RapidPlan<sup>TM</sup>, uses a TP library to predict dose-volume histograms (DVHs) and can generate Knowledge Based Plans (KBPs). We investigated 1) whether RapidPlan, currently designed for photons, could also generate proton KBPs and 2) if predicted DVHs alone, could provide an efficient and objective way to select patients for proton therapy.

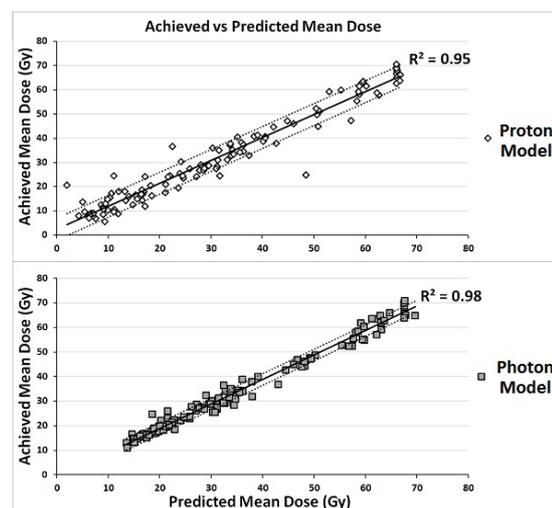

### Material and Methods

Thirty proton and photon TPs for head and neck cancer patients populated proton and photon model-libraries, and were used to create DVH predictions and KBPs for 10 evaluation patients. Accuracy of DVH-predicted OAR mean dose ( $D_{mean}$ ) was assessed by comparison with achieved

$D_{mean}$  of KBPs. KBPs were compared with manually optimized TPs using target homogeneity and  $D_{mean}$  of composite salivary ( $comp_{sal}$ ) and swallowing ( $comp_{swal}$ ) organs. To illustrate how patients might be selected for protons, the  $D_{mean}$  of the contralateral submandibular, average parotid glands and volume weighted swallowing structures were summated, and protons were selected if the model-predicted proton minus photon  $D_{mean}$  ( $\Delta Prediction$ ) was  $\geq 6$ Gy (arbitrarily chosen). A correction was applied to account for inaccuracies in predictions (see below). Selection was benchmarked with differences between proton and photon KBPs achieved  $D_{mean}$ .

### Results

$R^2$  values between achieved and predicted  $D_{mean}$  were 0.95 and 0.98 using proton and photon models, respectively (Figure). On average, photon KBPs resulted in 1.3Gy lower  $D_{mean}$  and proton KBPs 0.8Gy higher than predicted, however one patient exhibited  $>10$ Gy difference with the proton model. On average there was  $<2$ Gy difference between KBPs and manual TPs for  $comp_{sal}$  and  $comp_{swal}$   $D_{mean}$ , and  $<2\%$  for target homogeneity. Using  $\Delta Prediction \geq 6$ Gy correctly selected 4/5 patients for protons. Generating DVH-predictions and optimizing proton KBPs typically took  $<45$  seconds and 3 minutes, respectively.

### Conclusion

Once model libraries have been created, comparing knowledge-based DVH-predictions allows rapid patient selection for protons without the need to create TPs, minimizing subjectivity and the use of resources. Discrepancies between predicted and achieved  $D_{mean}$  for proton KBPs may have been due to the relatively small model libraries and the fact that the current RapidPlan algorithm is designed for photons. A proton-specific platform may address some of the shortcomings. Conversion of predicted DVH to estimated normal tissue complication probability, could further enhance the comparative process.

### OC-0257 Comprehensive MRI Acceptance Testing & Commissioning of a 1.5T MR-Linac: Guidelines and Results

R.H.N. Tijssen<sup>1</sup>, S.P.M. Crijns<sup>1</sup>, J.J. Bluemink<sup>1</sup>, S.S. Hackett<sup>1</sup>, J.H.W. DeVries<sup>1</sup>, M.J. Kruiskamp<sup>2</sup>, M.E.P. Philippens<sup>1</sup>, J.J.W. Lagendijk<sup>1</sup>, B.W. Raaymakers<sup>1</sup>

<sup>1</sup>UMC Utrecht, Department of Radiation Oncology, Utrecht, The Netherlands

<sup>2</sup>Philips Healthcare, MR Therapy, Best, The Netherlands

### Purpose or Objective

Currently the first MR-Linac systems (Elekta AB, Sweden) are being installed at several clinical institutions worldwide. In order to introduce this new technology safely into clinic it is imperative that the imaging component is rigorously tested. In this work we present a comprehensive set of tests for clinical acceptance and commissioning of a high field (1.5 Tesla) hybrid MR-Linac (MRL) system. Guidelines as well as initial results are presented.

### Material and Methods

The complete test protocol consists of a series of general MRI hardware tests, radiotherapy specific test, and hybrid tests. General MRI hardware and radiotherapy specific tests include established tests to allow comparison with diagnostic and radiotherapy planning 1.5T MRI systems. The hybrid tests are unique to the design and application of the MRL and were developed in on a non-clinical MRL prototype (U1) and performed on the clinical prototype (U2) after installation in September 2016. Hybrid tests include: Spurious Noise check, MR-MV alignment, Gantry influence on B0 homogeneity, and radiation effects. Finally, sequence specific tests are included to ensure geometric fidelity of the MRI protocols that will be performed during clinical use.

### Results

Table 1 lists the tests included in the commissioning protocol, subdivided into six sections. The first four sections contain quality control (QC) tests, which test the individual components of the system. The final two sections include quality assurance (QA) measurements, which probe overall image quality, and thus test a combination of several components. The QC measurements serve as a characterisation of the system, whereas the QA tests serve as a null measurement before the system is introduced into clinic.

Fig. 1 shows the results from two independent geometric fidelity measurements, with a) the vendor provided geometric fidelity phantom, and b) a third party phantom [Modus Medical Devices Inc, London, ON, Canada]. Geometric distortions were found to be 0.94mm, 1.82mm, and 2.35mm for diameter spherical volume (DSV) of 300mm, 350mm, and 400mm, respectively. The maximum geometric distortion occurred at the edge of the DSV. Further tests revealed that the influence of the gantry on magnetic field homogeneity was negligible ( $<0.1 \mu\text{T}$ ) and RF flip angle accuracy was within spec and comparable to our MRI-RT 1.5T Philips Ingenia scanner. Finally, the ACR resolution, geometry, and low contrast detectability tests all passed the ACR criteria using diagnostic imaging protocols (i.e., without additional averaging of the data). No spurious noise was observed during operation of the Gantry and Linac, suggesting good decoupling of the two systems.

### Conclusion

A comprehensive acceptance and commissioning protocol was developed and performed for clinical acceptance of the first 1.5T MR-Linac within the Atlantic consortium. Overall system performance is extremely similar to our diagnostic 1.5T MRI scanner, used for radiotherapy planning. Hybrid tests showed good decoupling of the two systems.

Table 1: commissioning protocol for the imaging component of the MR-Linac

B0-field	Hybrid tests
absolute field strength, magnetic field homogeneity, B0-stability,...	MR-MV alignment, radiation influence, gantry angle dependent B0, spurious noise,...
Imaging gradients	General Image Quality and QA
image orientation, gradient non-linearities, ghosting, gradient delays, eddy currents,...	PIQT tests, ACR tests, FBIRN test, coil covariance assessment,...
RF excitation and reception	Sequence specific tests
flip angle accuracy, RF cage seal, spurious noise, receiver coil performance,...	geometric fidelity, low contrast detectability, signal-to-noise, robustness,...

### OC-0258 Investigation of magnetic field effects on 3D dosimeters for MR-IGRT applications

H.J. Lee<sup>1,2</sup>, Y. Roed<sup>1,3</sup>, S. Venkataraman<sup>1</sup>, M. Carroll<sup>1,2</sup>, G. Ibbott<sup>1</sup>

<sup>1</sup>The University of Texas MD Anderson Cancer Center, Radiation Physics, Houston, USA

<sup>2</sup>University of Texas at Houston, Graduate School of Biomedical Sciences, Houston, USA

<sup>3</sup>University of Houston, Physics, Houston, USA

### Purpose or Objective

Conventional QA tools lack the ability to report changes in volumetric dose distributions and discrepancies out of the plane of measurement. The strong magnetic field in the integrated pre-clinical 1.5T MRI - 7MV linear accelerator system (MR-linac, Elekta AB, Stockholm, Sweden) influences secondary electrons resulting in changes in dose deposition in three dimensions. The purpose of this study was to investigate strong magnetic field effects on 3D dosimeters for magnetic resonance image-guided radiation therapy (MR-IGRT) applications.

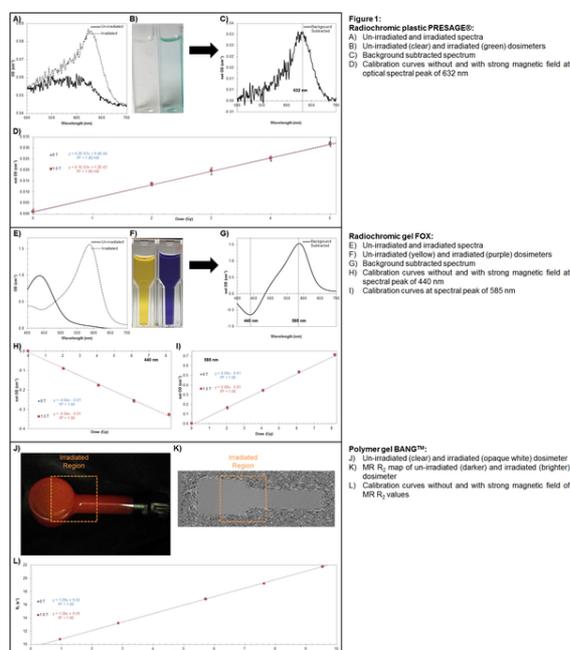

### Material and Methods

There are currently three main types of 3D dosimeters: radiochromic plastic, radiochromic gel, and polymer gel. For this study, the following three dosimeters were used: PRESAGE®, FOX (Fricke-type), and BANG™ (MGS Research Inc). For the purposes of batch consistency, an electromagnet was used for same-day irradiations with

and without a strong magnetic field. A magnetic field of 1.5T was used for PRESAGE® and FOX and 1.0T for BANG™ (1.5T was not feasible due to size constraints between the pole pieces for BANG™). PRESAGE® was irradiated with doses to 5 Gy, FOX to 8 Gy, and BANG™ to 10 Gy. Calibration curves fitting signal read-out and dose were compared between 0T and 1.5/1.0T for each dosimeter type.

### Results

The optical signal was analyzed for PRESAGE® and FOX, and the spin-spin relaxation rate  $R_2$  ( $=1/T_2$ ) MR signal was analyzed for BANG™. For all three types of 3D dosimeters, the calibration curves were linear. For PRESAGE®, the percent difference between 0T and 1.5T was 1.5% measured at the spectral peak of 632 nm; for FOX, there was a 1.6% difference at 440 nm and 0.5% difference at 585 nm ( $R^2 = 1.00$  for all optical calibration curves). The greatest percent difference for a given point dose was 5.0% at 2 Gy for PRESAGE®, 2.3% at 6 Gy (440 nm) for FOX, and 5.6% at 2 Gy (585 nm) for FOX. For BANG™, the percent difference between 0T and 1.0T was 0.7% ( $R^2 = 1.00$ ). The greatest percent difference for a given point dose was 0.3% at 10 Gy for BANG™.

### Conclusion

The same doses calculated for 0T were delivered for both 0T and 1.5/1.0T irradiations; the expected dose difference with the strong magnetic field is up to about 0.5%. Considering this potential dose difference and other uncertainties, the percent differences in response with and without strong magnetic field were minimal for all three 3D dosimeter systems, under 1.6% regarding the full dose response curves and up to 5.6% for a single dose point. All three dosimeter systems have already been used for preliminary investigations on the MR-linac, including electron return effect studies with an air cavity and assessing changes in the field edges with and without the strong magnetic field. This study encourages the continued use of all three types of 3D dosimeters for MR-IGRT applications without needing to apply a correction factor for the signal acquired for any of the above 3D dosimeter systems.

### OC-0259 Online quantitative imaging on the MR-Linac

F. Koetsveld<sup>1</sup>, L.C. Ter Beek<sup>2</sup>, P.J. Van Houdt<sup>1</sup>, L.D. Van Buuren<sup>1</sup>, U.A. Van der Heide<sup>1</sup>

<sup>1</sup>Netherlands Cancer Institute Antoni van Leeuwenhoek

Hospital, Radiotherapy department, Amsterdam, The Netherlands

<sup>2</sup>Netherlands Cancer Institute Antoni van Leeuwenhoek Hospital, Radiology department, Amsterdam, The Netherlands

### Purpose or Objective

Quantitative MR imaging provides information on tumor physiology and treatment response. For patients treated in a MR-Linac, it is possible to perform daily quantitative MR imaging. Online quantitative imaging provides valuable input for radiomics studies, and can potentially be used for adaptive dose painting.

Due to time constraints in an online setting, it is challenging to obtain accurate images that can give detailed information on tumor environment. Therefore we assessed the accuracy of four quantitative imaging sequences on the MR-Linac which are potentially relevant for radiomics and response assessment: T2 mapping, Dynamic Contrast Enhancement (DCE) including T1 mapping as input for pharmacokinetic modeling, and Diffusion Weighted imaging (DWI).

### Material and Methods

We compared phantom measurements on the MR-Linac with two diagnostic scanners: a 3T Philips Achieva dStream and a 1.5T Philips Achieva.

We tested T2 mapping using a slow but accurate Carr-Purcell-Meiboom-Gill sequence on the Eurospin T05 phantom (Eurospin T05, Diagnostic Sonar, Livingston, Scotland). We compared the results of this sequence with an accelerated sequence optimized to clinically feasible acquisition times by reducing the amount of spin echoes.

We tested T1 mapping with an Inversion Recovery series, which is more accurate but too slow to be used in clinical practice. We compared this with the fast and clinically applicable Variable Flip Angle (VFA) T1 mapping technique.

For DCE we further tested stability of the signal during a 7 min sequence on a phantom containing different contrast agent concentrations.

For DWI, we tested the accuracy of Apparent Diffusion Coefficient (ADC) measurements of water at 0°C with an Echo Planar Imaging (EPI) sequence and with a Turbo Spin Echo (TSE) DWI sequence, which is less susceptible to geometric distortions.

Finally, to demonstrate the image quality and clinical applicability on the MR-Linac, we made T1 and T2 maps of the pelvis on a healthy volunteer.

### Results

The phantom results for all four sequences are shown in figure 1. The accelerated T2 mapping is accurate to within 2% standard deviation on all systems. As expected the VFA sequence shows a bias of 10-15%. This sequence has similar precision (within 10% standard deviation) on all three systems. The DCE sequence on the MR-Linac is shown to be stable over a 7min long dynamic series like the regular MR scanners, with a coefficient of variation of < 1% for all contrast agent concentrations. For diffusion, it shows that the literature value ADC of water of  $1.13 \cdot 10^{-3} \text{ mm}^2/\text{s}$  (Holz et al, 2000) can be accurately measured using both EPI and TSE on the MR-Linac.

Figure 2 shows a T1 and a T2 map of the prostate of a healthy volunteer, using a scan with 2x2x2 mm voxels.

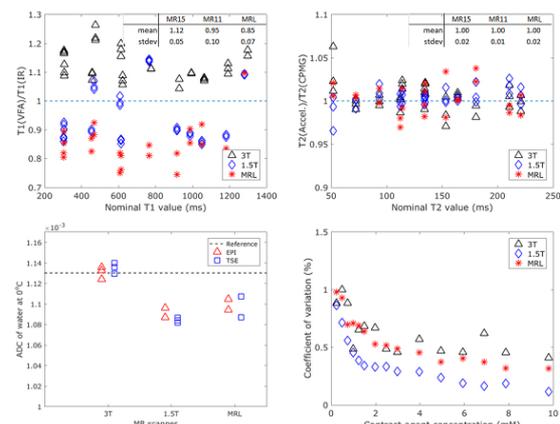

Figure 1. Top left: the ratio of T1(IR) to T1(VFA) as a function of nominal T1 value for all three systems. Top right: the ratio of T2(CPMG) to T2(accelerated) as a function of nominal T2. Bottom left: the ADC of water measured using EPI (triangles) and TSE (squares) on the three systems. Bottom right: stability of the DCE signal on the three systems. Each point in these graphs represents one measurement.

**Conclusion**

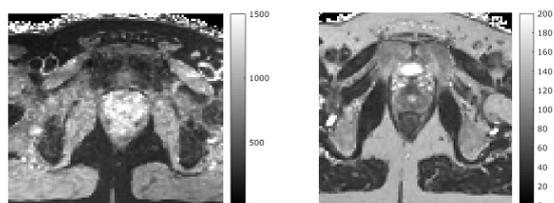

Figure 2: T1 map using a VFA sequence (left) and T2 map using an accelerated sequence (right)

These results show that T1 and T2 mapping, DCE and DWI are robust over different imaging platforms. The quality of T1 and T2 mapping on the MR-Linac has been demonstrated using a scan of a healthy volunteer.

**OC-0260 Experimental verification of dose enhancement effects in a lung phantom from inline magnetic fields**

B.M. Oborn<sup>1</sup>, M. Gargett<sup>2</sup>, T. Causer<sup>1</sup>, N. Hardcastle<sup>2</sup>, P. Metcalfe<sup>3</sup>, P. Keall<sup>4</sup>

- <sup>1</sup>Illawarra Cancer Care Centre, Medical Physics, Wollongong NSW, Australia
- <sup>2</sup>Royal North Shore Hospital, Medical Physics, Sydney, Australia
- <sup>3</sup>University of Wollongong, Centre for Medical Radiation Physics, Wollongong, Australia
- <sup>4</sup>University of Sydney, School of Medicine, Sydney, Australia

**Purpose or Objective**

To present for the first time experimental evidence of lung dose enhancement effects caused by strong inline magnetic fields. Such fields will be typical of future inline MRI-linac systems.

**Material and Methods**

A permanent magnet device was utilized to generate a 1.2 T magnetic field that encompassed a small lung-equivalent phantom of 0.3 g/cm<sup>3</sup>. 6MV and 10 MV photon beams with 0.5 x 3 cm<sup>2</sup> field size were incident parallel with the magnetic field direction and EBT3 film was placed inside the lung phantom (Fig 1 shows a schematic setup). Monte Carlo simulations were also performed of the identical setup, and of larger field sizes.

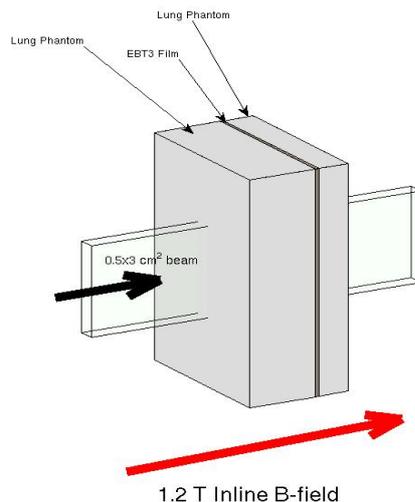

Figure 1. Schematic diagram of the lung phantom setup and magnetic field orientation.

**Results**

Inclusion of the 1.2 T inline magnetic field induced a 12% (6MV) and 14% (10MV) increase in the dose along the beam central axis as compared to the 0 T reference case (Fig 2). This increase arises from a relative reduction in the amount of lateral secondary electron scatter in the low density lung medium. Monte Carlo modeling matched well (+/- 2%) to the experimentally observed results. For simulated larger field sizes the enhancement effect drops off to around 3% at 5x5 cm<sup>2</sup>, which is a natural result of charged particle equilibrium being restored at larger field sizes. This dose enhancement effect will be expected to compliment the precise treatment of small tumors embedded in lung tissue using real-time inline MRI-linac systems.

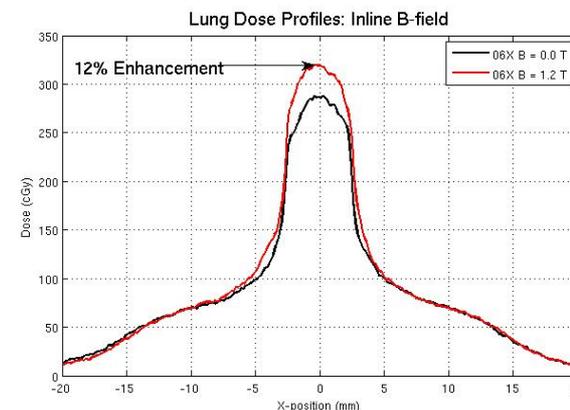

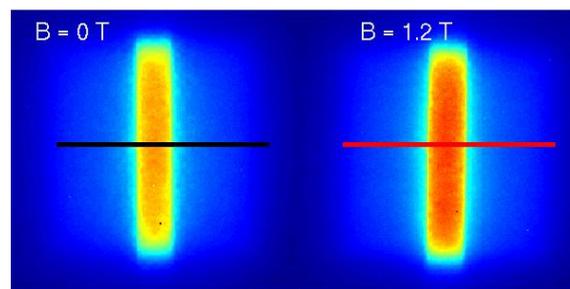

Figure 2. Film and profile results for the 6MV beam.

## Conclusion

A unique feature of strong inline magnetic fields is that they act to reduce lateral electron scatter in lower density mediums such as lung tissue. This work has demonstrated this experimentally for the first time. Clinically, such scenarios will arise in inline MRI-linac systems for treatment of small lung tumors.

## OC-0261 Monte Carlo Correction Factors for MRgRT Reference Dosimetry

S. Pojtinger<sup>1</sup>, O. Dohm<sup>2</sup>, D. Thorwarth<sup>1</sup>

<sup>1</sup>University Hospital Tübingen, Department of Radiation Oncology - Section for Biomedical Physics, Tübingen, Germany

<sup>2</sup>University Hospital Tübingen, Department of Radiation Oncology - Division for Medical Physics, Tübingen, Germany

## Purpose or Objective

Magnetic-Resonance guided Radiotherapy (MRgRT) is a new technique providing real-time MR-Im aging during Radiotherapy (RT). Caused by the strong magnetic field, trajectories of charged particles change, which results in a different deposited dose in the ionization chamber. Hence, a new chamber-specific correction factor  $k_B$ , taking into account the magnetic effect, has to be introduced. In this work  $k_B$  is determined for seven commercially available chambers by Monte-Carlo (MC) simulations.

## Material and Methods

Simulations were made using the MC package EGSnrc. Chambers were placed in 10cm depth, inside of a 30x30x20cm water phantom and dose was scored for magnetic field strengths ranging from 0 to 5T in steps of 0.5T.

The orientation of chambers was perpendicular to the central axis of the beam for thimble type chambers and axial for plane-parallel chambers (see fig. 1). The magnetic field was oriented perpendicular to the central axis of the beam.

Simulated chambers were PTW 30013, PTW 30015, PTW 34045 Advanced Markus, PTW 23343 Markus, PTW 34001 Roos (PTW Freiburg), NE2571 (Phoenix Dosimetry) and NACP02 (Scanditronix).

Modeling the PTW 30013 was based on plans provided by manufacturer as well as on a  $\mu$ CT scan. For all other chambers, geometries and material information were used that have been provided and used in publications by Wulff et al [1].

Incoming particles were simulated in 4 different ways:

1. Commercial Elekta 6MV FFF accelerator has been modeled as part of the MC simulation (Elekta 6MV FFF(Beam Sim))
2. A photon spectrum was calculated from an earlier simulation of a commercial Elekta 6MV FFF accelerator. This spectrum was used as an input for modeling the beam in form of photons dived from this distribution (Elekta 6MV FFF)
3. The beam was simulated by photons sampled from a photon spectrum that was calculated from an earlier simulation of a commercial Elekta 6MV accelerator with flattening filter (Elekta 6MV)
4. Photons were generated from a spectrum for a 6MV accelerator, published by Mohan et al [2] (Mohan 6MV)

## Results

Figure 1 shows the calculated dose  $D$  normalized to the dose without magnetic field  $D_{nb}$ .

This is the inverse of the correction factor  $k_B$  that is given for all simulation methods (at 1.5T) in table 1. Overall, large variations were observed depending on the type of ionization chamber and the magnetic field strength. Though effects are stronger for plane-parallel chambers

one can find points of stable dose, e.g.  $k_B=0.9997(19)$  for PTW 23343 Markus at 3.5T.

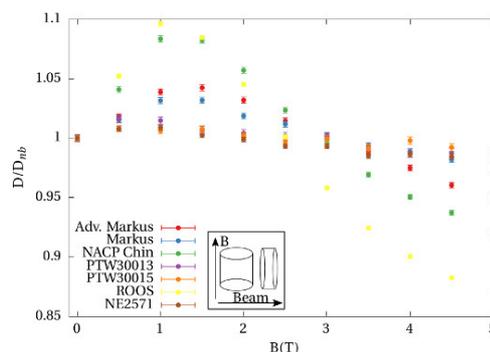

Figure 1: Simulated relative dose (Elekta 6MV FFF (BEAM-Sim)).

Table 1: Simulated correction factors  $k_B$  for various chambers and accelerator-inputs at 1.5 T.

## Conclusion

If plane-parallel chambers are used, there is a strong change in measured dose, as variations can range up to 10%. In contrast, the correction for thimble type chambers is below 2%.

The results demonstrate that reference dosimetry for MRgRT is possible, using the presented chambers, but measured dose must be corrected by the calculated factors  $k_B$ .

## OC-0262 Implementation of patient specific QA for daily adaptive MR-guided radiation therapy

M.A. Palacios<sup>1</sup>, T. Apicella<sup>2</sup>, D. Hoffmans<sup>1</sup>, T. R osario<sup>1</sup>, M. Admiraal<sup>1</sup>, I. Kawrakow<sup>2</sup>, J. Cuijpers<sup>1</sup>

<sup>1</sup>V U Medical Center, Radiation Oncology Department, Amsterdam, The Netherlands

<sup>2</sup>ViewRay- Inc., Research & Development, Mountain View, USA

## Purpose or Objective

To report on the successful implementation of a patient specific QA procedure for online treatment plan adaptation under MR guidance.

## Material and Methods

The ViewRay MRIdian system was recently installed at our institution. It allows for a fast online treatment plan adaptation based on the daily MR image and real time monitoring of the anatomy of the patient during treatment delivery. To facilitate the clinical implementation of online treatment plan adaptation we developed an online dosimetric verification procedure that uses an independent MC dose calculation engine and automatically checks relevant planning parameters. The independent MC includes the MLC, couch, and imaging coils in the simulation and takes into account the magnetic field. It runs on a computer equipped with a 4-core Intel® Core™ i3-2100 CPU @ 3.10GHz and 8 GB of RAM. A 3%/3mm Gamma comparison with the dose distribution from the TPS is performed before accepting an adapted treatment

plan for delivery. Gamma pass-rate and mean Gamma ( $\gamma_{\text{mean}}$ ) were evaluated for 380 daily adaptive fractions for over 5 months. The independent MC dose engine was verified for site specific class solutions (Pancreas, Liver, Lung and Prostate) using film dosimetry before clinical implementation.

### Results

Online patient specific QA for daily plan adaptation, including 3D MC dose calculation, gamma evaluation and automatic check of plan parameters is performed on average in 1 min 45 sec. A typical result is shown in Figure 1. Average gamma pass-rate and  $\gamma_{\text{mean}}$  over 380 fractions was 99.5 (95% CI [97.1, 100]) and 0.38 (95% CI [0.33, 0.44]), respectively. All daily adapted plans passed criteria for approval.

Verification of MC dose engine for site specific class-solutions exhibited an excellent agreement with film dosimetry, with average gamma pass-rate and  $\gamma_{\text{mean}}$  of 100% of 0.14, respectively.

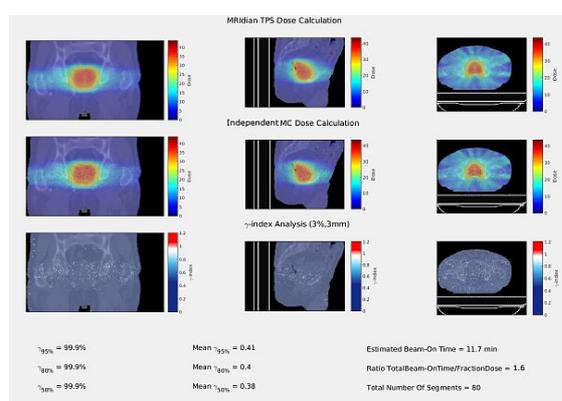

Figure 1. Dose distributions from ViewRay TPS (first row), online independent MC dose calculation (second row) and gamma evaluation (3%, 3mm). Gamma pass-rates, gamma mean and other plan parameters are automatically checked.

### Conclusion

A patient specific QA procedure for online adaptive MR-guided radiotherapy was successfully implemented at our institution. This procedure, which takes less than 2 minutes, include online independent 3D MC dose calculation after daily plan adaption and automatic check of plan parameters while the patient is in treatment position. A very good agreement with dose distribution from the TPS was found for all adaptive fractions.

### Proffered Papers: Variabilities in volume definition

**OC-0263 Single vs. multi-atlas auto-segmentation for prostate RT: Comparison of two commercial systems**  
A. Gulyban<sup>1</sup>, P. Berkovic<sup>1</sup>, F. Lakosi<sup>2</sup>, J. Hermesse<sup>1</sup>, P.A. Coucke<sup>1</sup>, V. Baart<sup>1</sup>, D. Dechambre<sup>1</sup>

<sup>1</sup>Liege University hospital, Department of Radiation Oncology, Liege, Belgium

<sup>2</sup>Health Science Center- University of Kaposvar, Radiation Oncology, Kaposvar, Hungary

### Purpose or Objective

Using atlas-based auto-segmentation during treatment planning has the potential to reduce the workload of the staff while improving delineation consistency. Our aim was to evaluate two commercial systems for prostate treatment planning: evaluating volumetric accuracy 1) while completing the atlas (learning curve), 2) using the full atlas (performance) and 3) determining dose volume histogram parameter (DVH) variations between of the auto-generated and reference contours.

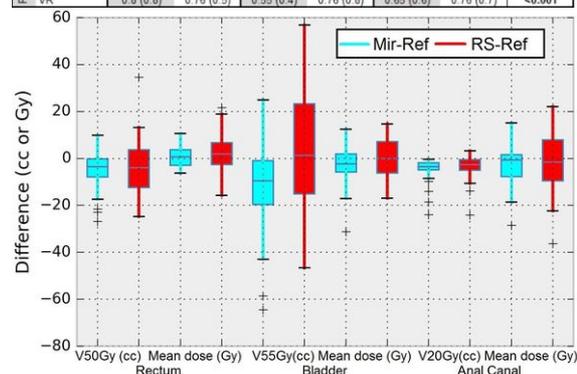

### Material and Methods

Forty random prostate patient cases were selected for this study. Each dataset consisted of a CT, a structure set (including prostate, rectum, bladder, anal canal and penile bulb) and the original dose matrix. Two systems were used, the single-atlas based Raystation (RS, version 5.0.2, Stockholm, Sweden) and the multi-atlas based RTx (MIR, version 1.6.3, Mirada Medical, Oxford, UK). The 1-5<sup>th</sup> case was used as base atlas. The learning phase was completed in an incremental way, where each new auto-contours generated using an atlas consisting of all former cases (6<sup>th</sup> case used the atlas of 1-5<sup>th</sup>, 7<sup>th</sup> the 1-6<sup>th</sup> etc.) until the 20<sup>th</sup> case. Performance was evaluated using the complete (1-20<sup>th</sup>) atlas on another 20 cases (21-40<sup>th</sup>). Analysis included the Dice Similarity Coefficient (DSC), Jaccard index (JI), commonly contoured volumes (CCV), volumetric ratios (VR) and 95% of the Hausdorff distance (HD95%). Furthermore using the dose matrix, DVHs were generated for all volumes and the differences of relevant organs at risk specific parameters were compared. Mean values and standard deviations (SD) were used for the descriptive statistics and paired t-test to compare the MIR vs. RS performance, while the Root mean squares (RMS) were compared for the dosimetrical differences.

### Results

For volumetric comparison (DSC, JI, and CCV, VR, HD95%) 21 vs. 14 out of 24 parameters improved from the learning to the performance stages for MIR vs. RS respectively (table 1). For rectum, MIR underestimated the volume (VR for MIR 0.75 vs. RS 0.79,  $p < 0.001$ ), while for all other parameters outperformed RS ( $p < 0.001$ ). Results for bladder and prostate showed superior performance of MIR with the exception of bladder CCV, which was not significantly better compared to RS. Anal canal and penile bulb showed poor agreement (for both systems). RS was more accurate to estimate the anal canal volume; similar results were obtained for penile bulb's CCV, while all other parameters were significantly better with MIR. RMS values of MIR vs. RS resulting in 10.1 vs. 11.9 cc of V50Gy and 4.7 vs. 8.0 Gy of mean dose for rectum, for bladder V55Gy 22.4 vs. 27.3 cc and mean dose 8.6 vs. 8.6 Gy, while for anal canal V20Gy of 6.9 vs. 6.3 cc and mean dose of 9.1 vs. 12.5 Gy respectively.

### Conclusion

Using multi-atlas (MIR) compared to single-atlas (RS) for prostate RT showed better in 19, similar in 2 and worse in 3 out of the 24 volumetric parameters. Even though the results are promising, discordances could lead to large DVH parameters differences.

#### OC-0264 Assessment of Atlas based auto-segmentation in Breast Contouring

P.H. Fok<sup>1</sup>, W.K. Fung<sup>1</sup>, C.H.P. Ho<sup>1</sup>, G. Chiu<sup>1</sup>  
<sup>1</sup>Hong Kong Sanatorium & Hospital, Department of Radiotherapy, Happy Valley, Hong Kong SAR China

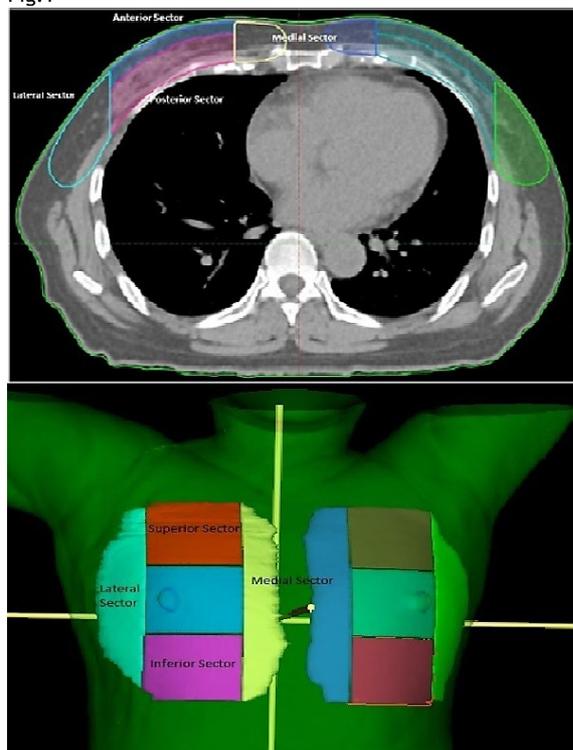

##### Purpose or Objective

To investigate the efficiency and accuracy of atlas based auto-contour segmentation (ABAS) for radiotherapy of breast cancer patients.

##### Material and Methods

Contour sets of 80 breast cancer patients were recruited to build an atlas in MIM Software for ABAS purpose. They consisted of structures including CTV, PTV, and OARs including the esophagus, heart, liver, spinal cord and contralateral breast. ABAS was evaluated by comparing auto segmented contours with manually drawn contours using Dice Similarity coefficients (DSC) and Hausdorff distance (HD). CTV and contralateral breast were dissected into superior, inferior, medial, lateral, anterior and posterior portions (Fig.1) for individual evaluations of their accuracy of ABAS. The study consisted of two parts. Part A: All patients from the atlas were used as the test subjects and the patient who was selected as the test subject would be excluded from the atlas. Manual contours of each subject were compared with those that were generated by ABAS. Part B: Another 16 patients with breast cancer were randomly recruited to evaluate the efficacy of ABAS in clinical practice. The time required for manual contouring and contouring by ABAS with or without manual refinement were compared. Radiation Oncologists (ROs) were asked for their satisfactory levels regarding the ABAS generated contours.

Fig.1

Results  
Part A

The comparison results of the ABAS generated contours and the manual contours were listed in Table 1. High levels of agreement (DSC=0.8 to 1) were shown in the right lung, left lung, liver, heart, spinal cord and left breast PTV; moderate levels of agreement (DSC=0.7 to 0.79) were shown in the left breast (CTV, contralateral breast) and the right breast (CTV, PTV, contralateral breast); poor agreement (DSC<0.69) was shown in the esophagus.

The lateral portions of the CTV, PTV and contralateral breast for both left and right sided breast cancer patients had the largest volume differences among the other portions. Thus, the lateral portion of the breast contour required the most refinement.

##### Part B

Level of agreement and satisfaction improvement were shown after refinement on ABAS generated TVs, with the mean DSC increased from 0.861 to 0.979 and the satisfaction score (range:1-5) increased from 2.2 to 4.3. The mean time for ROs to manually contour TVs and to modify ABAS generated TVs with refinement was 26.8 and 15.3mins respectively. The DSC, mean time for manually contouring OARs and that for ABAS generated contours with refinement were as follows: heart (DSC=0.949; 8.2 and 7.3mins), liver (DSC=0.904; 24.8 and 20.5mins), esophagus (DSC=0.556; 7.6 and 11.3mins), spinal cord (DSC=0.855; 9.2 and 10.4mins) and contralateral breast (DSC=0.904; 24 and 18mins).

Table 1

TVs / OARs	DSC mean	DSC SD	HD mean	HD SD
Left CTV	0.735	0.061	0.513	0.143
Left PTV	0.805	0.053	0.432	0.127
Contralateral Breast (Right)	0.779	0.074	0.476	0.214
Right CTV	0.725	0.066	0.56	0.183
Right PTV	0.795	0.068	0.452	0.155
Contralateral Breast (Left)	0.767	0.080	0.608	0.701
Heart	0.895	0.055	0.295	0.271
Liver	0.930	0.032	0.311	0.379
Left Lung	0.974	0.008	0.105	0.201
Right Lung	0.975	0.001	0.121	0.342
Esophagus	0.553	0.114	0.325	0.229
Spinal Cord	0.810	0.062	0.207	0.383

##### Conclusion

ABAS could speed up the contouring process especially in target delineation during breast patient treatment planning. However, improvement in the algorithm is still needed and auto post-ABAS refinement has to be developed to further increase its efficiency for clinical practice.

#### OC-0265 Evaluating variability of contouring using ESTRO guidelines for elective breast cancer radiotherapy

D. Megias<sup>1</sup>, M. Sydenham<sup>2</sup>, D. Wheatley<sup>3</sup>, M. MacLennan<sup>4</sup>, E. Spezi<sup>5</sup>, A.M. Brunt<sup>6</sup>

<sup>1</sup>Mount Vernon Hospital, National Radiotherapy Trials Quality Assurance Group RTTQA, Northwood, United Kingdom

<sup>2</sup>Institute of Cancer Research, ICR Clinical Trials and Statistics Unit, Sutton, United Kingdom

<sup>3</sup>Royal Cornwall Hospital, Clinical Oncology, Truro, United Kingdom

<sup>4</sup>Edinburgh Cancer Centre, Cancer Services, Edinburgh, United Kingdom

<sup>5</sup>Cardiff University, School of Engineering, Cardiff, United Kingdom

<sup>6</sup>Royal Stoke University Hospital & Keele University, Cancer Centre, Stoke on Trent, United Kingdom

##### Purpose or Objective

Outlining of target and OAR volumes is an integral part of the radiotherapy pathway but inherently subject to variability. With an emerging body of evidence supporting regional nodal irradiation in early breast cancer, there is continued emphasis for optimal, standardised and

consistent reporting of treatment planning for regional nodal radiotherapy, particularly within clinical trials. It is on this foundation that the ESTRO consensus guideline for elective breast cancer radiotherapy has been developed. We set out to evaluate variability of lymph node contouring using the ESTRO consensus guideline across multiple investigators and sites.

#### Material and Methods

As part of the UK FAST-Forward trial RTQA programme each co-investigator is required to delineate a LN CTV comprising of levels 1-4 as defined by the ESTRO guideline on an outlining benchmark CT dataset. LN CTV's were defined by three clinicians (LN\_CTV\_CLIN\_1/2/3) of the Trial Management Group (TMG) with experience of the ESTRO guidelines and a consensus LN CTV defined through discussion and comparison.

LN CTV's of 39 investigators from 32 radiotherapy centres were analysed using in-house software based on the Computational Environment for Radiotherapy Research (CERR). Discordance Index (DI), Geographical Miss Index (GMI), Jaccard Index (JI), and Mean Distance to Conformity (MDC) indices were generated, comparing LN\_CTV\_CLIN\_1/2/3 and investigators LN CTV's to the consensus LN CTV in addition to standard volume statistics.

#### Results

Quantity	LN_CTV_CLIN_1	LN_CTV_CLIN_2	LN_CTV_CLIN_3	INVESTIGATORS			
				Mean	Standard Deviation (SD)	Range	SD/Mean (%)
Volume (cm <sup>3</sup> )	92.1	95.6	108.3	127.40	26.67	60.7-179.16	20.9
JI	0.66	0.76	0.97	0.53	0.07	0.32-0.67	13.21
DI	0.15	0.09	0.03	0.36	0.07	0.23-0.55	19.44
GMI	0.25	0.18	-	0.24	0.13	0.04-0.57	56.52
MDC (cm)	Over	0.17	0.43	0.49	0.11	0.29-0.77	22.45
	Under	0.6	0.56	-	0.95	0.31	0.11-1.7

The interobserver variation (SD/Mean) in volume contoured between the investigators was lower compared to published literature (40.8%/55.9% axillary nodes and 60.5% SCF nodes- Li et al, 2009).

The JI results indicate investigator volumes achieved conformity in relation to the consensus comparable to LN\_CTV\_CLIN\_1 with the SD supporting low interobserver variability across submissions. Larger mean and minimum DI compared to GMI indicate a trend for over contouring across investigator submissions, however associated range and SD supports MDC analysis showing a larger degree of variation was associated with under contouring. MDC analysis on a slice by slice basis identifies defining the caudal extent of level 1 as the region associated with the largest degree of under contouring and the caudal aspect of levels 3/4 with over contouring.

It is important to consider the variation in volume and conformity in context of the ESTRO guidelines which acknowledge that the anatomical boundaries are not considered exact to mm, with a range in JI scores between consensus clinicians despite the indices indicating good spatial relationship to the consensus.

#### Conclusion

Contouring of the regional lymph nodes using the ESTRO consensus reduces interobserver variability in volume contoured. Comparing the consensus clinicians and investigator results suggest that experience and/or training is associated with less interobserver variability, promoting the role of RTQA when adopting new outlining guidelines as part of a multicentre trial.

#### OC-0266 Motion specific target delineation significantly reduce treated volumes in liver SBRT

J. Wielgaard<sup>1,2</sup>, C.H. Slump<sup>2</sup>, K. Muller<sup>1</sup>, A.W.H. Minken<sup>1</sup>, H. Westendorp<sup>1</sup>

<sup>1</sup>Radiotherapiegroep Behandellocatie Deventer, Medical Physics, Deventer, The Netherlands

<sup>2</sup>University of Twente, MIRA: Institute for Biomedical Technology and Technical Medicine, Enschede, The Netherlands

#### Purpose or Objective

Target volumes based on patient's individual respiratory motion, so-called motion specific target volumes, can possibly improve target coverage and reduce dose to healthy tissue. We have derived motion specific target volumes for stereotactic body radiation therapy (SBRT) of liver tumors based on deformable image registration (DIR) of 4DCT images and assessed the intrahepatic accuracy for these algorithms.

#### Material and Methods

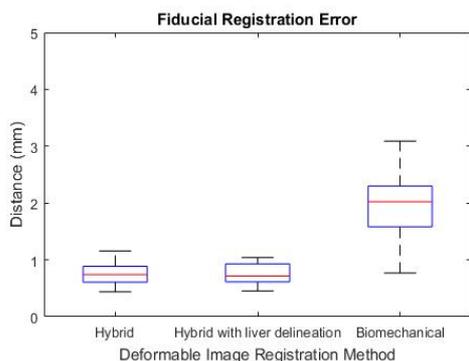

4DCT data sets of 15 patients in head-first supine position were obtained with a Brilliance Big Bore 16-slice CT scanner (Philips Healthcare, OH, US) and reconstructed using phase binning. Patients were positioned using a BlueBAG Vacuum Cushion (Elekta, Sweden) and immobilized with a SBRT Body Pro-Lok system with abdominal compression plate (CIVCO, IA, US). Consecutive DIR of the 4DCT images was used to track patient's individual respiratory motion by mapping voxels over 10 respiratory phases. Two DIR algorithms were used: a hybrid algorithm based on intensity and delineated contours (ANACONDA), and a biomechanical algorithm based on the finite element method (MORFEUS). The hybrid algorithm was employed with and without delineation of the liver contour. The motion specific target volume was created by propagating a gross target volume (GTV) contoured on a reference CT over the obtained vector fields. The target volume encompasses the GTV of 10 respiratory phases plus a 3 mm set-up margin in order to account for variations in patient setup. The motion specific target volumes were compared with volumes generated using static margins (6x6x10 mm) according to the clinical protocol. To evaluate the intrahepatic performance, fiducial markers were used as points-of-interest to calculate the residual error after registration. The fiducial registration error (FRE, mean absolute residual error) was chosen as the measure to compare the algorithms.

#### Results

The motion specific target volumes resulted in the following average target volumes: hybrid: 33 ± 36.1 cc, hybrid with liver contour guidance: 37.0 ± 27.5 cc and biomechanical: 39.7 ± 29.4 cc. The average volume using static margins of 6x6x10 mm was 56.9 ± 38.8 cc. In 7 out of 15 cases the static margins did not encompass the motion specific situation, leaving target tissue uncovered. The hybrid algorithm with and without additional liver contouring resulted in a FRE of 0.8 ± 0.8 mm and of 0.8 ± 0.5 mm respectively. The biomechanical algorithm showed a FRE of 1.9 ± 1.0 mm.

#### Conclusion

The motion specific target volumes show a volume reduction compared to the target volumes generated using static margins. Besides that, the motion specific target volume extends the with static margins derived target volume. Motion specific target volumes using deformable image registration could decrease the dose to healthy tissue and potentially improve target coverage. The hybrid algorithm resulted in a lower FRE compared to the biomechanical algorithm.

### OC-0267 Automatic contour propagation of breast and heart for re-planning in breast cancer radiotherapy

G.G. Sikkes<sup>1</sup>, L.T.C. Meijers<sup>1</sup>, A.N.T.J. Kotte<sup>1</sup>, I.E. Van Dam<sup>1</sup>, B. Van Asselen<sup>1</sup>, H.J.G.D. Van den Bongard<sup>1</sup>  
<sup>1</sup>UMC Utrecht, Radiation Oncology Department, Utrecht, The Netherlands

#### Purpose or Objective

Adaptive radiotherapy (RT) can improve the radiotherapy treatment when target volume, patient anatomy or treatment position has changed during treatment. Automatic, non-rigid, contour propagation in a clinical setting is expected, in comparison with rigidly transferred contours, to reduce delineation time and can increase the efficiency of adaptive radiotherapy. For breast cancer patients, adaptive radiotherapy is mainly performed due to breast contour changes (e.g. oedema) or reduction in seroma volume. The aim of this study was to determine the applicability of non-rigid contour propagation of breast (clinical target volume, CTVbreast) and heart for re-planning in breast cancer RT.

#### Material and Methods

25 breast cancer patients, each with a RT planning-CT(CT1) and a subsequent CT(CT2) taken before or during (fraction 0-9) treatment, were selected for this prospective study. For 11 of the 25 patients the changes visible on CT2 were clinically acceptable, consequently, no re-planning was needed. In 14 patients, 15 new RT plans (including patient with bilateral breast cancer) were performed, due to changes in target (n=11), treatment position (n=2) or switch from Breath hold technique to free breathing CT (n=1).

Heart and CTVbreast were manually delineated on CT1 by a radiation oncologist according to clinical delineation guidelines. Contours on CT1 were transferred to CT2 using a rigid registration technique, equal to the standard clinical procedure. The CT1 contours were also transferred to CT2 via deformable automatic contour propagation using 'Advanced Medical Image Registration Engine' (ADMIRE research software v1.12/v1.13.3/v1.13.5, Elekta AB, Sweden).

The rigidly transferred contours as well as the deformable propagated contours were compared to the clinical contours on CT2 using comparison measures target volume, DICE, Hausdorff distance and mean distance.

#### Results

The volume, DICE, Hausdorff distance and mean distance, presented in table 1 and figure 1, depict differences between the deformable propagated and rigidly transferred contours relative to the clinical contours. 14 of the 15 patients receiving new RT plans (including patient with bilateral breast cancer) had a higher DICE, a smaller Hausdorff distance and mean distance and had less volume differences between the deformable propagated CTVbreast and heart contours relative to the clinically used contours in contrast to the rigidly transferred contours.

	Propagated - Clinical		Rigid - Clinical	
	CTV Breast (N=15) Median (range)	Heart (N=14) Median (range)	CTV Breast (N=15) Median (range)	Heart (N=14) Median (range)
Dice	1.00 (0.96-1.00)	0.98 (0.89-1.00)	0.92 (0.20-0.97)	0.93 (0.75-1.00)
Volume (cc)	2.90 (0.00-6.70)	10.05 (2.80-124.10)	80.2 (6.50-1873.40)	21.55 (0.40-144.60)
Hausdorff (mm)	3.06 (0.00-12.38)	7.32 (3.00-14.84)	11.35 (5.40-28.75)	9.70 (2.23-21.12)
Mean distance (mm)	0.26 (0.00-1.00)	0.59 (0.00-2.70)	2.65 (0.73-7.46)	1.85 (0.04-8.79)

Table 1: Median and range minimum and maximum between propagated and clinically used contours as well as between rigid transferred and clinically used contours.

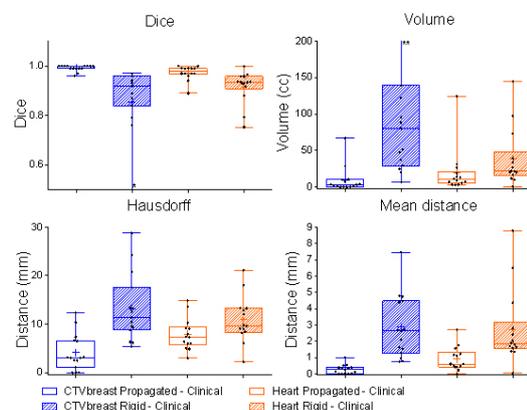

Figure 1: Boxplot of the median, mean, minimum to maximum between propagated and clinically used contours as well as between rigid transferred and clinically used contours. \*DICE: 0.20 \*\* Volume: 1873.40

#### Conclusion

These results show that the deformable propagated CTVbreast and heart contours are, as expected, more close to the clinical used contours than the rigidly transferred contours. Therefore, deformable contour propagation can reduce delineation time and can be used to optimize the workflow of adaptive RT for breast cancer.

### OC-0268 Volumetric comparison between PET/CT and CT simulation for target delineation in esophageal cancer

E. Jimenez-Jimenez<sup>1</sup>, P. Mateo<sup>2</sup>, N. Aymar<sup>1</sup>, I. Ortiz<sup>1</sup>, R. Roncero<sup>1</sup>, M. Vidal<sup>1</sup>, M. Gimenez<sup>3</sup>, F. Romero<sup>4</sup>, S. Sabater<sup>5</sup>

<sup>1</sup>Hospital Universitari Son Espases, Radiation Oncology Department, Palma de Mallorca, Spain

<sup>2</sup>Hospital Can Misses, Medical Physics Department, Ibiza, Spain

<sup>3</sup>Hospital Universitari Son Espases, Nuclear Medicine Department, Palma de Mallorca, Spain

<sup>4</sup>Hospital Universitari Son Espases, Medical Physics Department, Palma de Mallorca, Spain

<sup>5</sup>Complejo Hospitalario Universitario de Albacete, Radiation Oncology Department, Albacete, Spain

#### Purpose or Objective

FDG-PET/CT has proven to be useful in the staging process of esophageal tumors. However, evidence supporting the use of FDG-PET/CT in the tumor delineation process and radiotherapy planning is limited.

Our objective was to compare the volumes defined by PET-CT vs. CT simulation in esophageal planning.

#### Material and Methods

Nineteen esophageal carcinoma patients were referred for concomitant radio-chemotherapy with radical or neoadjuvant intent.

Each patient underwent CT and FDG-PET/CT for simulation treatment in the same treatment position. Two separate GTVs were defined; one based on CT data alone (GTV-CT) and another based on combined PET/CT data (GTV-PET/CT). Volume sizes for both data sets were compared and the spatial overlap was assessed by the Dice similarity coefficient (DSC), which represents the ratio of volume overlap between 2 contours.

The non-parametric Wilcoxon and Spearman tests were used to estimate the relationships. The data were analyzed using SPSS version 22.

### Results

The gross tumor volume (GTV-t) was greater by FDG-PET/CT-simulation but differences were not statistically significant. However, the gross node volume (GTV-n) and the length of the esophageal tumor were greater by FDG-PET/CT-simulation and these differences were statistically significant (Table 1).

The analyzed of DSC showed a great similarity of GTV-t: 0.71 (0.13). A very low DSC was observed in GTV-n: 0.08 (0.47). Data are expressed as median and inter-quantile range. Values greater than 0.7 are often regarded as an excellent agreement.

Correlations between volume sizes for PET/CT and CT were determined using a correlation coefficient. There was a very high correlation (0.82) between CT and FDG-PET/CT simulation ( $p=0.002$ ) in the GTV-tumor volumes. However, this correlation was very low (0.58) in the GTV-node ( $p=0.01$ ) and length of the esophageal tumor (0.67,  $p=0.001$ ).

	PET/CT		p-value	PET/CT		p-value	PET/CT		p-value
	GTV-t (cm <sup>3</sup> )	CT		GTV-n (cm <sup>3</sup> )	CT		Tumor length (cm)	CT	
Median	35.9	29.2	0.47	1.8	1.0	0.06	5.0	5.5	0.06
Inter-quantile range	34.6	30.4		5.6	1.5		3.0	2.0	
Maximum	108.9	110.1		10.0	8.4		11.8	14.5	
Minimum	7.5	6.2		0.0	0.0		2.3	2.5	

Table 1 Volumetric comparison between PET/CT and CT simulation

### Conclusion

Our study shows that the volume definition by FDG-PET/CT and CT simulation in esophageal cancer differs, especially with respect to GTV-node volume and tumor length. FDG-PET/CT appears to have an impact on treatment planning and management of esophageal carcinoma.

## Proffered Papers: Prostate 2

### OC-0269 Single Dose Compared to Fractionated High-Dose Rate Brachytherapy for Localised Prostate Cancer

P. Hoskin<sup>1</sup>, A. Rojas<sup>1</sup>, P. Ostler<sup>1</sup>, R. Hughes<sup>1</sup>, R. Alonzi<sup>1</sup>, G. Lowe<sup>1</sup>

<sup>1</sup>Mount Vernon Hospital, Cancer Centre, Northwood Middlesex, United Kingdom

#### Purpose or Objective

To evaluate late toxicity and freedom from biochemical relapse (FFbR) after high-dose-rate brachytherapy (HDR-BT) in localised prostate cancer.

#### Material and Methods

HDR-BT delivering 1 x 19 Gy, 1 x 20 Gy, 2 x 13 Gy, 3 x 10.5 Gy, 4 x 8.5 Gy and 4 x 9 Gy was given to patients with predominantly intermediate or high-risk prostate cancer. All patients were staged with at least pelvic MR and isotope bone scan to exclude metastatic disease. Transperineal-transrectal ultrasound guided implantation was followed by MR based CTV definition following the GEC ESTRO guidelines. Biochemical relapse was assessed using the Phoenix definition (PSA nadir plus 2 µg/L). Late urinary (GU) and gastrointestinal (GI) were assessed using the RTOG and the International Prostate Symptom Score (IPSS). Patients were evaluated prospectively from 6 months after implant and bi-annually thereafter. Pearson's Chi-square was used to test for significance between prevalence of GI, GU catheter use and IPSS events. Estimates of freedom from biochemical relapse, disease-free survival (DFS) and overall survival (OS) and of GI, GU and IPSS toxicity were calculated using the Kaplan-Meier (K-M) method and the log-rank test to test for significance.

### Results

Median age is 69 (19, 26 and 31.5 Gy), 70 (20 Gy), 68 (34 Gy) and 67 years (36 Gy). For 19, 20, 26, 31.5, 34 and 36 Gy median PSA was 8.2, 10.7, 11, 12.4 11.1 and 10.5 µg/l, Gleason Scores  $\geq 8$  were 4%, 31%, 11%, 6%, 11% and 13%, proportion with T<sub>3</sub> disease was seen in 29%, 35%, 32%, 36%, 43% and 35% of patients, and median follow-up 54, 48, 62, 107, 129 and 121 months, respectively. Neo-adjuvant and adjuvant androgen deprivation treatment was given to 76% of all patients; intermediate risk patients were treated for 6 months and high risk for up to 3 years. K-M estimates of FFbR, DFS and OS and p

Table 1. Kaplan-Meier estimates of treatment outcome and prevalence estimates of late morbidity after high-dose-rate brachytherapy

Variable	1 x 19 Gy n = 24	1 x 20 Gy n = 27 (%)	2 x 13 Gy n = 148 (%)	3 x 10.5 Gy n = 110 (%)	4 x 8.5 Gy n = 30 (%)	4 x 9 Gy n = 25 (%)
FFbR	48 months	91%	92%	92%	91%	90%
	60 months	91%	89%	90%	90%	90%
	84 months		76%	81%	85%	90%
DFS	48 months	83%	88%	90%	90%	90%
	60 months	83%	85%	88%	89%	90%
	84 months		67%	78%	71%	90%

	60 months	0%	0%	3%	7%	0%
	84 months		6%	4%	11%	4%
IPSS $\geq 20$	48 months	5%	6%	3%	5%	0%
	60 months	25%	4%	1%	4%	5%
	84 months		4%	4%	0%	4%

Abbreviation: FFbR = Freedom from biochemical relapse, DFS = Disease-free survival, OS = Overall survival, GI = Bowel, GU = Urinary, IPSS = International Prostate Symptom Score.

### Conclusion

The results indicate that large doses per fraction of high-dose-rate brachytherapy are feasible and late adverse events manageable. The incidence of severe urinary and IPSS scores events is similar for all groups with no significant difference in PSA control for single-dose versus 2 to 4 fractions of HDR-BT at this relatively early stage. Whilst longer follow up is required a large single dose of HDR brachytherapy appears both safe and effective.

### OC-0270 QoL and toxicity of HDR prostate brachytherapy as monotherapy 19Gy single fraction: phase II trial

A. Gomez-Iturrriaga<sup>1,2</sup>, F. Casquero<sup>1</sup>, P. Minguéz<sup>1</sup>, J. Espinosa<sup>1</sup>, A. Bueso<sup>1</sup>, J. Cacicedo<sup>1</sup>, L. Fernandez<sup>1</sup>, S. Pedraza<sup>1</sup>, J. Garcia Escovedo<sup>1</sup>, P. Bilbao<sup>1</sup>

<sup>1</sup>Hospital de Cruces, Oncologia-Radioterapia, Baracaldo Vizcaya, Spain

<sup>2</sup>Biocruces Health Research Institute, Radiation Oncology, Barakaldo, Spain

#### Purpose or Objective

High-dose rate brachytherapy (HDR-BT) is an advanced technology theorized to be more advantageous than Low Dose Rate-BT (seeds) and External Beam Radiotherapy (EBRT), to the patient himself, and in terms of resource consumption.

Evidence supports the use of HDR-BT as monotherapy for selected patients with low- and intermediate-risk prostate cancer when administered in 4 or more fractions. There is limited data on the safety and efficacy of HDR given in a single fraction.

The primary endpoint of this study is to evaluate the safety, tolerance and impact on quality of life (QoL) of the BT-HDR 19Gy administered in single fraction in patients with low and intermediate risk prostate cancer. Secondary endpoint is to measure the efficacy, in terms of cancer control and satisfaction of the patients undergoing the experimental treatment.

#### Material and Methods

From January 2014 to July 2016, 43 consecutive patients have been treated with HDR-BT 19Gy administered in a single fraction. Eligible patients had low or intermediate-risk prostate cancer; IPSS lower than 15; prostate volume

≤60cc; no use of androgen deprivation and no previous prostate surgery.

The patients were monitored prospectively for toxicity (CTCAE v. 3.0) and health-related quality of life (Expanded Prostate Cancer Index Composite [EPIC]). A clinically significant decrement was considered an EPIC score decrease greater than one-half of the SD of the baseline value for each domain. Patient satisfaction was evaluated using a five-category predetermined *Likert* scale question.

#### Results

The median age was 71 years (range 55-78), median initial PSA 7.05 ng/ml (4.2-17.8) and median baseline IPSS was 5 (0-14). Forty-four percent of the patients were low-risk and 56% intermediate-risk. The median prostate volume was 34cc (17-60). Median CTV and OAR doses were: V100: 96.5% (95-99.4), V150 20.5% (13.7-35.1), V200 5.3% (3.1-10.1), Urethral Dmax 106% (103-111) and rectum 2cc 53% (45-48)

After a median follow-up is 16 months (3-31), acute grade-2 genitourinary and gastrointestinal toxicity occurred in 4 patients (9%) and 2 patients (2.3%), respectively. Two patients presented late GU grade-2 toxicity (4.6%). No grade-3 toxicity occurred.

In terms of QoL, there was a statistically significant decline in EPIC urinary urgency domain between month 1 and month 6 ( $p=0.006$ ), and returned to baseline by month 12. Mean EPIC urinary irritative-obstructive, bowel, sexual and hormonal domains did not present significant changes. Of patients potent at baseline evaluation, 60% remained potent at last follow-up.

Patients rated their satisfaction at 6 months as "very-satisfied" (23%) or "extremely-satisfied" (77%).

#### Conclusion

HDR brachytherapy monotherapy administered in a single fraction of 19Gy, demonstrate excellent results in terms of toxicity, tolerance, safety, patient satisfaction and QoL. Longer follow-up is needed to confirm the efficacy of this strategy.

#### OC-0271 The clinical outcome after high dose rate brachytherapy as monotherapy in localized prostate cancer

S. Kariya<sup>1</sup>, K. Kobayashi<sup>1</sup>, I. Yamasaki<sup>2</sup>, S. Ashida<sup>2</sup>, K. Inoue<sup>2</sup>, T. Yamagami<sup>1</sup>

<sup>1</sup>Kochi Medical School, Department of Radiology, Nankoku, Japan

<sup>2</sup>Kochi Medical School, Department of Urology, Nankoku, Japan

#### Purpose or Objective

The aim of this study is to report the clinical outcome after a single implant, high dose rate (HDR) brachytherapy in localized prostate cancer.

#### Material and Methods

Eighty-three patients, 2 with low-risk (T stage < or = 2a, PSA < or = 10 ng/ml, and Gleason score (GS) < or = 6), 28 with intermediate-risk (T stage = 2b or 2c, PSA > 10 and < or = 20 ng/ml, GS = 7), and 53 with high-risk (T stage > or = 3a, PSA > 20 ng/ml, GS > or = 8) prostate cancer who underwent HDR brachytherapy as monotherapy (no external beam radiotherapy) using 27 Gy/2 fractions in one day from July 2011 to October 2014 were analyzed prospectively. Patient age ranged 57 to 81 (median 72) years old. Fifty-nine patients were received neoadjuvant hormonal therapy, and 10 patients were also adjuvant hormonal therapy. Acute and late toxicities were assessed as per Common Terminology Criteria for Adverse Events (CTCAE), Version 4.03. The dosimetric factors affecting the acute or late grade 2 to 3 GU toxicity were analyzed by univariate analysis. PSA failure was defined as the Phoenix definition of nadir + 2 ng/mL. Biochemical relapse-free survival was analyzed using the Kaplan Meir method.

#### Results

The median follow-up period was 52 months (range 21 - 64). The 4-year biochemical relapse-free survival rate was 89.0%. Neither acute nor late grade 2 to 3 rectal toxicities developed. Acute grade 2 genitourinary (GU) toxicity occurred in 12.0% (grade 3 in 0.0%). The predictor of acute grade 2 GU toxicity was urethra D90 (the dose that covers 90% volume of the urethra) > 11.5 Gy ( $p$ -value < 0.01). Late grade 2 to 3 GU toxicity occurred in 20.5% (grade 3 in 3.6%). However, any predictors of late grade 2 to 3 GU toxicity weren't founded.

#### Conclusion

HDR brachytherapy as monotherapy in localized prostate cancer is a highly effective treatment with minimal side effects.

#### OC-0272 Long-term rectal toxicity following I-125 prostate brachytherapy in 1,260 patients

A. Yorozu<sup>1</sup>, S. Sutani<sup>1</sup>, R. Kota<sup>1</sup>, A. Sunaguchi<sup>1</sup>, K. Toya<sup>1</sup>, S. Saito<sup>2</sup>

<sup>1</sup>Tokyo Medical Centre- NHO, Department of Radiation Oncology, Tokyo, Japan

<sup>2</sup>Tokyo Medical Centre- NHO, Department of Urology, Tokyo, Japan

#### Purpose or Objective

To analyze factors associated with long-term rectal toxicity in permanent prostate brachytherapy patients.

#### Material and Methods

This retrospective cohort study examined 1,260 patients treated with I-125 brachytherapy without external beam radiotherapy between 2003 and 2013. Neoadjuvant androgen deprivation (NAD) was given to 39% of patients. The patient, treatment, and dosimetry factors were examined for an association with rectal toxicity. Toxicity was graded according to the National Cancer Institute's Common Terminology Criteria for Adverse Events ver 4.0. Rectal dosimetry was calculated through dose-volume histogram of the rectum using day-1 and day-30 CT-based dosimetry, and expressed as volume of rectum in cc receiving 100% and 150% of the prescription dose (RV100 and RV150, respectively), and as dose to 5% and 30% of rectum (RD5 and RD30 respectively). The Kaplan-Meier method and Cox regression model were used for analysis.

#### Results

The median follow-up was 6.6 years. Median RV100 was 0.15 cc at day 1, and 0.56 cc at day 30. Any grade of proctitis, rectal bleeding, fecal incontinence, diarrhea, and anal pain was observed in 22.9%, 22.8%, 15.2%, 10.6%, and 9.9% of patients, respectively. Toxicities were categorized as grade 1 in 28.8% of patients and grade 2 in 1.7%. No Grade 3 toxicity was observed. Actuarial risk of grade 2 rectal toxicity was 2.0%. The majority cases (82%) of grade 2 toxicities were diagnosed by the third year. Upon univariate analysis, the likelihood of G2 toxicity was significantly associated with RV150, RV100, RD30, RD5 at day 1, and NAD. Only RV100 at day 1 and NAD fit a Cox regression model. Actuarial risk of grade 2 was 1.4%, 3.1%, 4.8%, and 6.7% for patients with RV100 ≤0.2cc, 0.2-0.5cc, 0.5-1cc, >1cc at day 1, respectively ( $P=0.029$ ). Actuarial risk of grade 2 was 1.1% for patients with NAD, and 2.2% for patients without NAD ( $p=0.032$ ).

#### Conclusion

I-125 prostate brachytherapy is well tolerated. Rectal dosimetry at day 1 is relevant to long-term rectal toxicity. RV100 and NAD are associated with rectal toxicity.

#### OC-0273 Prostate brachytherapy in African-Caribbean patients: A retrospective analysis of 370 cases

V. Atallah<sup>1</sup>, N. Leduc<sup>2</sup>, M. Creoff<sup>2</sup>, P. Escarmant<sup>2</sup>, V. Vinh-Hung<sup>2</sup>

<sup>1</sup>university hospital, radiotherapy, Pointe-a-pitre, Guadeloupe

<sup>2</sup>University hospital Martinique, Radiotherapy, Fort-de-france, Martinique

### Purpose or Objective

Prostate cancer is the most frequent malignancy in African-Caribbean men, a population sharing common genetic traits with African-American (AA) but presenting also genomic and epidemiologic specificities. Despite socio-economic disparities with French mainland, all patients were treated within the French state-financed equal-access healthcare system. In this study, we report biochemical outcomes of patients treated by brachytherapy in our department from 2005 to 2014 in an African-Caribbean population

### Material and Methods

370 consecutive patients receiving I125 brachytherapy as a curative treatment for early-stage (localized) disease between 2005 and 2014 were recorded. Selected patients presented with low risk disease: initial PSA (iPSA) < 10 ng/mL, clinical stage ≤ T2a, Gleason < 7. Patients with intermediate risk of recurrence were also included on a case to case basis with PSA < 15 or Gleason 7 (3+4). Biochemical failure free-survival (BFFS) was defined according to the ASTRO nadir+2 definition.

### Results

The 3-year and 5-year BFFS for the entire cohort were 98.3% and 91.6% respectively. For patients with low and intermediate-risk disease, the 5-year BFFS rates were 92.1 and 90.8%, respectively. In univariate and multivariate analysis, only Gleason score (< 7 vs 7;  $P = 0.030 < 0.05$ ) was a significant predictor of biochemical failure. The overall rate of late and acute grade 2 or higher Genito-urinary toxicity was 12.6% and 10.3%.

### Conclusion

In this large single-center series, brachytherapy achieved excellent rates of medium-term biochemical control in both low- and selected intermediate-risk localized prostate cancer in African-caribbean patients. Brachytherapy seems to be an excellent choice of treatment, with excellent outcomes and limited morbidity for African-Caribbean populations. To our knowledge, our series is the first presenting brachytherapy results in this specific population.

### OC-0274 Comparison of MRI/CT fusion and CT for prostate post-implant dosimetry using sector analysis

N. Katayama<sup>1</sup>, M. Takemoto<sup>2</sup>, A. Takamoto<sup>3</sup>, S. Sugiyama<sup>1</sup>, K. Hisazumi<sup>1</sup>, K. Watanabe<sup>1</sup>, H. Ihara<sup>1</sup>, K. Katsui<sup>1</sup>, Y. Nasu<sup>3</sup>, S. Kanazawa<sup>3</sup>

<sup>1</sup>Okayama University Graduate School of Health Sciences, Department of Radiology, Okayama, Japan

<sup>2</sup>Himeji Red Cross Hospital, Department of Radiotherapy, Himeji, Japan

<sup>3</sup>Okayama University Graduate School of Health Sciences, Department of Urology, Okayama, Japan

### Purpose or Objective

Anatomical structures are well defined, so MRI/CT fusion is considered the best method for postimplant dosimetry of permanent prostate brachytherapy. We compared the results obtained from MRI/CT fusion-based dosimetry with those of CT-based dosimetry using sector analysis, and analyzed the factors associated with the difference of the whole prostate dose between the two dosimetry. This is the first report which evaluated those factors using 3-Tesla MRI in which contouring and fusion are thought to be more accurate than in 1.5-Tesla MRI.

### Material and Methods

The subjects were 81 consecutive patients treated with 144 Gy of brachytherapy alone using loose I-125 radioactive seeds. For postimplant analysis, CT and MRI scans were obtained at 1 month after implantation. CT and 3-Tesla T2-weighted MR images were fused and aligned on the basis of seed distribution in MRI/CT fusion-based dosimetry. Dosimetry was computed for the whole prostate and for the prostate divided into anterior and posterior sectors of the base, mid-gland, and apex (Fig. 1). The volumetric and dosimetric results were compared

between MRI/CT fusion-based and CT-based dosimetry using a paired t test. Factors associated with the absolute value of the difference of D90 between the two dosimetry ( $|D90_{MRI/CT} - D90_{CT}|$ ) were analyzed by multiple regression. P values of < 0.05 were defined to be significant.

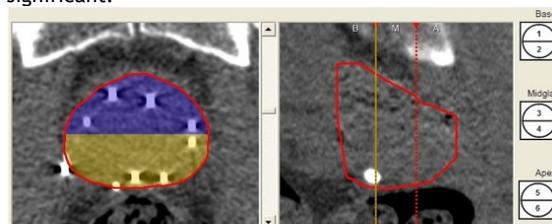

Fig. 1. The sector analysis tool was used to divide the prostate into six sectors: anterior and posterior sectors at the base, mid-gland, and apex.

### Results

D90 (176.7 Gy vs 173.0 Gy;  $p = 0.003$ ) and V100 (97.2% vs 96.5%;  $p = 0.013$ ) were significantly higher in MRI/CT fusion-based dosimetry than in CT-based dosimetry. Prostate volume (28.5 mL vs 30.8 mL;  $p < 0.001$ ) was significantly lower in MRI/CT fusion-based dosimetry than CT-based dosimetry. Sector analysis showed a decrease in MRI/CT fusion D90 at the anterior base (154.9 Gy vs 166.5 Gy;  $p < 0.001$ ) and the posterior apex (169.7 Gy vs 177.6 Gy;  $p < 0.001$ ), and increase in MRI/CT fusion D90 in the anterior mid-gland (195.2 Gy vs 181.7 Gy;  $p < 0.001$ ), the posterior mid-gland (196.1 Gy vs 193.9 Gy;  $p = 0.030$ ), and the anterior apex (198.7 Gy vs 175.0 Gy;  $p < 0.001$ ).  $|D90_{MRI/CT} - D90_{CT}|$  was largest at the anterior apex sector among 6 sectors (27.2 Gy). On multivariate analysis,  $|D90_{MRI/CT} - D90_{CT}|$  of whole prostate are associated with |prostate volume (PV)/MRI/CT - PV/CT| ( $p = 0.036$ ),  $|D90_{MRI/CT} - D90_{CT}|$  at the posterior base sector ( $p = 0.035$ ),  $|D90_{MRI/CT} - D90_{CT}|$  at the anterior mid-gland sector ( $p = 0.011$ ), and  $|D90_{MRI/CT} - D90_{CT}|$  at the anterior apex sector ( $p = 0.004$ ) (Table 1).

Table 1. Univariate and multivariate analysis of factors associated with  $|D90_{MRI/CT} - D90_{CT}|$  of whole prostate

	Univariate coefficient	p Value	Multivariate coefficient	p Value
$ PV_{MRI/CT} - PV_{CT} $ Whole prostate	0.396	< 0.001	0.213	0.036
Anterior base	0.086	0.446	—	—
Posterior base	0.102	0.364	—	—
Anterior mid-gland	0.336	0.002*	—	—
Posterior mid-gland	0.372	< 0.001*	0.149	0.135
Anterior apex	0.116	0.301	—	—
Posterior apex	0.086	0.445	—	—
$ D90_{MRI/CT} - D90_{CT} $ Anterior base	0.147	0.190	—	—
Posterior base	0.328	0.003	0.195	0.035
Anterior mid-gland	0.500	< 0.001	0.262	0.011
Posterior mid-gland	0.109	0.333	—	—
Anterior apex	0.409	< 0.001	0.291	0.004
Posterior apex	-0.051	0.654	—	—

Abbreviations:  $|PV_{MRI/CT} - PV_{CT}|$  = the absolute value of the difference between the prostate volume in MRI/CT fusion and the volume in CT,  $|D90_{MRI/CT} - D90_{CT}|$  = the absolute value of the difference of D90 between in MRI/CT fusion-based dosimetry and in CT-based dosimetry

\*  $|PV_{MRI/CT} - PV_{CT}|$  at anterior mid-gland sector is the collinearity factor of  $|PV_{MRI/CT} - PV_{CT}|$  at posterior mid-gland sector; therefore,  $|PV_{MRI/CT} - PV_{CT}|$  at anterior mid-gland sector is excluded in the multivariate analysis.

### Conclusion

Several postimplant dosimetric variables were significantly different on MRI/CT fusion vs CT. The differences between the two methods of PV, D90 at the posterior base, anterior mid-gland, and anterior apex sectors may greatly influence the difference of D90 of the whole prostate.

### Proffered Papers: Physics treatment verification

### OC-0275 Testing an MR-compatible afterloader for MR-based source tracking in MRI guided HDR brachytherapy

E. Beld<sup>1</sup>, P.R. Seevinck<sup>2</sup>, J. Schuurman<sup>3</sup>, F. Zijlstra<sup>2</sup>, M.A. Viergever<sup>2</sup>, J.J.W. Lagendijk<sup>1</sup>, M.A. Moerland<sup>1</sup>

<sup>1</sup>UMC Utrecht, Department of Radiotherapy, Utrecht, The Netherlands

<sup>2</sup>UMC Utrecht, Image Sciences Institute, Utrecht, The Netherlands

<sup>3</sup>Elekta NL, Veenendaal, The Netherlands

### Purpose or Objective

In HDR brachytherapy, image guidance is crucial for accurate and safe dose delivery. Accordingly, MR-guided HDR brachytherapy is in development at our institution. This study demonstrates the testing of a recently developed MR-compatible afterloader, while operating simultaneously with MR imaging, as well as an MR-based method for real-time source position verification.

#### Material and Methods

##### Experimental set-up:

A prototype of an MR-compatible afterloader (Flexitron, Elekta) was developed. This afterloader was made MR-compatible by providing every part as well as the cover with RF shielding. The source cable was replaced by a plastic cable containing a piece of steel at its tip, serving as a dummy source. The afterloader was placed next to the MRI scanner and connected to a catheter positioned in an Agar phantom (doped with  $MnCl_2$ ), see Fig. 1.

##### Afterloader management:

The afterloader was programmed to send the source (I) to 10 dwell positions, with a 10 mm step size, remaining 10 s at each position, and (II) to 20 dwell positions, with a 5 mm step size, remaining 0.5 s at each position.

##### MRI acquisition:

While sending the source to its predefined dwell positions, MR imaging was carried out on a 1.5 T MR scanner (Ingenia, Philips) using a 2D gradient echo sequence (TR/TE 2.2/1.0 ms, slice thickness 10 mm, FOV 192x192 mm, acq. matrix 96x96, flip angle 30°, SENSE=2), scanning two orthogonal slices interleaved with a temporal resolution of 0.114 s per image.

##### HDR source localization:

The MR artifact induced by the magnetic susceptibility of the metallic source was exploited. The artifacts (complex data) were simulated based on the susceptibility induced  $B_0$  field disturbance [1]. The localization was executed offline in a post processing operation by phase-only cross correlation [1,2], to find the translation between the experimental image and the simulated artifact.

#### Results

The experiments demonstrated that the prototype MR-compatible afterloader and the MRI scanner fully functioned while operating simultaneously, without influencing each other. The afterloader was able to send the source to the predefined dwell positions when placed next to the MRI scanner, without being attracted to or being disturbed by the scanner. The HDR source positions could be determined by the described localization method (now accomplished offline), see Fig. 2. The average distances between the determined 3D source positions for cases (I) and (II) were  $9.9 \pm 0.2$  mm and  $5.0 \pm 0.2$  mm, respectively. The short dynamic scan time ( $\sim 0.15$  s) and the fast reconstruction/post processing ( $< 0.15$  s) guarantee that source localization will be possible in real time.

#### Conclusion

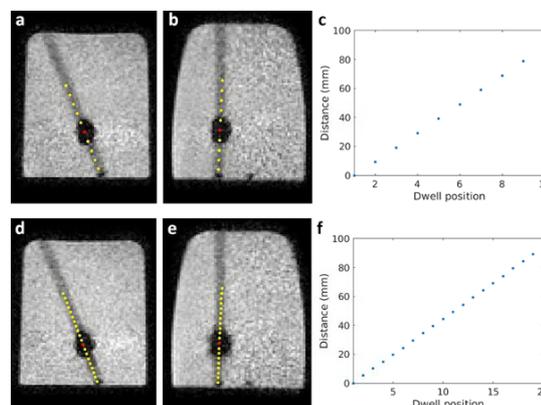

The MR-compatible afterloader developed in this study and a commercial 1.5 T MRI scanner were demonstrated to fully function while operating simultaneously, enabling real-time HDR source position verification for MR-guided HDR brachytherapy, using a phase-only cross correlation localization method.

[2] De Oliveira A. et al. 2008 MRM 59 1043-1050.

**Figure 1.** Experimental set-up with the prototype MR compatible afterloader placed next to the MRI scanner, a phantom placed inside the MR bore and the afterloader connected to a tube positioned in the phantom.

**Figure 2.** Sagittal slices (a and d) and coronal slices (b and e) presenting the MR artifacts induced by the HDR source for the case where the afterloader sent the source (I) to 10 dwell positions with a 10 mm step size (a-c) and (II) to 20 dwell positions with a 5 mm step size (d-f). The determined HDR source dwell positions for the depicted positions (position 5 in a-b and position 9 in d-e) are overlaid in red and the other determined dwell positions are overlaid in yellow. Besides, figures (a-b and d-f) show the saturation artifact due to the cross-sectional interleaved acquisition of two slices. Figures c and f present the distances of the HDR source positions determined with respect to the first position, calculated from the 3D coordinates (with average determined step sizes of  $9.9 \pm 0.2$  mm and  $5.0 \pm 0.2$  mm respectively).

#### OC-0276 Toward adaptive MR-guided HDR prostate brachytherapy - Simulation study based on anatomy movements

M. Borot de Battisti<sup>1</sup>, B. Denis de Senneville<sup>2</sup>, G. Hautvast<sup>3</sup>, D. Binnekamp<sup>3</sup>, M. Peters<sup>1</sup>, J. Van der Voort van Zyp<sup>1</sup>, J.J.W. Lagendijk<sup>1</sup>, M. Maenhout<sup>1</sup>, M.A. Moerland<sup>1</sup>

<sup>1</sup>University Medical Center Utrecht, Departement of Radiotherapy, Utrecht, The Netherlands

<sup>2</sup>UMR 5251 CNRS/University of Bordeaux, Mathematics, Talence, France

<sup>3</sup>Philips Group Innovation, Biomedical Systems, Eindhoven, The Netherlands

#### Purpose or Objective

Dose delivery during a single needle, robotic MR-guided HDR prostate brachytherapy may be impaired by: (1) needle insertion errors caused by e.g. needle bending, (2) unpredictable anatomy movements such as prostate rotations (induced by the insertion or retraction of the needle), prostate swelling or intra-procedural rectum or bladder filling. In this study, a new adaptive dose planning strategy is proposed to assess the second challenge. The

performance of this approach is evaluated by simulating brachytherapy procedures using data of 10 patients diagnosed with prostate cancer.

#### Material and Methods

Throughout HDR prostate brachytherapy, unpredictable anatomy movements may cause errors in dose delivery and potentially, this may result in failure to reach clinical constraints (e.g. for single fraction monotherapy: D95% PTV > 19 Gy, D10% urethra < 21 Gy, D1cc bladder < 12 Gy and D1cc rectum < 12 Gy). In this study, a novel adaptive dose planning pipeline for MR-guided HDR prostate brachytherapy using a single needle robotic implant device is proposed to address this issue (Figure 1a). The dose plan (needle track positions, source positions and dwell times) and needle insertion sequence are updated after each needle insertion and retraction with MR-based feedback on anatomy movements (cf. Figure 1b). The pipeline was assessed on moving anatomy by simulating MR-guided HDR prostate brachytherapy with varying number of needle insertions (from 2 to 14) for 10 patients. The initial anatomy of the patients was obtained using the delineations of the prostate tumor and the OAR considered (urethra, bladder and rectum) on MR images. Each needle insertion and retraction induced anatomy movements which were simulated in 2 steps: (1) a typical 3D rotation of the prostate was imposed (2) a regularization of the movement in space was then applied. The initial and final dose parameters were compared in the situations with and without update of dose plan and needle insertion sequence.

#### Results

The computation time for re-planning was less than 90 seconds with a desktop PC. The actual delivered dose improved with vs. without update of dose plan and needle insertion sequence: On average, the dose coverage of the PTV was higher in the situation with vs. without update (Figure 1c). Moreover, the difference increased with the number of needle insertions. The dose received by the PTV in the situation with re-planning was not significantly different compared to the initial dose plan. Finally, the dose to the OAR's was not significantly different between the initial dose plan and the dose delivered in the situation with and without update.

#### Conclusion

This study proposes a new adaptive workflow with feedback on the anatomy movements for MR-guided HDR prostate brachytherapy with a single needle robotic implant device. The assessment of the pipeline showed that the errors in the dose delivered due to movement of anatomy can be compensated by updating the dose plan and the needle insertion sequence based on MRI.

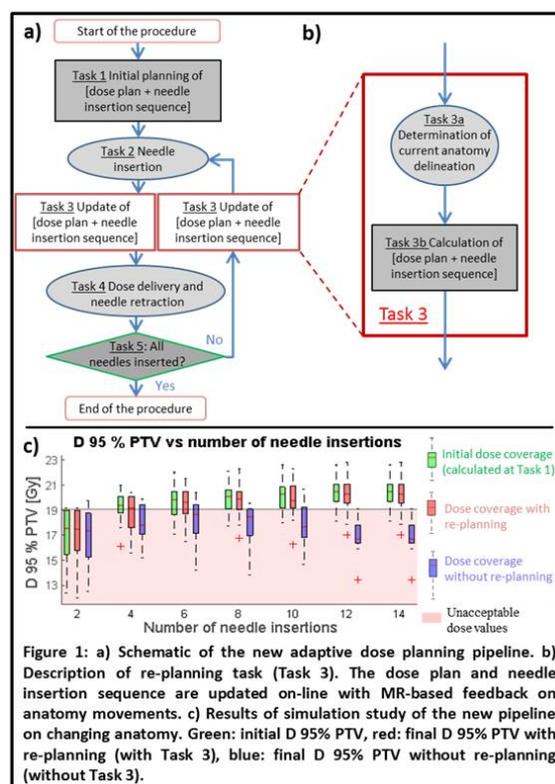

Figure 1: a) Schematic of the new adaptive dose planning pipeline. b) Description of re-planning task (Task 3). The dose plan and needle insertion sequence are updated on-line with MR-based feedback on anatomy movements. c) Results of simulation study of the new pipeline on changing anatomy. Green: initial D 95% PTV, red: final D 95% PTV with re-planning (with Task 3), blue: final D 95% PTV without re-planning (without Task 3).

OC-0277 Assessment of the implant geometry in interstitial brachytherapy by a hybrid tracking system  
N. Pallast<sup>1</sup>, M. Kellermeier<sup>1</sup>, K. Kallis<sup>1</sup>, B. Steinmetz<sup>1</sup>, V. Strnad<sup>1</sup>, C. Bert<sup>1</sup>  
<sup>1</sup>Universitätsklinikum Erlangen- Friedrich-Alexander-Universität Erlangen-Nürnberg, Department of Radiation Oncology, Erlangen, Germany

#### Purpose or Objective

Electromagnetic tracking (EMT) is a promising approach to measure variations of the implant geometry in interstitial brachytherapy. The coordinate system for EMT data measurements is usually decoupled from the one of computed tomography (CT) used for treatment planning. Therefore, an optical tracking system (OTS) is introduced to associate EMT and CT coordinate systems. The accuracy of this hybrid tracking system was investigated in phantom studies and the system is currently used in a clinical feasibility study.

#### Material and Methods

EMT data providing the implant geometry were measured by an implant sensor integrated in the cable of an afterloader prototype (Flexitron, Elekta, The Netherlands). Breathing motion was compensated by three additional fiducial sensors on the chest. Simultaneously, an OTS (Polaris, NDI, Canada) collected data of eight infrared (IR) markers of which three were attached to the EMT fiducial sensors and five to the skin. A reproducible marker position was ensured by adhesive pads glued on the patient prior the first measurement. To align both coordinate tracking systems, a transformation between the OTS and EMT ( ${}^{OTS}T_{EMT}$ ) was estimated by a so-called hand eye calibration. An additional registration from the OTS to the CT ( ${}^{CT}T_{OTS}$ ) was determined to associate their coordinate systems. Finally, both transformations were combined to get a direct relation of EMT- and CT-derived data. The resulting calibration error of the  ${}^{OTS}T_{EMT}$  transformation was evaluated by measuring different poses of an in-house developed calibration tool. This tool

was also used to assess the registration error of  $^{CT}T_{OTS}$ . To prove the overall accuracy of this approach, another in-house developed phantom was used, equipped with eleven catheters and eight IR-markers. The feasibility of a daily patient data acquisition was examined in an institutional review board-approved study by using the afterloader prototype and the OTS in addition to regular iBT treatments.

### Results

Based on different poses of the calibration tool, the root mean square errors for  $^{OTS}T_{EMT}$  and  $^{CT}T_{OTS}$  were 0.56 mm and 0.49 mm, respectively. The overall accuracy of  $^{CT}T_{EMT}$  resulted in 0.74 mm. The determined transformations were applied to the phantom measurements and showed a mean deviation to the CT data of 0.92 mm. Currently, 65 catheters from four patients were tracked by the EMT system in combination with the OTS. The deviations of the implant geometry, determined by this hybrid tracking approach, are comparable to the previous results, obtained using only the EMT procedure.

### Conclusion

The novel hybrid tracking system allows direct mapping of EMT and CT data. So far, the system was successfully used to measure the implant of four patients. The clinical study is ongoing.

### OC-0278 Red-emitting inorganic scintillation detectors to verify HDR brachytherapy treatments in real time

G. Kertzscher<sup>1</sup>, S. Beddar<sup>1</sup>

<sup>1</sup>The University of Texas MD Anderson Cancer Center, Department of Radiation Physics, Houston, USA

### Purpose or Objective

Treatment verification during brachytherapy (BT) is presently limited because only few detectors can measure accurate and precise dose rates in the steep gradients that are characteristic for HDR BT. Red-emitting inorganic scintillation detectors (ISDs) are promising for BT because they can generate large signal intensities. Furthermore, they facilitate efficient background suppression because of the small overlap with the Cerenkov and fluorescence light contamination induced in the fiber-optic cable (the stem signal) primarily emitted in blue/green regions. The purpose of this study was to assess the suitability of red-emitting ISDs for real-time verification during BT.

### Material and Methods

We investigated ISDs based on the 5 inorganic scintillators ruby,  $Y_2O_3:Eu$ ,  $YVO_4:Eu$ ,  $Y_2O_2S:Eu$  and  $Gd_2O_2S:Eu$ , of which the first was rigid and the others in powder form. The ISDs were compared with plastic scintillation detectors (PSDs) based on the organic scintillator BCF-12. Each detector consisted of a 1 mm-diameter scintillator that was coupled to a 1 mm-diameter and 15 m-long fiber-optic cable. Optical filters were placed between the ISD volume and the fiber-optic cable to prevent the stem signal from striking the scintillator and inducing photoluminescence. The fiber-optic cable was coupled to a charge-coupled device camera or a spectrometer to measure signal intensities and emission spectra, respectively. The detectors were exposed to an  $^{192}Ir$  HDR BT source in experiments dedicated to determine their scintillation intensities, the influence of the stem signal and photoluminescence, and time-dependent luminescence properties.

### Results

Figure 1 shows the emission spectra of all detectors (left) and that the scintillation intensities were up to 19, 44, 16, 54 and 130 times larger than that of the PSD (right). Figure 2 shows time dependent luminescence properties of the ISDs. The  $Y_2O_2S:Eu$  and  $Gd_2O_2S:Eu$  ISDs are not recommended because their accuracy was compromised by their time dependence. The scintillation of the ruby,  $Y_2O_3:Eu$  and  $YVO_4:Eu$  ISDs changed by +1.6%, -2.8% and +1.1%, respectively, during 20 Gy, which is the dose that the ISD inserted in urethra could absorb during a typical

HDR prostate plan. The fluctuation could be reduced to <0.5% by mixing the  $Y_2O_3:Eu$  and  $YVO_4:Eu$  phosphors in a ratio 1-to-10. The stem signal of the ruby,  $Y_2O_3:Eu$  and  $YVO_4:Eu$  ISDs was up to 3%, 1% and 2%, respectively, of the total signal, and the photoluminescence was <1%, when the BT source moved 8 cm away from the detector and 1 cm from the fiber-optic cable. In contrast, the stem signal of the PSD was up to 70%.

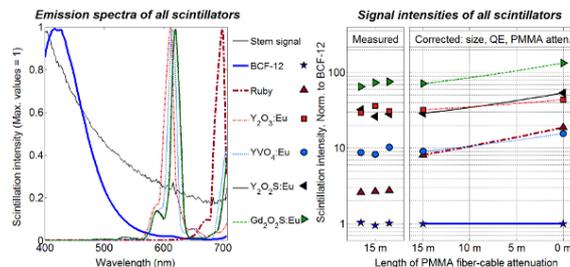

Figure 1: Emission spectra of the organic and inorganic scintillators and the stem signal (left-hand panel), and the scintillation intensities normalized to the BCF-12 based PSD (right-hand panel). The measurements were corrected for the quantum efficiency of the photodetectors and the attenuation in the fiber-optic cable made of poly(methyl methacrylate).

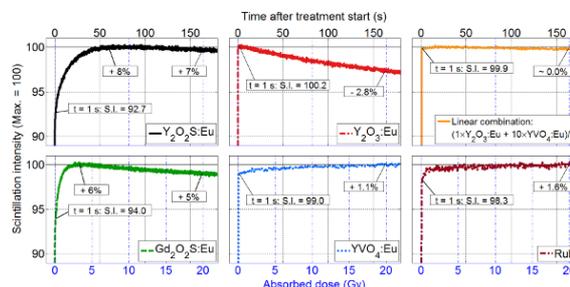

Figure 2: The scintillation intensity (S.I.) of the inorganic scintillators during constant irradiation. The non-constant scintillation was determined as the percent-difference of the signal intensities at different time instances with respect to the baseline intensity 1 s after the start of the constant irradiation.

### Conclusion

Red-emitting ISDs based on ruby,  $Y_2O_3:Eu$  and  $YVO_4:Eu$  are suitable for HDR BT treatment verification in real time. Their large signal intensities and emission properties facilitate accurate detector systems that are straightforward to manufacture and use which can result in widespread dissemination and improved patient safety during BT.

### OC-0279 Removing the blindfold - a new take on real-time brachytherapy dosimetry

J. Johansen<sup>1</sup>, S. Rylander<sup>1</sup>, S. Buus<sup>1</sup>, L. Bentzen<sup>1</sup>, S.B. Hokland<sup>1</sup>, C.S. Søndergaard<sup>1</sup>, A.K.M. With<sup>2</sup>, G. Kertzscher<sup>3</sup>, C.E. Andersen<sup>4</sup>, K. Tanderup<sup>1</sup>

<sup>1</sup>Aarhus University Hospital, Department of oncology, Aarhus C, Denmark

<sup>2</sup>Örebro University Hospital, Department of Medical Physics, Örebro, Sweden

<sup>3</sup>The University of Texas MD Anderson Cancer Center, Department of Radiation Physics, Houston- TX, USA

<sup>4</sup>Technical University of Denmark, Center for Nuclear Technologies, Roskilde, Denmark

### Purpose or Objective

Although in-vivo dosimetry has been available for decades it is still not a standardized verification tool in brachytherapy (BT). Major limitations are that in-vivo dosimeters only provide point dose information and that the steep dose gradient leads to strong positional dependency. The aim of this study is to examine whether it is possible to utilise in-vivo dosimetry for evaluation of the implant geometry during irradiation in addition to post hoc dose verification.

### Material and Methods

This study includes in-vivo dosimetry measurements from 22 HDR BT procedures for prostate cancer. Needles were placed in the prostate guided by TRUS with a subsequent

T2W MRI with 2mm slice thickness for treatment planning. Dose rates were measured using a fiber-coupled Al<sub>2</sub>O<sub>3</sub>:C luminescent crystal placed in a dedicated needle in the prostate.

The dose measurements were analysed retrospectively. The total accumulated dose was compared to the predicted dose. Secondly, the measured dose rate originating from each dwell position in a needle was compared to the predicted dose rate obtained from the dose planning system. The discrepancies between measured and predicted dose rates were assumed to be caused by geometrical offsets of the needles relative to the dosimeter from the treatment plan. An algorithm shifted each treatment needle virtually in radial and longitudinal directions relative to the dosimeter until optimal agreement between the predicted and measured dose rates was achieved.

### Results

Table 1 shows the relative difference between the measured and predicted accumulated dose and the average radial and longitudinal shifts of 337 needles in 22 treatments. The average shifts are expected to correspond to systematic uncertainties in dosimeter positions, and the standard deviations reflect the shift of needles relative to the dosimeter. Two treatments were not further analysed because of dosimeter drift by >15mm.

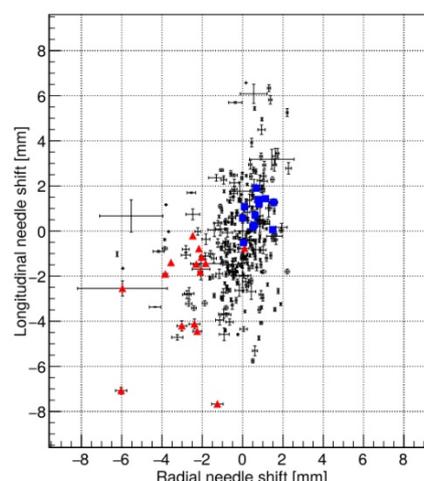

Patient number	Number of needles	Dose difference (%)	Average longitudinal shift (mm)	Average radial shift (mm)
1	16	8.3	-2.1±1.4	-0.2±0.7
2	15	13	-2.7±2.2	-2.7±1.6
2	16	-0.78	-1.8±1.8	-0.6±0.5
3	18	0.19	-1.0±2.1	1.1±1.8
3	17	94	-71±2.4	-3.2±8.6
4	16	-8.4	-0.6±1.2	-0.6±0.4
4	13	3.2	-2.1±0.8	-0.3±0.5
5	15	-6.1	-0.3±1.0	-0.7±0.5
5	16	6.3	-0.8±1.1	0.5±0.6
6	15	-1.4	-1.1±1.5	-0.2±0.4
7	12	6.3	0.8±0.7	0.7±0.5
7	12	-15	0.2±1.5	-0.4±0.6
8	13	6.0	0.2±1.3	0.4±0.2
8	14	1.3	0.5±1.1	0.6±0.4
9	15	7.9	-1.2±1.2	1.3±0.6
9	15	11	-1.4±2.1	0.5±0.4
10	13	11	2.0±2.1	0.0±0.7
10	13	-15	0.5±1.9	-1.4±1.5
11	19	3.6	0.9±2.3	0.6±0.9
11	19	5.5	3.1±2.2	1.2±0.6
12	16	-9.5	-0.8±1.4	-2.7±1.6
12	19	-16.3	-14±3.8	-1.2±1.9
Total	301	1.4±8.3	-0.4±2.2	-0.3±1.4

Table showing the results from each of the 22 treatments. Patient 3, treatment 2 and patient 12 treatment 2 are marked grey because of their large longitudinal shifts, indicating a drift of the dosimeter. These treatments have been omitted in the total, due to large longitudinal shifts.

The red and blue highlights indicate the treatments highlighted in Fig. 1

The longitudinal and radial shifts of each needle are plotted in Fig. 1. The relative needle-dosimeter geometry was determined with sub-millimetre precision for 98% of the treatment needles (error bars in Fig. 1). More than 90% of the needles were shifted less than 4mm longitudinally and 2mm radially, which is consistent with typical uncertainties in needle and dosimeter reconstructions and

needle movements between MR-scan and treatment.  
Needle shifts

The overall shift of each of the 301 needles in 20 of the treatments. Two treatments were left out, due to too large uncertainty in the dosimeter position.

Red triangles: Patient 2 treatment 1

Blue squares: Patient 7 treatment 1

There was no relation between deviations in measured dose and shifts of needles. E.g. patient 6 and patient 7 have similar shifts but very different accumulated dose deviations. This illustrates how a small shift in a nearby needle can lead to significant changes in the measured dose, making it hard to use the accumulated dose for treatment verification.

### Conclusion

Accumulated dose and dose rate have been measured in real-time for 22 treatments. We have used real-time in-vivo dosimetry to determine the relative geometry between needles and dosimeter with high precision. This could potentially lead to real-time treatment verification in BT.

**OC-0280 Benefit of repeat CT in high-dose rate brachytherapy as radical treatment for rectal cancer**  
R.P.J. Van den Ende<sup>1</sup>, E.C. Rijkmans<sup>1</sup>, E.M. Kerkhof<sup>1</sup>, R.A. Nout<sup>1</sup>, M. Ketelaars<sup>1</sup>, M.S. Laman<sup>1</sup>, C.A.M. Marijnen<sup>1</sup>, U.A. Van der Heide<sup>1</sup>

<sup>1</sup>Leiden University Medical Center, Department of Radiation Oncology, Leiden, The Netherlands

### Purpose or Objective

High-dose rate endorectal brachytherapy (HDR-BT) for rectal cancer can be used to increase the dose to the tumor while sparing surrounding organs due to a smaller treated volume and the steep dose gradient. Conventionally, one treatment plan is derived from a planning CT with applicator in situ prior to the start of treatment, which is then used for all further applications (non-adaptive approach). An adaptive approach would be to acquire a repeat CT scan at each application for treatment planning. The purpose of this study was to evaluate the difference in dose conformity and clinical target volume (CTV) coverage between the non-adaptive and the adaptive approach.

### Material and Methods

Eleven patients included in a dose-escalation study were included in this study. Patients received a radical treatment consisting of 13x3 Gy external beam radiotherapy (EBRT) followed by three weekly applications HDR-BT of 5-8 Gy. A planning CT with applicator in situ was acquired at application one and repeat CT scans with applicator in situ were acquired at application two and three. The CTV was defined as residual macroscopic tumor or scarring after EBRT. The CTV, rectal wall without CTV, mesorectum and anus were delineated by an expert

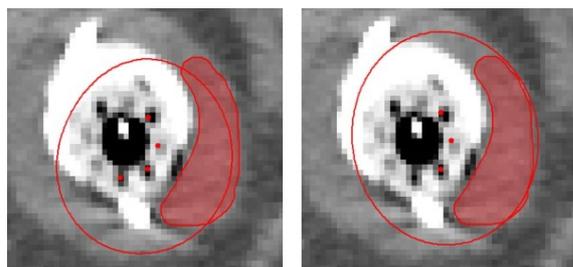

radiation oncologist and a resident radiation oncologist on all repeat CT scans and consensus was reached. The treatment plan of application one was projected on the repeat CT scans to simulate the other applications. Projected treatment plans were categorized as clinically acceptable or unacceptable. Additionally, new treatment plans were derived from the repeat CT scans by an experienced treatment planner. A conformity index, taking into account CTV coverage and dose to organs at risk, was used to quantify conformity of both the projected and the repeated treatment plans. Dose distributions were scaled to a prescription dose of 7 Gy. Using the Wilcoxon signed rank test, the conformity index and cumulative CTV D98 of the projected and repeated treatment plans were compared.

### Results

Fourteen out of 22 projections were clinically unacceptable. In 8 of those 14 projections, replanning was of added value. In the remaining 6 unacceptable cases, replanning was of limited value as first an intervention would have been necessary to remove air and/or faeces. The figure shows a repeat CT with an unacceptable projection and corresponding replanning. The table summarizes the conformity index and cumulative CTV D98 of the non-adaptive and the adaptive approach. Parameters are presented both for all cases and for all cases excluding those that needed an intervention. Repeat CT-based adaptive HDR-BT resulted in a significantly higher conformity.

### Conclusion

Repeat CT-based adaptive HDR-BT resulted in a more conformal treatment and should be standard practice in radical treatment with HDR-BT in rectal cancer patients.

Two images of the same repeat CT scan with the tumor delineated in red. The red line represents the prescribed isodose of an unacceptable projection (left) and the corresponding replanning (right).

Conformity index and cumulative CTV D98 of the adaptive and non-adaptive approach. Prescribed cumulative CTV D98 was 21 Gy. Data is presented as mean  $\pm$  SD.

	Projections (non-adaptive)	Replanning (adaptive)	p-value	Projections (excluding cases requiring intervention)	Replanning (excluding cases requiring intervention)	p-value
Conformity index	0.72 $\pm$ 0.16	0.79 $\pm$ 0.18	p = 0.002	0.76 $\pm$ 0.13	0.86 $\pm$ 0.07	p < 0.001
Cumulative CTV D98	17.21 $\pm$ 3.77	18.09 $\pm$ 3.27	p = 0.182	18.65 $\pm$ 3.62	19.49 $\pm$ 2.45	p = 0.237

on MRI are potentially smaller than CT-based volumes, which could lead to lower dose to organs at risk (OARs) and, in turn, reduction of RT-induced toxicity. The purpose of this study is to ascertain potential reduction in target volume and OAR dose.

### Material and Methods

23 breast cancer (cTis-3N0M0) patients from the MILANO trial (NL50046.041.14) were scanned in supine position on 1.5 T, arms abducted, after SN biopsy and breast-conserving surgery. MRI included a 3-dimensional (3D) T1-weighted (T1w) spoiled gradient echo (T1-SPGR) anatomical scan and two T2w fast spin echo (FSE) techniques for LN detection, which were co-registered. Axillary levels were delineated, using ESTRO guidelines [Offersen *et al.* 2015, *IJROBP*], as well as OARs, including the lungs, heart, chest wall (CW), brachial plexus (BP), and humeral head (HH). LNs were identified by 4 observers, and delineated. Encompassing LN volumes - and after 5 mm isotropic expansion of the LNs - were related to axillary levels. In 5 patients (17-26 LNs), elective RT of 16 x 2.66 Gy = 42.56 Gy, delivered by 13 intensity-modulated RT beams, was simulated on MRI for two situations: (i) axillary levels I-IV, and (ii) all individual LN-based targets (1 mm PTV margin). For this, pseudo-CT scans were generated by bulk assignment of Hounsfield units on MRI for water, lungs and air. OAR dose parameters in both (i) and (ii) were compared.

### Results

A median of 26 axillary LNs were delineated per patient. Compared to the respective axillary levels, LN-based target volumes, even after 5 mm isotropic expansion, are considerably smaller [table 1]. Coverage of all targets was excellent ( $V_{95\%} > 99\%$ ,  $V_{107\%} = 0$ ; all PTVs) in (i) and (ii). For elective RT on LN-based PTVs [figure 1], dose to all OARs was substantially reduced compared to standard elective RT: the average reduction of mean dose to lungs, heart, and HH was 2.3 Gy, 2.2 Gy, and 13.3 Gy, respectively; reduction of maximum dose to the BP and CW was 25.5 Gy and 9.4 Gy.

## Poster Viewing : Session 6: Imaging

### PV-0281 Lymph node MRI in regional breast radiotherapy leads to smaller target volumes and lower OAR dose

T. Van Heijst<sup>1</sup>, H.J.G.D. Van den Bongard<sup>1</sup>, N. Hoekstra<sup>1</sup>, M.E.P. Philippens<sup>1</sup>, D. Eschbach<sup>1</sup>, J.J.W. Lagendijk<sup>1</sup>, B. Van Asselen<sup>1</sup>

<sup>1</sup>UMC Utrecht, Radiotherapy, Utrecht, The Netherlands

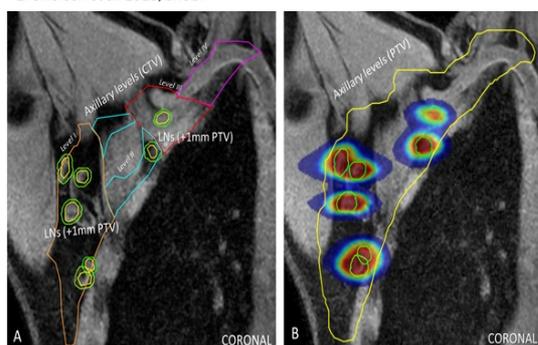

#### Purpose or Objective

Elective axillary regional radiotherapy (RT) in breast cancer patients is performed with RT-planning CT scans, using delineation guidelines based on anatomical boundaries. In contrast to CT, MRI can directly image axillary lymph nodes (LNs) in RT position [van Heijst *et al.* 2016, *BJR*]. Our MRI linac (MRL) system is designed to be able to treat those LNs precisely. LN-based target volumes

**Table 1:** Volumes calculated from delineations on postoperative supine MRI scans from 23 breast cancer patients. Volumes are listed per axillary level, as determined by ESTRO guidelines. The encompassing volumes are given of all individual LNs, as well as after 5-mm isotropic expansion. The volume of the axillary level is listed in the last column. Values are denoted: 'median (range)'.

Median (range)	Encompassing volume (cc)		Volume (cc)
	Individual LNs	Individual LNs (+5 mm expansion)	Standard axillary levels (ESTRO guidelines) <sup>1</sup>
n = 23 patients			
Level I	2.2 (0.9 – 8.0)	32.8 (16.2 – 52.5)	71.9 (23.4 – 162.4)
Level II	0.4 (0.1 – 0.8)	10.0 (2.9 – 20.4)	32.0 (17.6 – 61.7)
Level III	0.1 (0.1 – 0.3)	3.0 (1.1 – 10.3)	17.6 (8.8 – 30.3)
Level IV	0.1 (0.1 – 0.4)	3.7 (1.4 – 7.9)	15.4 (11.2 – 20.7)

1. Offersen et al. 2015, *UROBP*

**Figure 1:** Visualization of target volume reduction when using LN-based target volumes, compared to standard anatomy-based axillary target volumes. In (A), axillary LNs are individually delineated on T1-weighted MRI (yellow), depicted in the coronal plane. The LN delineations are expanded by a 1-mm PTV isotropic margin (green). The four standard axillary levels (CTV), defined by ESTRO guidelines are seen in the figure (I-IV) in varying colours. In (B), the same MRI scan is depicted with a projected dose of 16 x 2.66 Gy = 42.56 Gy, delivered to the individual LN-based PTVs. Conventionally, the PTV of the axillary levels (yellow), determined by anatomical boundaries on CT, is irradiated with the same elective RT dose. Addition of MRI in RT planning that explicitly image individual LNs leads to considerable reduction in target volume and dose to healthy tissue.

## Conclusion

LN-based target volumes on MRI are considerably smaller than axillary levels, conventionally delineated on CT according to the ESTRO guidelines. Addition of dedicated MRI in regional RT planning leads to reduced OAR dose, and a potential reduced RT-associated toxicity for breast cancer patients. In the near future, this will be investigated for more patients, and these results will be available at ESTRO 36. Moreover, MR imaging of lymph vessels is being investigated. Introduction of MRI-guided regional RT, by direct visualization and delineation of individual LNs and OARs, and future use on the MRL, may reduce RT-induced toxicity.

## PV-0282 Out-of-plane motion correction in orthogonal cine-MRI registration

M. Seregni<sup>1</sup>, C. Paganelli<sup>1</sup>, J. Kipritidis<sup>2</sup>, G. Baroni<sup>1,3</sup>, M. Riboldi<sup>1</sup>

<sup>1</sup>Politecnico di Milano University, Dipartimento di Elettronica- Informazione e Bioingegneria, Milano, Italy

<sup>2</sup>University of Sydney, Radiation Physics Laboratory- Sydney Medical School, Sydney, Australia

<sup>3</sup>Centro Nazionale di Adroterapia Oncologica, Bioengineering Unit, Pavia, Italy

## Purpose or Objective

Online motion monitoring in MRI-guided treatments currently relies on the acquisition of 2D cine-MRI images that are registered to the planning anatomy<sup>1</sup>. However, out-of-plane motion (OOPM) cannot be measured and it could affect the accuracy of 2D-2D registration

algorithms. This work investigates the feasibility of a-priori estimation and correction of OOPM.

## Material and Methods

Data from a thoraco-abdominal numeric MRI phantom developed in-house were used<sup>2</sup>. A 10-phases 4DMRI, simulating the planning dataset, was registered to the exhale volume using 3D optical flow<sup>3</sup>, thus measuring in-plane motion ( $IPM^{3D}_p$ ) and OOPM<sub>p</sub> along the three orthogonal slices intersecting in the GTV. In addition,  $IPM^{2D}_p$  was obtained with 2D slice-to-slice optical flow<sup>3</sup> registration and the difference  $C = IPM^{3D}_p - IPM^{2D}_p$  represented the phase-specific a-priori correction.

A 36-frames volume sequence (duration 5.4s) represented treatment data: sagittal/coronal/axial slices simulated cine-MRI sequences, whereas 3D volumes served as ground-truth. The diaphragm position measured on each sagittal slice was used to identify the corresponding breathing phase within the 4DMRI. Each axial and coronal slice of the sequence was registered to the corresponding exhale slices of the 4DMRI ( $IPM^{2D}_T$ ) and the phase-specific correction was applied ( $IPM^{COR}_T = IPM^{2D}_T + C$ ). The average end-point distances (EPD) against ground-truth IPM (obtained through 3D registration) were measured with and without correction. OOPM was estimated for each frame as OOPM<sub>p</sub> measured in the corresponding 4DMRI phase. Finally, the planning GTV was propagated from the 4DMRI exhale phase to each treatment frame using: (1)  $IPM^{2D}_T$  with OOPM = 0 and (2)  $IPM^{COR}_T$  combined with OOPM<sub>p</sub>. Dice indexes against ground-truth GTVs were calculated for both scenarios. The sagittal slice, showing OOPM < 1 mm, was excluded from the analysis.

## Results

GTV motion amplitude was (4.0, 1.7, 0.2) mm (SI, AP, LR) in the 4DMRI and (5.1, 1.2, 0.6) mm in treatment data. Fig.1 reports EPDs and Dice indexes as a function of the ground-truth OOPM. On average, the a-priori correction/estimation approach resulted in EPD reduction and in Dice index increase with respect to the scenario without IPM correction and OOPM estimation (Tab.1).

**Table 1:** IPM end-point distances and GTV dice indexes against ground-truth with and with applying the correction/estimation procedure. \*P values are calculated with non-parametric Wilcoxon ranksum test ( $\alpha = 5\%$ ).

	Measure / Slice	Axial	Coronal
IPM	w/o correction (mean±STD) [mm]	1.6 ± 1.0	2.8 ± 4.2
	with correction (mean±STD) [mm]	0.9 ± 0.8	1.7 ± 2.9
	percentage difference [%]	-6.7 %	-13.6 %
	p-value*	< 10 <sup>-3</sup>	< 10 <sup>-3</sup>
GTV	w/o correction + OOPM = 0 (mean±STD) [a.u.]	0.76 ± 0.09	0.84 ± 0.02
	with correction + OOPM <sub>plan</sub> (mean±STD) [a.u.]	0.84 ± 0.04	0.86 ± 0.03
	percentage difference [%]	+11.01 %	+1.70 %
	p-value*	< 10 <sup>-3</sup>	0.07

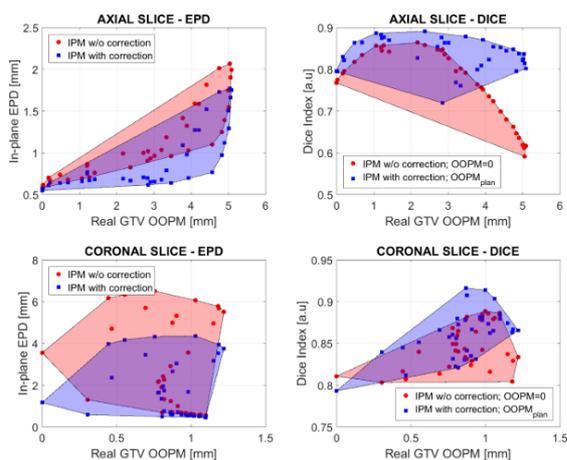

Figure 1: Top-left: in-plane motion field end-point distances with respect to ground-truth (axial slice). Data are reported as a function of GTV out-of-plane motion. Red and blue circles refer to non-corrected and corrected motion fields, respectively. Top-right, GTV dice indexes (same color code). Bottom plots show the same data for the coronal slice

### Conclusion

A-priori information from 4DMRI provides a breathing phase-specific approximation of OOPM and can be used to correct OOPM in slice-to-slice registrations. Such procedure significantly improved GTV position estimation when relevant OOPM is observed, i.e. on the axial slice. The corrected IPM represents a more accurate approximation of the motion field that would be measured if full 3D volumes were acquired and registered in real-time to the planning data. Future work should focus on robustness to inter-fraction variations in patients' data.

### PV-0283 Gated liver SBRT based on internal electromagnetic motion monitoring

E. Worm<sup>1</sup>, M. Hoyer<sup>2,3</sup>, R. Hansen<sup>1</sup>, L.P. Larsen<sup>4</sup>, B. Weber<sup>1</sup>, C. Grau<sup>1,3</sup>, P. Poulsen<sup>1,3</sup>

<sup>1</sup>Aarhus University Hospital, Department of Oncology, Aarhus, Denmark

<sup>2</sup>Aarhus University Hospital, The Danish Centre for Particle Therapy, Aarhus, Denmark

<sup>3</sup>Aarhus University, Institute of Clinical Medicine, Aarhus, Denmark

<sup>4</sup>Aarhus University Hospital, Department of Radiology, Aarhus, Denmark

### Purpose or Objective

To present our results with the new technique of respiratory gated liver SBRT based on internal electromagnetic motion monitoring. The study presents the geometric and dosimetric improvements in treatment accuracy of the gating compared to standard CBCT-guided non-gated treatment.

### Material and Methods

Thirteen patients with primary liver cancer or metastases had three electromagnetic transponders (Calypso) implanted near the target and received three-fraction gated liver SBRT at a TrueBeam Linac. The PTV was created by a 5mm axial and 7mm (n=10) or 10mm (n=3) cranio-caudal (CC) expansion of the CTV as defined on an exhale breath-hold CT. A mean homogenous dose between 45 and 61.8Gy was prescribed to the CTV using 7-field IMRT or 3D conformal planning. The PTV was covered with 67% of the prescribed dose. Treatment was delivered in free-breathing but gated to the exhale breathing phase according to the continuously monitored (25Hz) transponder centroid position. Gate ON windows were set to +/- 3mm LR/AP and +/- 4 mm CC around the exhale position of the transponders. The couch was adjusted remotely if baseline drifts above -1mm of the exhale transponder position occurred. Post-treatment, log files of

the transponder motion and treatment delivery were used to calculate the motion-induced geometrical errors during beam-on in the actual gated treatments and in simulated non-gated standard treatments with CBCT-guided setup to the mean transponder centroid position before each fraction. The observed motion was used to reconstruct the actually delivered CTV dose distribution with gating and the would-be dose distribution without gating.

### Results

Fig. 1 shows the internal tumor motion during a single fraction. Due to drift and respiratory motion the mean (+/- SD) geometric error during non-gated treatment at this fraction (Fig1A) would have been 1.3mm (1.7) LR, 5.0mm (7.7) CC, and -2.0mm (1.8) AP. The gated treatment, including 5 couch shifts to counteract drift (Fig1B), reduced the errors to 0.7mm (0.7) LR, 0.4mm (1.9) CC, and -0.1mm (0.9) AP. Fig. 1C shows the CC geometrical errors for all patients. The mean (range) number of couch corrections for drifts during each gated fraction was 2.8 (0-7). The mean duty cycle during gated treatment was 60.8% (31.7-72.7%). As shown in Fig 2A, gating markedly reduced the population based PTV margin needed for intrafraction motion. Motion-including dose-reconstruction provided the CTV-DVHs of all fractions of planned, actual gated delivered, and simulated non-gated delivered doses. Mean CTV-DVHs are shown in Fig 2B. Note the large DVH variation for non-gated treatments. The mean (range) reduction in CTV D<sub>95</sub> relative to the planned dose was 0.9 percent points (0.1-2.3) with gating and 6.8 percent points (0.9-29.6) without gating.

### Conclusion

Gating based on internal motion monitoring markedly reduced geometric and dosimetric errors in liver SBRT compared to non-gated standard treatment. Results of the full trial (15 patients) are expected for presentation at ESTRO.

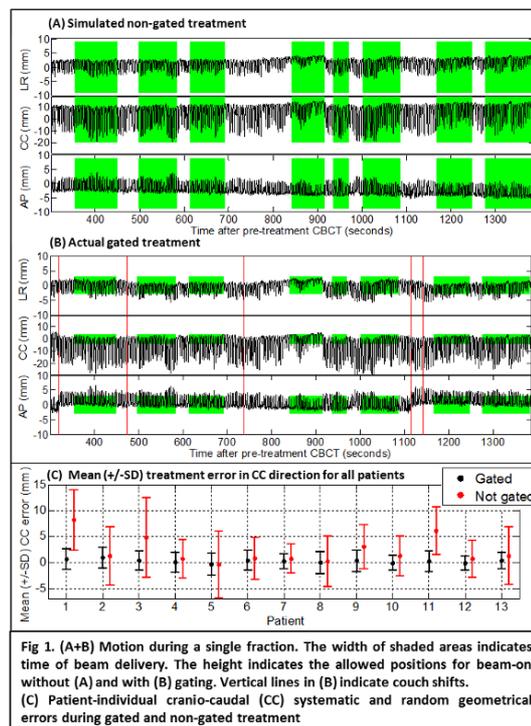

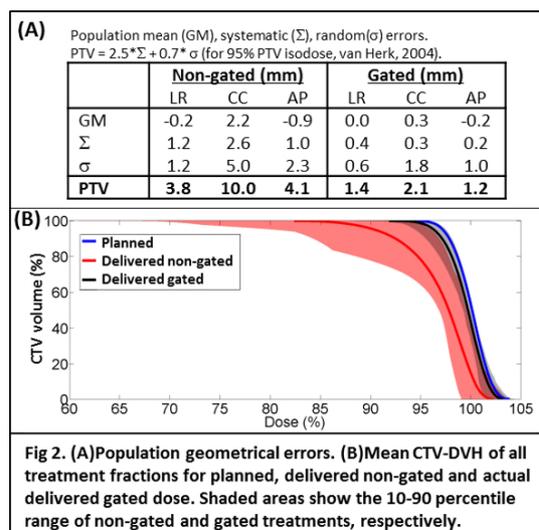

Fig 1. (A+B) Motion during a single fraction. The width of shaded areas indicates time of beam delivery. The height indicates the allowed positions for beam-on without (A) and with (B) gating. Vertical lines in (B) indicate couch shifts. (C) Patient-individual cranio-caudal (CC) systematic and random geometrical errors during gated and non-gated treatment

#### PV-0284 3D Performance Analysis of Cyberknife Synchrony® Respiratory Tracking System

M.C. Sahin<sup>1</sup>, P. Hurmuz<sup>1</sup>, M. Yeginer<sup>1</sup>, G. Yazici<sup>1</sup>, G. Ozyigit<sup>1</sup>

<sup>1</sup>Hacettepe University Faculty of Medicine, Radiation Oncology, Ankara, Turkey

#### Purpose or Objective

Tumor movement is a challenging issue for the precise delivery of radiation for thoracic tumors. The Synchrony respiratory motion tracking system (RMTS) of Cyberknife® robotic radiosurgery unit synchronizes radiation beam delivery with the respiration induced tumor motion. This study aims to investigate the performance of Synchrony RMTS for different movement widths using polymer gel dosimetry. To the best of our knowledge this is the first study to make the three dimensional performance analysis of Synchrony RMTS.

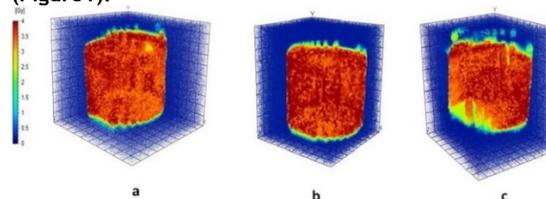

#### Material and Methods

The MultiPlan® treatment planning system (TPS) of Cyberknife® was used to deliver 4 Gy to a tumor of 1X1X1 cm<sup>3</sup>. BrainLab Gating lung phantom was used to simulate lung movements with three different amplitudes (1 cm, 2 cm and 3 cm). Three fiducials were inserted to the phantom for tracking. Radiochromic film and polymer gel dosimetry were used and measurements were compared with the dose distributions acquired from the TPS. The dose information of irradiated gel were read out using 1.5 T magnetic resonance imaging. The gamma index values were analysed using the Ashland FilmQA Pro 3.0 software for film dosimeters and PolyGevero software for gel dosimeters using the 3mm/3% criteria. PolyGevero gamma index value of  $\leq 1$  is accepted as a passing criteria according to the literature.

#### Results

The mean 3 mm/3% gamma index values of film dosimetry were 92.6±1.94%, 91.0±4.00%, 90.3±2.04% for tumor motions of 1 cm, 2 cm and 3 cm, respectively (p<0.001). For polymer gel dosimetry, the mean gamma index values calculated over almost three million points were 0.56±0.10, 0.60±0.24 and 0.65±0.30 for tumor motions of 1 cm, 2 cm and 3 cm, respectively (p<0.001). Although the difference was statistically significant for 3 different amplitudes, the performance of the system was within the acceptance limits

(Figure 1).

#### Conclusion

Three dimensional performance analysis showed that Cyberknife Synchrony® RMTS is successful in tumor tracking regardless of the amplitude of movement. This study is supported by TUBITAK 3001 project, project number 115S446

#### PV-0285 Using a surface scanner for positioning of pelvic patients - can X-ray images be omitted?

J.B. Thomsen<sup>1</sup>, S. B.N. Biancardo<sup>1</sup>, S.H. Hattel<sup>1</sup>, L. Søndergaard Vinther Merckelsen<sup>1</sup>, B. Roche<sup>1</sup>, J.P. Bangsgaard<sup>1</sup>

<sup>1</sup>Rigshospitalet, Finsenscentret- Radiotherapy, Copenhagen, Denmark

#### Purpose or Objective

Reproducing the correct treatment position prior to radiotherapy is crucial for accurate dose delivery. The golden standard for positioning is X-ray based imaging with the drawback of exposing the patient to ionising radiation. More recently surface scanners using infrared light has been introduced to monitor the patient surface. We investigate a surface monitor system "AlignRT" for positioning pelvic patients prior radiotherapy [Vision RT, [www.visionrt.com](http://www.visionrt.com)]. This is attractive in terms of saving time and reducing imaging dose to the patient. Even when acquiring daily X-ray images routinely, the ability to correct rotations using AlignRT is of value to limit repeated X-ray images.

#### Material and Methods

Patients undergoing pelvic irradiation were positioned using the surface scanner. The body surface was extracted from the CT therapy scan acquired before radiotherapy and imported in the surface scanner software. With the patient on the couch it is possible to monitor the surface in the treatment region and the system displays the deviations from the CT therapy scan translational and rotational. We chose a region of interest (ROI) around the treatment region of about 20 cm in cranio-caudal direction and extending on both sides of the patient. Following positioning using the surface scanner, a cone-beam CT scan (CBCT) was acquired which makes a comparison between the positioning using the surface scanner and the CBCT possible. For the CBCT an automatic bone match was applied using commercial software (Varian inc., offline review) and visually inspected. In total, 105 fractions from 6 patients were analyzed and a paired T-test was applied to detect any significant differences between the two systems.

#### Results

In 50 of 105 fractions (48%) the difference between the two positioning procedures was larger than 5 mm in at least one direction. In 39 of 78 fractions (37%) the difference in rotations was larger than 3 degrees. In 71 of 105 fractions (68%) either a difference in translations was above 5mm or rotation above 3 degrees. In fig. 1 and fig. 2 the difference in translations and rotations are shown for all 105 fractions originating from 6 patients. For the translation there was a significant difference for vertical and longitudinal directions (P<0,001 for vertical, P<0,001 for longitudinal, P<0,9 for lateral). The difference in rotations were all significant (P<0,001 for pitch, P<0,05 for roll, P<0,01 for rotation around the vertical axis).

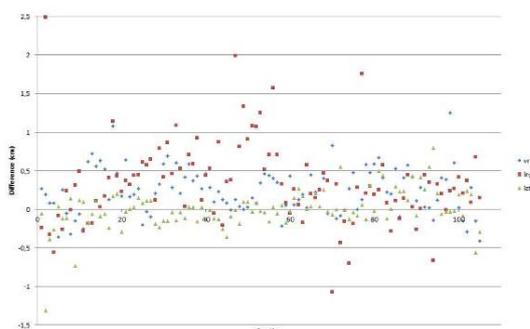

Fig. 1. Difference between positions measured with AlignRT and CBCT using a bone match. In total 105 fractions from 6 patients are shown.

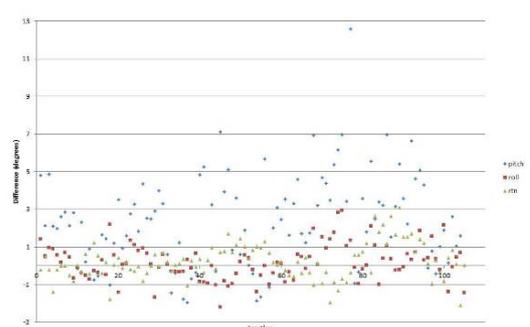

Fig. 2. Difference between rotations measured with AlignRT and CBCT using a bone match. In total 105 fractions from 6 patients are shown.

## Conclusion

We did show significant deviations between positioning using the surface scanner and CBCT with the chosen ROI. In this small patient cohort, 68% of the fractions would have been out of tolerance using a threshold of 5mm and 3 degrees if positioned solely based on the surface scanner. Therefore a surface scanner does not replace the usual X-ray image guidance procedure. Furthermore, for pelvic patients it does not seem possible to use the surface scanner for reliable estimations of rotational deviations which could have limited repeated x-ray imaging.

## PV-0286 Quantifying registration uncertainties in image-based data mining

E.M. Vasquez Osorio<sup>1</sup>, A. McWilliam<sup>1,2</sup>, J. Kennedy<sup>3</sup>, C. Faivre-Finn<sup>1,4</sup>, M. Van Herk<sup>1,2</sup>

<sup>1</sup>The University of Manchester, Division of Molecular & Clinical Cancer Studies- School of Medical Sciences- Faculty of Biology- Medicine and Health, Manchester, United Kingdom

<sup>2</sup>The Christie NHS Foundation Trust, Christie Medical Physics and Engineering, Manchester, United Kingdom

<sup>3</sup>The Christie NHS Foundation Trust, Informatics, Manchester, United Kingdom

<sup>4</sup>The Christie NHS Foundation Trust, Clinical Oncology, Manchester, United Kingdom

## Purpose or Objective

Image based data mining relies on non-rigid registration to bring image data on a common frame of reference. Registration uncertainties will affect the analysis and must be quantified and incorporated. We have developed a method to quantify global and local random registration uncertainties. Additionally, we evaluated the impact of accounting for global random registration uncertainties on the results of a recent lung data mining study that identified the base of the heart as a dose sensitive region affecting survival in lung cancer patients [1].

## Material and Methods

CT data and heart delineations from 386 lung cancer patients were used to quantify random registration uncertainties. Inter-patient registration included an affine and a non-rigid registration (NRR) using the first patient in our database as reference. The affine registration was initialized by scaling the clip-box that encompassed both lungs to match the reference patient's clip-box and then an automatic intensity-based affine registration was run. Subsequently a non-rigid registration was performed using NiftyReg on the same region. Both registrations ignored bony anatomy. Global random registration uncertainty was estimated by assessing standard deviation of all centres of mass of the transformed organ of interest contours, here the heart. Local random uncertainties on the heart surface were estimated by calculating the standard deviation of the distances of individual transformed delineations to the median heart. To determine the impact of the random registration uncertainty in our study, we compared the results of the data mining analysis between the original dose distributions and the Gaussian blurred dose distributions using the global registration uncertainty found, excluding outliers.

## Results

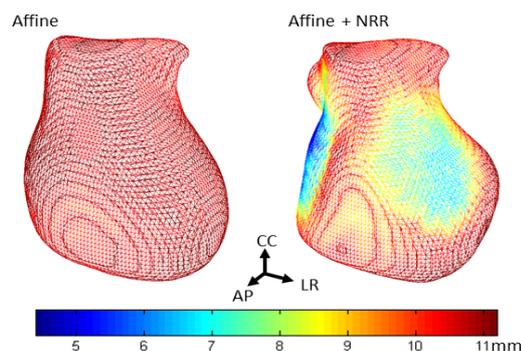

Figure 1 summarizes the global and local random uncertainties. The smaller local uncertainties were seen on the lateral aspects of the heart close to the heart-lung interface; conversely, the largest local uncertainties were observed on the caudal regions of the heart close to the lung-diaphragm-liver interface.

Figure 1: Global and local random registration uncertainties.

**Global random registration uncertainty:** standard deviation of all centres of mass of the transformed hearts.

	Affine	Affine + NRR
Left-Right (LR)	5.6 mm	3.9 mm
Anterior-Posterior (AP)	7.1 mm	4.9 mm
Cranial-Caudal (CC)	7.9 mm	7.4 mm
Percentage of outliers	3.4%	4.6%

**Local random registration uncertainty:** standard deviations of the distances of individual transformed delineations to the median heart surface.

Including the random registration uncertainties in the data mining analysis did not change the conclusions of the study, mainly because significant regions exceeded the registration accuracy in size (figure 2).

**Figure 2:** T-maps resulting from data mining. The arrow points to the base of the heart, which is within an area of high significance.

### Conclusion

This work proposed a method to quantify global and local random registration uncertainties for data mining approaches related to an organ of interest. Changes in the registration algorithm or its parameters will affect the uncertainty, therefore, quantification of registration random uncertainties should be run parallel to data mining and accounted for in the analysis. The found registration uncertainties did not change the conclusions of our previous study.

### PV-0287 Determination of MC-based predictive models for personalized and fast kV-CBCT organ dose estimation

H. Chesneau<sup>1</sup>, M. Vangvichith<sup>1</sup>, E. Barat<sup>1</sup>, C. Lafond<sup>2</sup>, D. Lazaro-Ponthus<sup>1</sup>

<sup>1</sup>Commissariat à l'Energie Atomique- LIST, Département de physique, Gif-sur-Yvette, France

<sup>2</sup>Centre Eugène Marquis, Département de Physique Médicale, Rennes, France

### Purpose or Objective

Monte Carlo (MC) simulations were shown to be a powerful tool to calculate accurately 3D dose distributions of kV-CBCT scans for a patient, based on planning CT images. However, this methodology is still heavy and time consuming, preventing its large use in clinical routine. This study hence explores a method to derive empirical functions relating organ doses to patient morphological parameters, in order to perform a fast and personalized estimation of doses delivered to critical organs by kV-CBCT scans used in IGRT protocols.

### Material and Methods

Doses to critical organs were first computed using a PENELOPE-based MC code previously validated [H. Chesneau et al., *ESTRO* 2016], for a set of fifty clinical cases (40 children and 10 adults) covering a broad range of anatomical localizations (head-and-neck, pelvis, thorax, abdomen) and scanning conditions for the Elekta XVI CBCT. Planning CT images were converted into voxelized patient geometries, using a dedicated tissue segmentation procedure: 5 to 7 biological tissues were assigned for soft tissues, whereas ten different bone tissues were required for accurate dosimetry in the kV

energy range. Correlations between calculated mean organ doses and several morphological parameters (age, weight, height, BMI, thorax and hip circumference ...) were then studied for each anatomical localization to derive appropriate empirical fitting functions.

### Results

As expected, results on the paediatric cohort show dose variations highly correlated with the patient morphology, varying in the range 3:1 between a 17-y old teenager and a 2-y old baby, for the same CBCT scan. Except for the head-and-neck localization, for which the mean organ doses show no significant variations with the morphology, doses to all major organs at risk can be predicted using linear or exponential functions for thorax, pelvis and abdomen scans. The use of morphological parameters directly measured on the planning CT allows to reach better correlations than global parameters such as BMI, because they represent most relevant indicators of the patient morphology at the scan time.

### Conclusion

This study demonstrates that it is possible to derive mathematical models predicting the doses delivered to major critical organs by kV-CBCT scans according to morphological parameters. This method allows a fast and personalized estimation of imaging doses usable in clinical routine.

### Presidential symposium

#### SP-0288 Mind the gaps!

Y. Lievens<sup>1</sup>

<sup>1</sup>University Hospital Ghent, Department of Radiation Oncology, Gent, Belgium

In 2012, ESTRO has formulated its vision statement for 2020: "Every cancer patient in Europe will have access to state of the art radiation therapy, as part of a multi-disciplinary approach where treatment is individualised for the specific patient's cancer, taking account of the patient's personal circumstances".

Now five years later, it is timely to overlook the advances that have been made and the challenges that are still ahead of us, in order to make our dream of accessible, qualitative, safe and efficient radiotherapy for all cancer patients in Europe, and beyond, come true.

### Award Lecture: Regaud Award Lecture

#### SP-0290 More than one century after the serendipitous discovery of X-rays, there is still a bright future for radiation oncology ...

J. Bourhis<sup>1</sup>

<sup>1</sup>Centre Hospitalier Universitaire Vaudois, Department of Radiation Oncology, Lausanne Vaud, Switzerland

Radiotherapy (RT) was born a few weeks after the serendipitous discovery of X-rays. Soon after this revolutionary breakthrough, the founders of RT understood that fractionation could allow the tolerance of "relatively high total doses of RT in large fields". Claudius Regaud was one of the most distinguished of these pioneers: "Observe and Translate" was his message. One century later, the fantastic advances in science, biology, physics and imaging led to more efficient and much better tolerated RT". One of the most dramatic advances was stereotactic-RT allowing the safe delivery of "extremely high doses of RT" in small fields with very few fractions and no or minimal side effects. In the rapidly evolving field of oncology, this powerful tool can be also successfully combined with other advanced oncologic treatments, such as cancer immunotherapy ... More than ever, RT remains at the forefront of the fight against cancer and ... perhaps

there is still some room for serendipity: an example of this will be presented with flash-RT.

### Symposium: New paradigm in HNSCC

---

#### SP-0291 Modern biomarkers for therapeutic strategy: radiation dose or volume modification

M. Krause<sup>1</sup>

<sup>1</sup>TU Dresden- Med. Faculty Carl Gustav Carus, Dresden, Germany

Decisions on radiotherapy indication, dose or combined treatments are today based on tumour stage and localisation as well as surgical factors. Over the last years, an increasing number of translational studies has shown biological parameters that are associated with locoregional tumour recurrences, metastases and/ or patient survival. Most prominent and already in clinical intervention trials is Human Papillomavirus (HPV) subtype 16, which is present in a high percentage of head and neck squamous cell carcinoma (HNSCC) and has been shown to lead to radiosensitivity of tumours in preclinical as well as in clinical studies. Other biomarkers like hypoxia related markers or putative cancer stem cell markers are expected to indicate a higher radioresistance of tumours. Such biomarkers, after systematic validation in independent datasets, may build a basis for interventional trials with different radiation doses for different risk-stratified patient groups.

Less data is currently available on biomarkers predicting the efficacy of radiotherapy to different treatment volumes, e.g. unilateral versus bilateral neck irradiation or selective inclusion of different lymphnode levels. Such data are harder to generate as they need to be based on patient groups that have been treated using different treatment volumes.

The talk will give an overview on current clinical evidence, translational studies and promising biomarkers evaluated within clinical trials.

#### SP-0292 The changing role of head and neck surgeon in HPV-positive oropharyngeal squamous cell carcinoma, or do we still need surgery?

C. Simon<sup>1</sup>

<sup>1</sup>Centre Hospitalier Universitaire Vaudois, Lausanne Vaud, Switzerland

HPV-positive oropharyngeal squamous cell carcinomas (OPSCCs) are delineating a separate disease entity with an overall better prognosis and different biology in comparison to HPV-negative OPSCCs. The role of the surgeon for this disease remains to be elucidated and depends on the outcome of surgical trials, i.e. the "Best-of" EORTC 1420 trial, that is comparing IMRT with transoral surgery in early-stage OPSCCs. Also for advanced-stage disease trials are currently underway to better define adjuvant treatment after surgery (PATHOS, ECOG 3311) or compare surgery-based treatments for operable advanced OPSCCs with RT-strategies (ORATOR). It will depend on the outcome of these trials, which role the surgeon will play in the future in the treatment of HPV-positive OPSCCs.

#### SP-0293 Radiation de-escalation strategies in HPV-positive squamous cell carcinoma

J. Giral<sup>1</sup>

<sup>1</sup>Hospital Universitario Vall d'Hebron, Barcelona, Spain

Human papillomavirus-related (HPV+) oropharyngeal cancer is a rapidly emerging disease in many countries that differs from tobacco-related and alcohol-related (HPV-) oropharyngeal cancer. HPV+ oropharyngeal carcinoma is now established as a distinct biological entity, being

prognosis significantly superior than HPV negative tumor. Although their survival is excellent, standard RT-CT regimens produce substantial toxicity. In that scenario strategies for de-intensification have been developed. De-intensification is to modify the standard treatment in order to reduce the long-term toxicities associated with radiation / chemotherapy while maintaining the high cure rates. Prognostic factors allow us to select patients with excellent outcomes that can benefit from de-intensification strategies. These factors are: Oropharyngeal cancer, P16+, minimal smoking history, non-bulky primary and non-extensive nodal spread (not N2c-N3). Strategies for de-intensification are: Select chemo responders and reduce RT dose or the volume, reduce RT dose and cisplatin, replace cisplatin with cetuximab, use TORS resection and reduce adjuvant RT dose. Published de-escalation clinical trial will be presented and discussed as well as the most important ongoing trials. As conclusions: radiation de-escalation is experimental and should be conducted in clinical trials, appropriate candidates for de-escalation are well defined, there are different strategies for de-intensification, preliminary data show efficacy but the effect on long-term toxicity reduction needs to be proved.

### Symposium with Proffered Papers: Costs and value of radiotherapy innovations: how to assess

---

#### SP-0294 Health Technology Assessment: what's in a word?

A. Aggarwal<sup>1</sup>

<sup>1</sup>London School of Hygiene and Tropical Medicine, Health Services Research and Policy, London, United Kingdom

Health Technology Assessments (HTA) aim to ensure rational and fair decisions are made on resource allocation for new health interventions. The advantage of HTAs are their universality when making decisions regarding which treatments across all medical specialities represent the best value to society. However, few if any countries internationally use HTA in the evaluation of radiation technologies. Instead these processes have largely focussed on new cancer drugs, informing reimbursement policy for public health systems.

In the absence of HTA processes, low regulatory barriers have resulted in the relentless diffusion of increasingly expensive radiotherapy innovations which offer ever-marginal gains in the therapeutic ratio. Without a rational and evidence based approach to evaluation the costs of delivering cancer care will continue to rise exponentially.

I will discuss how a commitment to HTA processes is imperative in order to avoid many of the entrenched interests and inefficient practices that have manifested in high income countries due to differences in cancer care delivery, and health system financing. I will also highlight the challenges in establishing HTA for radiotherapy interventions, given the diversity in innovation, and limitations within the evidence base to enable comparative effectiveness research.

In addition I will offer insights into the challenges of implementing HTA decisions in practice, using the experiences of the UK National Institute for Health and Clinical Excellence (NICE) as an example. Specifically, the impact of political, public and media pressure on HTA assessments of cancer therapies as well as the negative consequences of bypassing these value driven approaches to reimbursement policy.

### SP-0295 Radiotherapy costs: the good, the bad and the ugly

L. Perrier

<sup>5</sup>Cancer Centre Léon Bérard, Clinical Research and Innovation Direction, Lyon, France

Abstract not received

### OC-0296 A critical quality appraisal of studies estimating the cost of radiotherapy

N. Defourny<sup>1</sup>, P. Dunscombe<sup>2</sup>, C. Grau<sup>3</sup>, Y. Lievens<sup>4</sup>, L. Perrier<sup>5</sup>

<sup>1</sup>ESTRO A.I.S.B.L., HERO, Brussels, Belgium

<sup>2</sup>University of Calgary, Department of Oncology, Calgary, Canada

<sup>3</sup>Aarhus University, Department of Clinical Medicine, Aarhus, Denmark

<sup>4</sup>University Hospital Ghent, Radiation Oncologist, Ghent, Belgium

<sup>5</sup>Cancer Centre Léon Bérard, Clinical Research and Innovation Direction, Lyon, France

#### Purpose or Objective

In the context of growing healthcare expenses combined with reduced economic growth, health economics (HE) studies are becoming paramount. Considerable interest in the domain is apparent when looking at the number of articles indexed with HE keywords. Nevertheless, a recent literature review has revealed very few articles calculating the cost of radiotherapy, and a large heterogeneity in the methodologies used. The aim of this complementary review is to report on existing guidance in HE and to critically assess guideline compliance in the radiotherapy literature.

#### Material and Methods

A systematic literature review of cost computation studies in external photon beam radiation therapy (EBRT) from 1981-2015 was recently conducted by us. Building on this earlier work, existing HE guidelines have been reviewed and a list of relevant items for cost estimations has been compiled. The guidelines searched were ISPOR's Good Practices For Outcome Research guidelines, HE evaluation quality appraisal instruments and National guidelines (EUnetHTA). A standardised framework focusing on recommendations on cost assessment was designed with the help of these guidelines. Fifty-two HE studies meeting criteria established in our earlier literature review were studied in-depth: cost assessment methods, descriptions of methodologies (e.g. sample size, time horizon, or discounting clearly mentioned), and relevant statistical analyses performed (e.g. selection bias treated, sensitivity analyses done) were all critically appraised within the framework.

#### Results

Guidance on HE analyses is often provided in the form of a checklist of items to be addressed. Direction on the cost type to estimate, the analysis to conduct, and methods for tackling uncertainty of data are outlined, e.g. "identify relevant cost for each alternative and value the cost appropriately". Evaluation of the 52 studies against published HE recommendations revealed shortcomings in the cost assessment methodologies, the implications of that choice, and the calculation methods used.

Among selected studies, heterogeneity was observed in the quantity and quality of the information disclosed. While documentation of cost items and sample size was found in 67% of the 52 articles, and the reference year of cost data was present in 85%, only 37% of the articles specified data sources used by the authors, 35% stated their discounting methods and just 8% mentioned the study's time horizon. Descriptive statistics analyses were present in 35% of the studies and uncertainty treatment in 48%.

#### Conclusion

Existing guidance on formulating the cost part of HE evaluation studies establishes an outline framework while giving researchers a high degree of freedom. The limited number of studies investigating the cost of EBRT do not systematically follow these published HE guidance leaving room for quality improvement in this increasingly influential research area.

### SP-0297 Method of development of ESMO Magnitude of Clinical Benefit applicable for radiotherapy?

E.G.E. De Vries<sup>1</sup>, R. Sullivan<sup>2</sup>, N.I. Cherny<sup>3</sup>

<sup>1</sup>UMCG University Medical Center Groningen, Department of Medical Oncology, Groningen, The Netherlands

<sup>2</sup>Institute of Cancer Policy, Kings Health Partners Integrated Cancer Centre- King's College London, London, United Kingdom

<sup>3</sup>Shaare Zedek Medical Center, Cancer Pain and Palliative Medicine Service- Department of Medical Oncology, Jerusalem, Israel

The value of any new therapeutic strategy or treatment is determined by the magnitude of its clinical benefit balanced against its cost. Evidence for clinical benefit from new treatment options is derived from clinical research, in particular phase III randomised trials, which generate unbiased data regarding the efficacy, benefit and safety of new therapeutic approaches. Until recently, there was no standard tool for grading the magnitude of clinical benefit of cancer therapies, which may range from trivial (median progression-free survival advantage of only a few weeks) to substantial (improved long-term survival). Indeed, in the absence of a standardised approach for grading the magnitude of clinical benefit, conclusions and recommendations derived from studies are often hotly disputed and very modest incremental advances have often been presented, discussed and promoted as major advances or 'breakthroughs'. Recognising the importance of presenting clear and unbiased statements regarding the magnitude of the clinical benefit from new therapeutic approaches derived from high-quality clinical trials, the European Society for Medical Oncology (ESMO) has developed a validated and reproducible tool to assess the magnitude of clinical benefit for cancer medicines, the ESMO Magnitude of Clinical Benefit Scale (ESMO-MCBS). An ESMO Task Force to guide the development of the grading scale was established in March 2013. A first-generation draft scale was developed and adapted through a 'snowball' method based upon previous work of Task Force members who had independently developed preliminary models of clinical benefit grading. The first-generation scale was sent for review by 276 members of the ESMO faculty and a team of 51 expert biostatisticians. The second-generation draft was formulated based on the feedback from faculty and biostatisticians and the conceptual work of Alberto Sobrero regarding the integration of both hazard ratio (HR), prognosis and absolute differences in data interpretation [J Clin Oncol 2009, Clin Cancer Res 2015]. The second-generation draft was applied in a wide range of contemporary and historical disease settings by members of the ESMO-MCBS Task Force, the ESMO Guidelines Committee and a range of invited experts. Results were scrutinized for face validity, coherence and consistency. Where deficiencies were observed or reported, targeted modifications were implemented and the process of field testing and review was repeated. This process was repeated through 13 redrafts of the scale preceding the current one (ESMO-MCBS v1.0). The final version and fielded testing results were reviewed by selected members of the ESMO faculty and the ESMO Executive Board. Version 1.0 appeared in 2015 (Cherny et al. Ann Oncol).

This tool thus provides a rational, structured and consistent approach to derive a relative ranking of the magnitude of clinically meaningful benefit that can be

expected from a new anti-cancer treatment. The ESMO-MCBS is an important first step to the critical public policy issue of value in cancer care, helping to frame the appropriate use of limited public and personal resources to deliver cost-effective and affordable cancer care. The ESMO-MCBS is a dynamic tool and its criteria will be revised on a regular basis. The next version will include also an approach to grade the clinical benefit data derived from the registration trials of medications approved on the basis of these single arm studies. Currently the grading of newly registered drugs is included in ESMO-guidelines. A similar approach to develop a scale can potentially be used for other treatment or diagnostic areas in oncology including radiotherapy. For a scale grading radiotherapy, there will likely be a number of similarities and differences versus a scale for drug treatment. Factors taken into account for the radiotherapy scale might well include the adjuvant and curative outcomes: overall survival, disease free survival, local recurrence free survival, pathological complete response and non-curative/palliative outcomes such as: single symptom relief (complete response, partial response, relief duration of response), control of hemorrhage, relief of obstruction, effects on skeletal events (pain, fracture) and neurological function. We anticipate methodological challenges in the relative weighting and scoring of palliative outcomes from localized radiotherapy as distinct from systemic therapies.

---

**Debate: This house believes that proton guided photons (online MR guided therapy) will be superior to photon guided protons (CBCT proton therapy)**

---

**SP-0298 For the motion**

*B. Raaymakers<sup>1</sup>*

<sup>1</sup>*UMC Utrecht, Department of Radiation Oncology, Utrecht, The Netherlands*

The common ground for proton and photon guidance, that is MRI and CBCT guidance, is the desire to localize the target and the surrounding structures in order to improve the spatial accuracy of dose delivery. This is especially important to better target and to minimize the high dose volumes which are leading to the most acute toxicity and are often dose limiting.

With modern accelerators, both proton- and photon therapy can generate a conformal high dose volume, while image guidance is the most important parameter on delivering this high dose volume to the correct position and with that minimize this high dose volume. Doing so, also hypo-fractionated treatments for more and more tumor sites can become feasible.

MRI guidance is superior because:

- 1) Soft-tissue guidance of MRI will out-perform CBCT based set-up
- 2) MRI provides dynamic imaging to track breathing and peristalsis without the need for retrospective binning
- 3) MRI enables daily full re-planning
- 4) MRI provides intra-fraction (volumetric) imaging for dose reconstruction and plan adaptation
- 5) Integrated MRI provides functional response assessment during the course of radiotherapy

CBCT has greatly improved radiotherapy by offering 3D imaging just prior to radiation delivery, these images can be used for improved patient set up and assessment of the breathing pattern. These data, even though they have limited soft-tissue contrast, are acquired just prior to treatment. Using these instead of relying on pre-treatment images of days (if not weeks) old, provides much more representative information on the target and surrounding structures and will improve patient set-up. With MRI integrated in the radiotherapy system, all the

aims from CBCT guidance can be brought to the next level. MRI offers soft-tissue contrast, so one can much better distinguish tumor from surrounding tissues. Also dynamic MRI can provide 4D anatomical data with high temporal resolution (e.g. 3Hz) to detect breathing and peristaltic irregularities. The limitation of CBCT for needing bony landmarks, surrogates, the need for large tissue density differences or the retrospective binning to assess motion data will be solved when using MRI. So MRI is at the very least a much better CBCT in the sense that it provides direct visualization of target and surrounding structures. CBCT guided proton therapy is lagging behind on the much needed image guidance offered by MRI and hybrid MRI radiotherapy systems will improve position verification. On-line MRI will also enable on-line re-planning strategies that are not, or only for some sites, feasible with CBCT as an input. This on-line re-planning fits seamlessly into the large research interest of the radiotherapy community to adapt the dose more to the actual anatomy and deliver more conformal dose distributions, currently being implemented via library of plans or off-line re-planning strategies.

Moreover, integrated MRI allows imaging during radiation delivery. This way, assumptions on anatomical stability or motion as determined on pre-treatment data can be verified. Also, the intra-fraction volumetric imaging provides the input for dose reconstruction, so even if the pre-treatment assumptions are failing and the anatomy is moving/deforming unexpectedly, one can reconstruct exactly what the dose delivered is. This can be used for off-line re-optimization for remaining fractions. Additionally, as this dose reconstruction can be done in near real-time, one can also build adaptation triggers on it such as gating and ultimately intra-fraction re-planning strategies. The latter would be truly interventional radiosurgery where the dose distribution is continuously adapted to the mobile anatomy.

Another advantage of integrated MRI radiotherapy systems is the capability to assess functional parameters such as perfusion or water diffusion, from the patient in treatment position. This can provide great insight in treatment response and temporal behavior during the course of radiotherapy.

**In summary**, there is a clear desire from the image guided radiotherapy community to use more and better imaging prior and during radiation delivery. MRI guided photon therapy can fulfill this desire and will contribute to more precise radiation delivery and to a more hypo-fractionated approach. With that hybrid MRI radiotherapy systems will become the first choice for radiotherapy and CBCT guided proton therapy is mainly indicated in case the integral dose is treatment limiting, e.g. for pediatrics.

**OC-0300 Proof of tumor position during SBRT delivery using (limited-arc) CBCT imaging**

*C. Hazelaar<sup>1</sup>, M. Dahele<sup>1</sup>, B. Slotman<sup>1</sup>, W. Verbakel<sup>1</sup>*

<sup>1</sup>*VU University Medical Center, Radiotherapy, Amsterdam, The Netherlands*

**Purpose or Objective**

SBRT requires accurate patient positioning and robust positional verification during irradiation itself is desirable. We investigated if CBCT scans reconstructed from (collimated) fluoroscopic kV images acquired during irradiation, including over a limited arc length, can

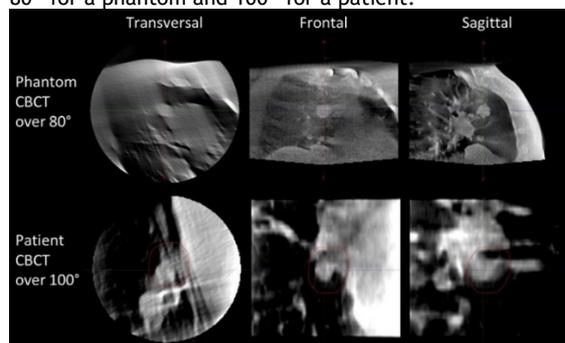

provide information on the average tumor position, for spine and lung SBRT.

#### Material and Methods

In total, 38 fluoroscopy datasets (1 dataset/arc) of 16 patients treated with spine SBRT were used for full-arc CBCT reconstruction. The kV images were continuously acquired at 7, 11, or 15 frames/s with a field size ranging from 10.5x9cm<sup>2</sup> to 26.6x20cm<sup>2</sup> (full field) during flattening filter free VMAT delivery. For reconstruction, a standard "spotlight" mode template was modified to suit our data, i.e. full 360° trajectory, full fan, no filters, and 100 kV. The FDK filtered back projection algorithm was used to reconstruct the CBCTs and the scans were matched to the planning CT in Offline Review (Varian Medical Systems, Palo Alto, CA). For validation purposes, the resulting match values were compared to the average spine offset values found using template matching + triangulation of the individual kV images. For lung SBRT, limited-arc CBCTs were reconstructed from fluoroscopic images acquired during irradiation of a lung lesion embedded in a 3D printed anthropomorphic thorax phantom and of one patient treated in breath-hold. In order to determine which arc length is required to obtain sufficient image quality for reliable CBCT-CT matching, multiple limited-arc CBCTs were reconstructed using arc lengths from 180° down to 20° in steps of 20°.

#### Results

3D spine CBCT-CT registration revealed mean positional offsets of  $-0.1 \pm 0.8$  mm (range:  $-1.5$ - $2.2$ ) for the lateral,  $-0.1 \pm 0.4$  mm (range:  $-1.3$ - $0.7$ ) for the longitudinal, and  $-0.1 \pm 0.5$  mm (range:  $-1.1$ - $1.3$  mm) for the vertical direction. Comparison of these match results to the average spine offsets found using template matching + triangulation showed mean differences of  $0.1 \pm 0.1$  mm for all directions (range:  $0.0$ - $0.5$  mm). For limited-arc CBCTs of the lung phantom, the automatic CBCT-CT match results were  $\leq 1$ mm in all directions for arc lengths of 60-180°, but in order to perform 3D visual verification, an arc length of at least 80° was found to be desirable. 20° CBCT reconstruction still allowed for positional verification in 2 dimensions. The figure illustrates a limited-arc CBCT over 80° for a phantom and 100° for a patient.

#### Conclusion

Using standard techniques, we have been able to obtain CBCT reconstructions of planar kV images acquired during VMAT irradiation. For treatments consisting of partial arcs, e.g. lung breath-hold treatments, limited-arc CBCTs can show the average tumor position during the actual treatment delivery. It is anticipated that this capability could be implemented clinically with few modifications to current treatment platforms. This could substantially improve positional verification during irradiation.

#### OC-0301 Target position uncertainty during visually guided breathhold radiotherapy in locally advanced NSCLC

<sup>3</sup>DTU Nanotech, Department of Micro- and Nanotechnology- Center for Nanomedicine and Theranostics, Lyngby, Denmark

<sup>4</sup>Aarhus University Hospital, Department of Oncology, Aarhus, Denmark

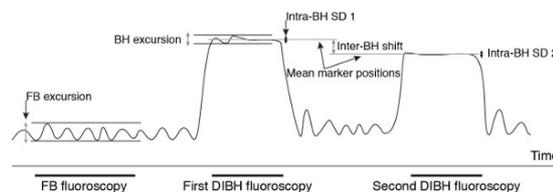

#### Purpose or Objective

The purpose of this study was to estimate the intra- and inter-breath-hold tumour position uncertainty in voluntary deep-inspiration breath-hold (DIBH) radiotherapy for patients with locally advanced non-small cell lung cancer.

#### Material and Methods

Patients had liquid fiducial markers injected in mediastinal lymph nodes, and, if possible, in the primary tumours. Treatment was delivered during DIBH. Anterior and lateral fluoroscopic movies were acquired in free breathing (FB) and visually guided DIBH at three fractions (start, middle and end) during radiotherapy (33 fractions, 2 Gy per fraction) of nine patients with locally advanced non-small cell lung cancer. Fluoroscopies were acquired post treatment for two perpendicular gantry angles (Figure 1). Marker excursions in free breathing and DIBH, inter-breath-hold position uncertainty, systematic and random errors during DIBH in each of the three cardinal directions were investigated using an image based tracking algorithm, defining the marker template as one of the images from the middle of the first DIBH fluoroscopy.

The mean marker position during each DIBH, relative to a template frame for the first fluoroscopy, was regarded as each fraction and markers uncertainty during the DIBH. A systematic error for the patient group was calculated as the standard deviation (SD) of all these mean marker positions. The standard deviation of the markers position within each DIBH was used to quantify the intra-breath-hold uncertainty (Figure 1). A root mean square (RMS) of the intra-DIBH SD was calculated to estimate random errors.

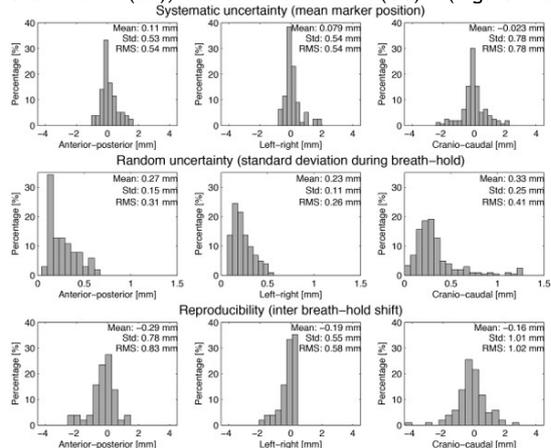

Grey arrows indicate min-max distances  
 Black arrows indicate standard deviations

#### Results

A reduction of 2-6 mm in marker excursion in DIBH compared to FB was observed in the three cardinal directions (anterior-posterior (AP), left-right (LR) and cranio-caudal (CC)). Fourier transformation of the motion trajectories indicated that the lymph node motion during DIBH mainly originated from cardiac motion. The systematic errors during DIBH were 0.5 mm (AP), 0.5 mm (LR) and 0.8 mm (CC). The random errors during DIBH were 0.3 mm (AP), 0.3 mm (LR), and 0.4 mm (CC). The standard deviation of the inter-breath-hold shift was 0.8 mm (AP),

## 0.6 mm (LR), and 1.0 mm (CC) (Figure 2).

### Conclusion

Our study showed that the motion of lung tumours could be substantially reduced, but not eliminated, using visually guided DIBH radiotherapy. Intra- and inter-breath-hold position uncertainty of the tumour and lymph nodes were mostly less than 2 mm for visually guided DIBH radiotherapy of non-small cell lung cancer.

### OC-0302 Dosimetric evaluation of a global motion model for MRI-guided radiotherapy

C. Paganelli<sup>1</sup>, S. Albertini<sup>1</sup>, F. Iudicello<sup>1</sup>, B. Whelan<sup>2</sup>, J. Kipritidis<sup>2</sup>, D. Lee<sup>2</sup>, P. Greer<sup>3</sup>, G. Baroni<sup>1</sup>, P. Keall<sup>2</sup>, M. Riboldi<sup>1</sup>

<sup>1</sup>Politecnico di Milano, Dipartimento di Elettronica- Informazione e Bioingegneria, Milano, Italy

<sup>2</sup>University of Sydney, Radiation Physics Laboratory- Sydney Medical School, Sydney, Australia

<sup>3</sup>Calvary Mater Newcastle, Department of Radiation Oncology, Newcastle, Australia

### Purpose or Objective

MRI-Linac therapy will enable real time adaption of radiotherapy and is being actively developed by several academic and commercial groups. To acquire images of high spatial and temporal resolution, interleaved 2D imaging is typically used. However, to enable closed loop adaptive radiotherapy, accumulated 3D dose is required. A possible way to bridge the gap between 2D and 3D images is via patient-specific motion models. To date, no dosimetric evaluation of a global motion model based on interleaved MRI images has been reported. In this work, we present the use of a global motion model to compensate for geometric changes during treatment and to evaluate dosimetric variations between the delivered and planned dose distributions.

### Material and Methods

4DCT and interleaved sagittal/coronal cine-MRI from a diagnostic scanner (1.5T) were acquired for a lung cancer patient. A global motion model was built on the 4DCT dataset using principal component analysis, and updated through the use of surrogates derived from in-room cine-MRI data (tumor, diaphragm and lung vessel motion). An ITV-based IMRT treatment plan (60Gy in 30 fractions) was developed on the 4DCT and applied to the model output for dose evaluation. Validation of the motion model was performed on a CT/MRI XCAT phantom (1mm resolution), in which the ground truth CT output of the in-room scenario was available at the time sample of the simulated cine-MRI. Analysis of different surrogates as well as their sagittal/coronal motion components were performed in terms of both geometric and dosimetric variations.

### Results

Based on the phantom data, the accuracy of the motion model was 1.2mm/1.6mm on tumor/diaphragm.

Dosimetric analysis confirmed the ability of the model to approximate the ground truth (mean differences of 0.49Gy, 0.12Gy and 0.38Gy for PTV D98, PTV D2 and spinal cord, respectively). For the patient, variations between the in-room inhale phase and the corresponding planning phase were 3.1mm/4.9mm on the tumor/diaphragm. With respect to the planning inhale CT, the model output CT presented differences mainly on the diaphragm position (Figure A). Dosimetric changes with respect to the planned dose were 3.14Gy, 1.82Gy and 0.42Gy for tumor PTV D98, PTV D2 and spinal cord, respectively (Figure B and C). The delivered dose was higher than planned since less motion was present in the MR images than the planning CT.

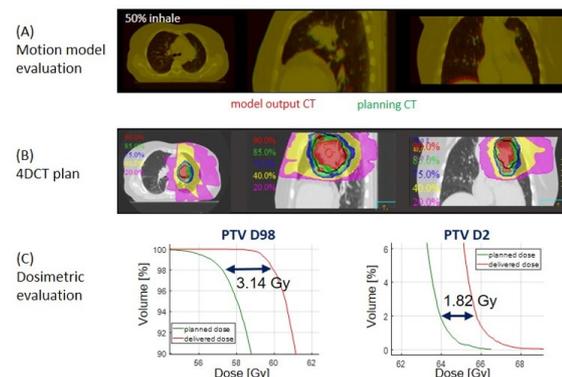

Figure. Geometric and dosimetric evaluation on patient. (A) overlap of model output CT (red) and planning CT (green) at the 50% inhale phase. (B) iso-dose curves of the 4DCT plan. (C) Dose volume histogram of tumor PTV D98 and D2 of planned (green) and delivered (red) dose.

### Conclusion

We provided a dosimetric evaluation based on a global motion model for MRI-guidance. The proposed model built on 4DCT was updated based on interleaved 2D MRI data and validated using a digital phantom. Dosimetric variations on tumor were observed in the patient study, demonstrating the utility and importance of using motion models for dose accumulation. Future work will include improvements in the motion model for MRI-guidance and its application to a larger number of patients.

### OC-0303 Evaluation of lung anatomy vs. lung volume reproducibility for scanned proton treatments under ABC.

L.A. Den Otter<sup>1</sup>, E. Kaza<sup>2</sup>, R.G.J. Kierkels<sup>1</sup>, M.O. Leach<sup>2</sup>, D.J. Collins<sup>2</sup>, J.A. Langendijk<sup>1</sup>, A.C. Knopf<sup>1</sup>

<sup>1</sup>UMCG University Medical Center Groningen, Department of Radiation Oncology, Groningen, The Netherlands

<sup>2</sup>The Institute of Cancer Research and The Royal Marsden Hospital, CR-UK Cancer Imaging Centre, London, United Kingdom

### Purpose or Objective

Proton therapy is a highly conformal way to treat cancer. For the treatment of moving targets, scanned proton therapy delivery is a challenge, as it is sensitive to motion. The use of breath hold mitigates motion effects. Due to the treatment delivery over several fractions with delivery times extending the feasible breath hold duration, high reproducibility of breath holds is required. Active Breathing Control (ABC) is used to perform breath holds with controlled volumes. We investigated whether the lung anatomy is as reproducible as lung volumes under ABC, to consider ABC for scanned proton treatments.

### Material and Methods

For five representative volunteers (3 male, 2 female, age: 25-58, BMI: 19 - 29) MR imaging was performed during ABC at two separate fractions. The image voxel size was 0.7x0.7x3.0 mm<sup>3</sup>. Each fraction consisted of four subsequent breath holds, resulting in a total of eight MRIs per volunteer. The interval between fractions was 1-4

weeks, keeping the same positioning. The intra-fraction reproducibility of the lung anatomy during breath hold was investigated, by comparing the MRI of the first breath hold with the three other MRIs of the same session. The inter-fraction anatomical reproducibility was investigated by comparing the first breath hold MRI of the first session with the four MRIs during the second session. To avoid any influence of setup variation, first a global rigid image registration was performed. Then the lung volume was semi-automatically segmented to define a region of interest for the deformable image registration (DIR). DIR was performed using Mirada RTx v1.2 (Mirada Medical, Ltd.), with a DIR grid resolution of  $3.5 \times 2 \times 3 \text{ mm}^3$ . The deformation vector fields were analyzed using MATLAB v2014b. Magnitudes of the deformation vectors were calculated and combined for all five volunteers. The lung volumes were divided into six segments, to analyze the anatomical displacements on a local level. A boxplot showing the intra- and inter-fraction displacements with a schematic view of the six segments can be seen in figure 1.

## Results

The lung volumes for all breath holds varied by 2% within and 7% between fractions. Looking at all five volunteers, up to 2 mm median intra- and inter-fraction displacements were found for all lung segments. The anatomical reproducibility decreased towards the caudal regions. Inter-fraction displacements were larger than intra-fractional displacements. Maximum displacements (99.3% of the magnitude vectors) reached 6 mm intra-fractionally and did not exceed 8 mm inter-fractionally.

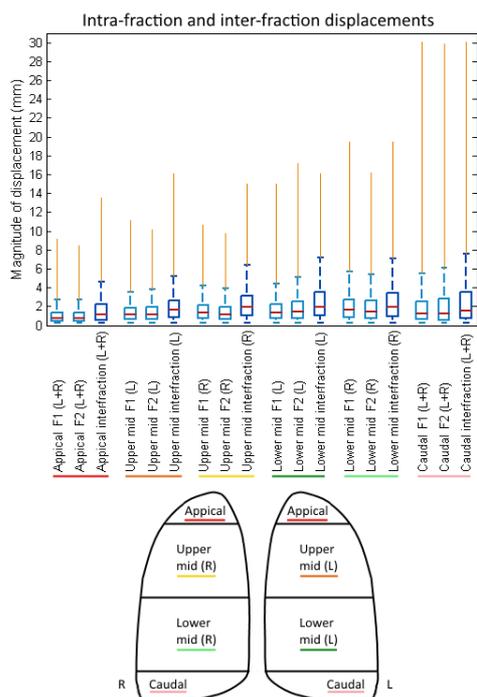

Figure 1: Range of intra-fractional (F1+F2, light blue) and inter-fractional (dark blue) displacements for the five volunteers. Calculated on a local level as shown in the schematic drawing below.

## Conclusion

While the lung volume differences were insignificant, relevant anatomical displacements were found. Moreover, a trend of increased displacements over time could be seen. ABC mitigates motion to some extent. Nevertheless, the remaining reproducibility uncertainties need to be considered during scanned proton therapy treatments. As next step, we aim to include this knowledge in a model to estimate their dosimetric influence for scanning proton therapy.

## OC-0304 Real-time gamma evaluations of motion induced dose errors as QA of liver SBRT tumour tracking

T. Ravkilde<sup>1</sup>, S. Skouboe<sup>1</sup>, R. Hansen<sup>1</sup>, E.S. Worm<sup>1</sup>, P.R. Poulsen<sup>1</sup>

<sup>1</sup>Aarhus University Hospital, Department of Oncology, Aarhus N, Denmark

### Purpose or Objective

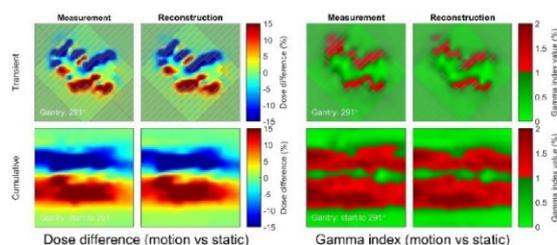

Organ motion during radiotherapy can lead to serious deterioration of the intended dose distribution. As modern radiotherapy shifts increasingly towards escalated doses, steeper dose gradients and hypofractionation, the demands on accurate delivery increase concurrently. A large body of studies show that tumour tracking can be applied to mitigate the effects of motion and restore dose fidelity, yet clinical introduction seems reluctant. In this study we report on a method for continuous evaluation of the tracking dose delivery that conforms to common dose analysis practice and can be acted upon in real time.

### Material and Methods

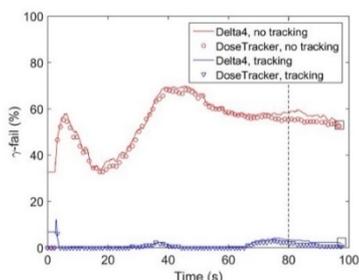

Experiments were performed on a TrueBeam linear accelerator (Varian Medical Systems) with target motion being recorded by an electromagnetic transponder system (Calypso, Varian Medical Systems). A HexaMotion motion stage (Scandidos) reproduced the liver motion traces for five different liver SBRT patients as previously measured using intrafraction kV imaging. VMAT SBRT treatment plans were delivered to the moving phantom with MLC tracking, without tracking (simulating the actual delivery) as well as to a static phantom for reference (planned delivery). Temporally resolved dose distributions were measured at 72 Hz using a Delta4 dosimeter (Scandidos). Accelerator parameters (monitor units, gantry angle, MLC leaf positions, etc.) were streamed at 21 Hz to prototype software that performed continuous reconstruction of the dose in real time by a simplified non-voxel based 4D pencil beam convolution algorithm. Also in real time, but on a separate thread, 3%/3mm gamma evaluations were calculated continuously throughout beam delivery to quantify the deviation from the planned intent. After experiments, the time-resolved gamma tests were compared with the same quantities from the measured data.

### Results

The motion induced gamma errors were well reconstructed both spatially (Figure 1) and temporally (Figure 2). In 95% of the time both actual and planned doses were reconstructed within 100 ms. The median time for reconstruction was 65 ms, which translates into a typical frequency of about 15 Hz. Asynchronously, but also continuously, 95% of gamma evaluations were performed within 1.5 s with the median being at 1.2 s. Over all experiments the root-mean-square difference between reconstructed and measured gamma failure rates was 2.9%.

**Figure 1:** Example of motion induced errors in dose as quantified by dose differences (left) and 3%/3mm gamma failure rates (right). The example was selected as a time of imperfect dose error reconstruction and is marked with a vertical dashed line in Figure 2.

**Figure 2:** Measured (line) and real-time reconstructed (circles) motion induced errors in dose as quantified by 3%/3mm gamma failure rates with tracking (blue) and without tracking (red). Gamma failure rates for the accumulated dose available in the commercial Delta4 software are shown as black boxes. The vertical dashed line marks the time of Figure 1.

## Conclusion

Motion induced errors in dose were accurately and continuously reported by gamma evaluations within two seconds of occurring. Such monitoring may improve patient safety by treatment intervention in case of gross treatment errors and may help to expedite clinical use of tracking. While developed mainly with tumour tracking in mind its use is also readily available for standard non-tracking treatments.

## OC-0305 Validation of Dynamic Treatment-Couch Tracking for Prostate SBRT

S. Ehrbar<sup>1</sup>, S. Schmid<sup>1</sup>, S. Klöck<sup>1</sup>, M. Guckenberger<sup>1</sup>, O. Riesterer<sup>1</sup>, S. Tanadini-Lang<sup>1</sup>

<sup>1</sup>University Hospital Zürich, Department of Radiation Oncology, Zurich, Switzerland

### Purpose or Objective

In stereotactic body radiation therapy (SBRT) of prostatic cancer, a high dose per fraction is applied to the treated region with steep dose gradients. Intrafractional prostate motion can occur unpredictably during the treatment and lead to target miss. Missing the target results in high doses to nearby organs which can cause complications. It is essential for a prostate SBRT treatment to observe and mitigate this motion. Dynamic treatment-couch tracking is a real-time adaptive therapy technique, compensating the prostate displacement by counter-movement with the treatment couch. This work investigated the dosimetric benefit of couch tracking for prostate SBRT treatments in the presence of prostatic motion.

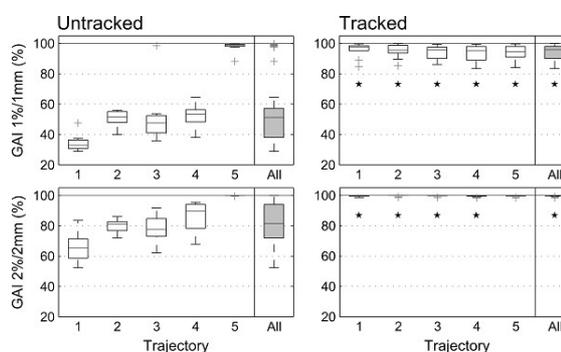

### Material and Methods

Ten previously treated prostate cancer patients with one index lesion were selected. Treatment target volumes (prostate and index lesion), and organs at risk (OAR: bladder, rectum and urethra) were delineated using the patient's treatment CT and MRI scans. SBRT treatment plans with integrated boost were prepared with a prescribed dose of 5x7 Gy to the prostate and 5x8 Gy to the index lesion. The treatment plans were applied with a linear accelerator to a phantom, which was either i) in static position, ii) moved according to five prostate motion curves without motion compensation or iii) with real-time compensation using electromagnetic guided couch tracking. Electromagnetic transponders were mounted on the phantom surface and their geometrical position was evaluated in the tracked and untracked situation.

Radiation dose was measured within the phantom by a biplanar diode array. The dosimetric performance of couch tracking was compared to no compensation: Gamma agreement and other dose parameters were evaluated within the biplanar array, as well as target- and organ-specifically.

### Results

The root-mean-square error of the motion traces (range: 0.8-4.4 mm) was substantially reduced with couch tracking (0.2-0.4 mm). Spikes (>1 mm) in the compensated motion curve were only observed at steep gradients (>7.5 mm/s). The dose measurements with the phantom showed on the 1%/1 mm level significantly better gamma agreement with tracked motion (range: 83.4%-100%) than with untracked motion (28.9%-99.7%). Also with the 2%/2 mm criterion, gamma agreement was significantly superior for the tracked motion (98.4%-100%) compared to the untracked (52.3%-100%) (see Fig. 1). Also the organ specific evaluation resulted in significantly better target coverage with tracking, however the dose to the rectum and bladder showed a dependency on the motion direction.

**Figure 3:** Gamma agreement of either no motion compensation (untracked) or couch tracking (tracked) with the static reference. Significant differences ( $p < 0.05$ ) between tracked and untracked groups are marked with stars.

## Conclusion

Couch tracking was able to mitigate the prostate motion and improved the dosimetric accuracy of prostate SBRT. The treatment couch was able to compensate the prostatic motion with only some minor residual motion at steep motion gradients. Therefore, couch tracking combined with electromagnetic position monitoring for prostate SBRT is feasible and improves the accuracy in treatment delivery when prostate motion is present.

## OC-0306 Is re-gating a robust motion mitigation approach independent of PBS scanning scenario?

Y. Zhang<sup>1</sup>, I. Huth<sup>2</sup>, M. Wegner<sup>2</sup>, D.C. Weber<sup>1</sup>, A.J. Lomax<sup>1</sup>

<sup>1</sup>Paul Scherrer Institute PSI, Center for Proton Therapy, Villigen PSI, Switzerland

<sup>2</sup>Varian Medical Systems, Particle Therapy GmbH, Troisdorf, Germany

### Purpose or Objective

Different scanned proton therapy (PBS) systems provide different scanning dynamics, directly changing the temporal interference between pencil beam delivery and tumour motion. With this study, we have systematically evaluated interplay effects, and compared motion mitigation performance, for different PBS scanning delivery scenarios.

### Material and Methods

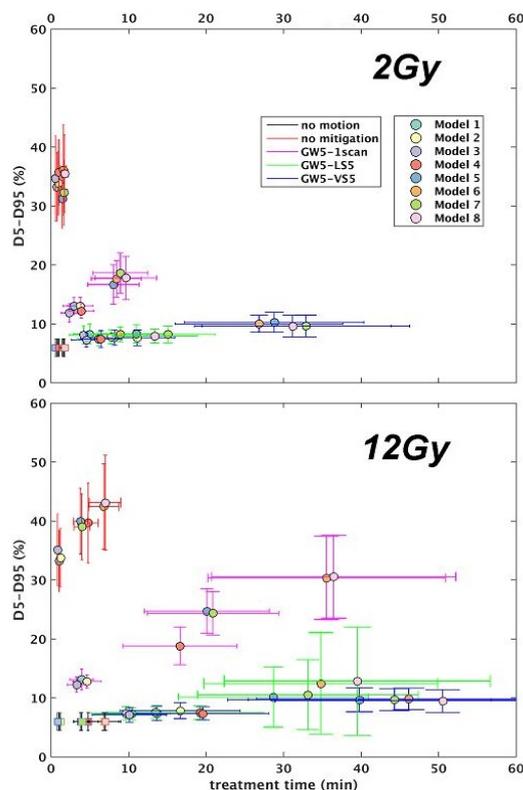

Using 6 4DCT(MRI) datasets of liver tumours, with irregular motions >10mm (CTV: 100-400cc; period: 5.3/6.3s), 4D treatments assuming different prescription doses (2/12Gy), field directions (AP/LR) and mitigation approaches (3 gating windows (GW) with or without 1-9 layered (LS) or volumetric (VS) rescanning) were simulated for 8 PBS scanning scenarios (see table). As such,

simulations were performed for spot or raster scanning (positioning with/without beam pulse between successive spots), for constant and varied beam current, and for cyclotron or synchrotron beam dynamics (e.g. continuous or pulsed beam). The resulting 4D plans were compared using dose-volume metrics (D5-D95, V95) for the CTV, as well as total predicted treatment time (TT).

Model NO.	Lateral scanning	Beam current (proton number/second)	Energy switching
1	Raster (20mm/ms)	varied	Cyclotron
2	Spot (3ms)	0.8-12 x 10 <sup>9</sup>	700ms
3	Raster (20mm/ms)	Constant 1.8 x 10 <sup>9</sup>	Cyclotron
4	Spot (3ms)		80ms
5	Raster (20mm/ms)	Varied 0.8-12 x 10 <sup>9</sup>	Synchrotron
6	Spot (3ms)	Constant 2.27 x 10 <sup>9</sup>	
7	Raster (20mm/ms)	Varied 0.8-12 x 10 <sup>9</sup>	(p#/load = 10 <sup>10</sup> , Spill time= 4.4s)
8	Spot (3ms)	Constant 2.27 x 10 <sup>9</sup>	

## Results

Independent of the delivery scenario and prescribed dose, neither gating alone nor rescanning alone could mitigate motion effects completely, with residual interplay effects (D<sub>5-95</sub>) of more than 10-20% being observed for GW=5mm w.o. rescanning (shown by purple error-bars). Moreover, the D<sub>5-95</sub> of synchrotron based simulations were found to be >5% higher than for cyclotron scenarios. However, with re-gating (re-scanning + gating, shown by green and blue error-bars), motion mitigation performance was found to be similar effective (close to static reference) for all scanning dynamics and rescan modes, with the main difference being only in treatment efficiency. Without any mitigation, mean TT's for the 2Gy/12Gy plans were 2x/3x longer for synchrotron than for cyclotron scenarios. For re-gating (GW5+LS5), mean TT's of synchrotron based plans were on average 2.5x higher when combined with LS and 3.5x higher when combined with VS. Moreover, the advantage of varying beam current has been demonstrated by the approximately constant TT as a function of prescription dose. In addition, for the high dose scenario, variations caused by differences in geometry, motion amplitude, field direction and starting phase, are smaller for varying beam current scenarios in comparison to corresponding constant scenarios.

## Conclusion

In sum, independently of PBS delivery scenario, the treatment of liver tumours under free-breathing conditions is not recommended for motions over 10mm, even when applying large numbers of rescans. However, re-gating (LS5+GW5) is predicted to be sufficient to achieve acceptable 4D plan quality for all scenarios, even though synchrotron based delivery could have a significant added time cost in comparison to cyclotron based systems.

## Symposium: Focus on ART: the clinical difficulties

### SP-0307 Multi-parametric functional PET/MR imaging for RT individualisation

D. Thorwarth<sup>1</sup>

<sup>1</sup>University of Tübingen, Section for Biomedical Physics-Department of Radiation Oncology, Tübingen, Germany

Multi-parametric functional imaging using combined positron emission tomography and magnetic resonance (PET/MR) imaging may be highly beneficial for the assessment of tumour stage, size, therapy response and functional information before and during radiotherapy (RT) in order to guide not only geometrical but also biological adaptation during the course of RT treatment. This talk will discuss a number of issues, which might compromise the use of multi-parametric functional imaging in a clinical setting. In order to register functional PET/MR image data to the planning CT of an individual patient, tailored patient positioning devices and dedicated algorithms for PET attenuation correction with respect to the hardware components of the positioning aids are required. Furthermore, robust and accurate deformable registration strategies may be required to match PET/MR data acquired during RT to baseline imaging data.

In addition, first results of a multi-parametric PET/MR imaging study in head-and-neck cancer (HNC) patients will be discussed. Here, [18F]FDG PET/CT images were acquired in addition to functional PET/MR data consisting of [18F]FMISO PET, anatomical T1- and T2-weighted as

well as diffusion weighted (DW) and dynamic contrast enhanced (DCE) MR imaging. Voxel-based and regional correlation analysis of mutual parameter pairs showed moderate to low parameter correlations. However, on a patient-to-patient basis large variations were observed for most parameter correlations. Consequently, robust and accurate workflows and image acquisition protocols need to be identified in order to use multi-parametric functional PET/MR imaging in the future for adapted RT concepts in a clinical context.

**SP-0308 Metabolic and functional MRI integration for glioblastoma dose-painting trial.**

A. Laprie<sup>1</sup>

<sup>1</sup>*Institut Claudius Regaud, Toulouse Cedex 09, France*

The ongoing spectro-glio trial (NCT01507506) is a phase III multicentric randomized trial for newly diagnosed glioblastoma.

It has included 165 patients among the 220 planned. It compares arm A : STUPP protocol ( 60 GY + TMZ) with arm B that includes an additional SIB targeted at MR spectroscopic abnormalities ( CHO/NAA>2)+tumor bed at a dose of 72Gy/2.4Gy

In this presentation we will discuss the original modalities, the difficulties met and the solutions found for the particularity of this trial :  
 - multicentric use of 3D MR spectroscopic imaging  
 - development of an innovative technique of integration of MR spectroscopic imaging to RT-scan  
 - centralized delineation of arm B patients - online quality control of dosimetry in arm B patients  
 - database development  
 - analysis techniques of this large prospective database of anatomic, perfusion, diffusion and spectroscopic imaging of glioblastoma. ( follow-up every 3 months until relapse)  
 - preliminary imaging results

**SP-0309 Plan of the day and dose-escalation for bladder cancer (RAIDER Trial)**

H. McNair<sup>1</sup>

<sup>1</sup>*The Institute of Cancer Research and The Royal Marsden NHS Foundation Trust, Sutton, United Kingdom*

The major challenge in delivering accurate radiotherapy to the bladder is to compensate for the daily variation in organ size, shape and position. This change is mainly due to differing degrees of bladder filling and can be influenced by change in rectal volume. The plan of the day approach has the potential to improve outcomes by improving target coverage and decrease the dose to bowel. However the unpredictable nature of bladder filling and changes in organ dimensions require confident and timely decision making for treatment delivery. This is of particular importance when the dose to the tumour bed is escalated. This presentation will discuss the importance of achieving a representative reference image and the practicalities of the patient maintaining a consistent drinking protocol. Clinical examples will be used to illustrate common imaging problems with appropriate decision making, in particular when not to proceed to treatment. The importance of staff training and maintaining competency to achieve consistent image selection will also be discussed.

**SP-0310 Rigid registration techniques for different imaging modalities**

N. Nesvacil<sup>1</sup>

<sup>1</sup>*Medical University of Vienna, Department of Radiotherapy- CCC- Christian Doppler Laboratory for Medical Radiation Research for Radiation Oncology, Vienna, Austria*

Image registration has become an important part of treatment planning and execution in 3D image guided external beam radiotherapy (EBRT) and brachytherapy (BT) during the last decades. In principle, the same algorithms for rigid or non-rigid image registration can be applied to either type of radiotherapy. However, for their application in brachytherapy the presence of the brachytherapy delivery device, i.e. the applicator, plays an essential role. This presentation will provide an overview of rigid registration techniques in brachytherapy, compared to external beam radiotherapy.

In gynaecological brachytherapy, where the applicator and CTV might move in relation to the bony anatomy during the course of a (multi-fractionated) treatment, applicator-based rigid registration can be used to combine images for treatment planning acquired with the same or different modalities at different time points. One of the most useful applications of this technique is to transfer target contours defined on a reference image, e.g. an MRI at the time of the first BT, to subsequent CT image volumes for planning of further BT fractions, if MRI is not always available for dose plan adaptation to the anatomy of the day. Requirements and pitfalls for clinical applications of this technique will be discussed. In order to analyse interfraction variations for target and organs at risk (OARs) based on image volumes acquired at different time points, rigid image registration can provide a good estimate of the dosimetric impact of anatomical changes between applicator, CTV and OARs. Clinical examples will be discussed for different treatment sites. Limitations of the technique will be summarized and special focus will be given to prostate and gynaecological BT treatment planning.

Multi-modal rigid image registration for brachytherapy is also used to improve target delineation and dose plan optimization for a single fraction. MRI acquired before brachytherapy can be combined with CT images for treatment planning of prostate cancer, in order to visualize and delineate intraprostatic lesions as boost target volumes in HDR or LDR brachytherapy. In the setting of gynaecological cancer brachytherapy where only CT is available for visualization of the applicator and surrounding organs after implantation, rigid registration of ultrasound images obtained with applicator in situ could be used in the future for dual modality dose planning of a single fraction. Challenges and solutions for the registration of ultrasound and CT images, such as determining the applicator position in the ultrasound image volume, will be explored to conclude this presentation.

**SP-0311 Deformable registration for dose summation**

K. Tanderup<sup>1</sup>

<sup>1</sup>*Aarhus University Hospital, Department of Oncology, Aarhus C, Denmark*

Dose summation across brachytherapy fractions and accumulation with external beam radiotherapy (EBRT) dose is essential for assessment of total dose to both targets and organs at risk in treatments with fractionated brachytherapy and in combinations with EBRT. Brachytherapy dose distributions are highly

heterogeneous, and the EBRT dose distribution may also include significant dose gradients in the vicinity of the brachytherapy high dose region, e.g. in case of lymph node boosts. Organ motion between fractions as well as change in anatomy between brachytherapy and EBRT constitute specific challenges for dose summation. Deformable image registration (DIR) aims to match each tissue voxel irradiated by each fraction of external-beam radiation with the corresponding voxel irradiated by each fraction of brachytherapy. However, DIR is related with specific uncertainties and does not necessarily provide added value for dose accumulation. The alternative of accumulating dose through DIR is to perform direct addition of DVH parameters as recommended in the ICRU report 89. Direct addition assumes inherently that hot spots and cold spots remain in the same spatial region across succeeding fractions and is therefore also related with uncertainties or even not appropriate for certain scenarios. DIR can be carried out with deformation models based on image intensity, biomechanical models, or combinations of these. Biomechanical models take into account organ shapes and potentially biomechanical properties of organs or organ walls/surfaces, such as elasticity. Biomechanical models based on contours need to have these defined in both source and target images, and the correspondence of contours becomes part of the objective function which drives the optimisation. DIR models based entirely on image intensity do not take into account contours, and the objective function is based on correspondence in image intensity. The major questions with regard to DIR and dose accumulation in brachytherapy are: 1) Is it problematic to accumulate dose without DIR? I.e. what is the accuracy and limitations of dose accumulation with DVH addition? 2) Can DIR solve the problem? I.e. what is the accuracy of DIR-based dose accumulation? For summation of EBRT and brachytherapy, direct DVH addition is accurate if the EBRT dose distribution is homogenous in the region where the BT boost is going to be delivered. In case of a homogeneous EBRT dose, the EBRT dose contribution to the primary target  $D_{90\%}$  and  $D_{98\%}$  as well as  $D_{2cm3}$  for organs at risk will be equal to the prescribed EBRT dose. Dose distributions from four-field -box techniques are normally homogeneous. Furthermore, it is also possible to control the homogeneity of IMRT and VMAT in the region the the BT boost through dose optimisation, e.g. by introducing help structures in the region of the primary target/GTV with specific constraints on homogeneity. However, in the case of lymph node boosts which are in close relation to the primary target and the BT boosted region, direct addition of EBRT and BT DVH parameters may not reflect the true accumulated dose. DIR has not been investigated for this purpose, but may provide an added value. For summation of dose from succeeding BT fractions, there are indications that DVH addition has an accuracy better than 5% for organs such as bladder and rectum, as hotspots are quite stable across brachytherapy fractions. For target structures, there have not been any systematic evaluations, but often cold spots are located in the same region of the target, and DVH addition is assumed to work well. For highly mobile organs such as sigmoid colon or bowel loops, it is well known that hotspots may end up in very different parts of the loops and DVH addition is expected to significantly overestimate the hotspot dose. DIR algorithms which are based on contours and biomechanical models have been demonstrated to work well for bladder and improves dose assessment although the improvement with DIR as compared to direct DVH addition is normally less than 5%. However, some DIR algorithms based on image intensities can be related with significant uncertainties and may provide dose assessments which are less accurate than with DVH addition, and DIR should therefore be used with great caution. Sigmoid and bowel are highly deformable organs and represent a significant challenge for DIR. There are

currently not any deformable registration algorithms which have shown performance in sigmoid and bowel which is sufficient for dose accumulation. In conclusion, DVH addition is currently recommended by the ICRU 89 report for dose summation in brachytherapy, and provides in most scenarios a good accuracy for assessment of total dose in targets and in organs such as bladder and rectum. Dose summation in highly mobile organs such as sigmoid and bowel is currently related with significant uncertainties, and there could be potential to improve this with appropriate DIR algorithms.

#### SP-0312 Imaging and fusion techniques for focal brachytherapy

L. Beaulieu<sup>1</sup>

<sup>1</sup>Laval University - Faculty of Science and Engineering, Université laval Cancer Research Centre, Québec City, Canada

Over the last decade, numerous technological developments have made brachytherapy one of the most precise needle-based procedures on the market. The cornerstone of interstitial brachytherapy for many years now has clearly been real-time ultrasound (US) image-guidance and more recently real-time 3DUS image-guidance. From whole gland prostate cancer treatments to focal boosts and now focal therapy, brachytherapy is head of the curve of any other prostate focal therapy modality at this time in terms of precision and accuracy. However, current standard US-guidance is not sufficient for focal therapy; our real-time image-guidance technique needs to be supplemented with more information. This presentation will look at the role of multi-parametric MRI in prostate focal therapy as well as US-augmented with MRI for real-time guidance. This brings the notion of augmented reality as well as the challenge of image fusion among two very different imaging modalities and image sets also taken under very different conditions. We will also discuss the topic of merging tissue information (e.g. biopsy) with imaging data to provide a complete cancer burden maps for targeting purposes. Finally, we will provide a forward-looking view of real-time multi-parametric 3DUS guidance and targeting for such procedures.

#### OC-0313 What is the effect of axillary treatment on patient reported outcomes in breast cancer patients?

M.L. Gregorowitsch<sup>1</sup>, H.M. Verkooijen<sup>1</sup>, N. Fuhler<sup>1</sup>, D.A. Young Afat<sup>1</sup>, A.N.T. Kotte<sup>1</sup>, M. Vulpen van<sup>1</sup>, C.H. Gils van<sup>2</sup>, D.H. Bongard van den<sup>1</sup>

<sup>1</sup>University Medical Center, Radiation Oncology, Utrecht, The Netherlands

<sup>2</sup>Julius Center for Health Sciences and Primary Care-University Medical Center, Epidemiology, Utrecht, The Netherlands

#### Purpose or Objective

In breast cancer patients with limited (sentinel) lymph node involvement, axillary lymph node dissection (ALND) is increasingly being replaced by axillary radiotherapy. Since ALND is associated with a high risk of upper-body morbidity, axillary radiotherapy might be favorable in patients with limited lymph node involvement. However radiation-induced morbidity can also influence quality of life, the extent of which may depend on the irradiated volumes. We compared patient reported outcome measures (PROMs) of breast cancer patients at the start adjuvant radiotherapy, during and after radiotherapy according to the extent of axillary treatment.

## Material and Methods

This study was conducted within the Dutch UMBRELLA cohort (i.e. prospective observational cohort including breast cancer patients indicated to receive adjuvant radiotherapy at the department of Radiation Oncology at the University Medical Centre Utrecht). All participants consented to collection of clinical data and patient reported outcomes (PROMs). Arm function and Quality of Life (QoL) were measured by EORTC QLQ-C30 and BR23. We first compared differences in mean PROM scores between patients who underwent ALND and those who did not by two sample t-test. In a second step, we estimated the effect of extent of axillary radiotherapy on PROM scores in patients stratified on ALND, and used analyses of variance (ANOVA) to test for differences. Finally, we compared patients who underwent ALND and local RT with non-ALND patients treated with axillary RT to estimate the differences between axillary RT and ALND.

## Results

Between October 2013 and December 2015, 521 patients were enrolled. In total 75% (n=390) of the patients were treated with local radiotherapy on the breast/chest wall (local RT), 10% (n=53) received additional axillary radiotherapy on level I and II (local RT + level I-II) and 15% (n=78) of the patients received local radiotherapy with axillary irradiation including levels III and IV (local RT + level I-IV) (Table 1). ALND (n=84) was performed in 10% (n=40) of the patients in the local RT group and in 56% (n=44) of the locoregional RT group (Table 1). Patients in the ALND group reported significantly lower arm function compared to the non-ALND group (Figure 1A-B). For patients who underwent ALND and local RT, arm symptoms were significantly worse at baseline and 3 months compared to non-ALND patients who received local RT and axillary (level I-II or level I-IV) irradiation (MD -15.2, p=0.00 and -13.4, p=0.00) (Figure 1C). Overall QoL scores were similar.

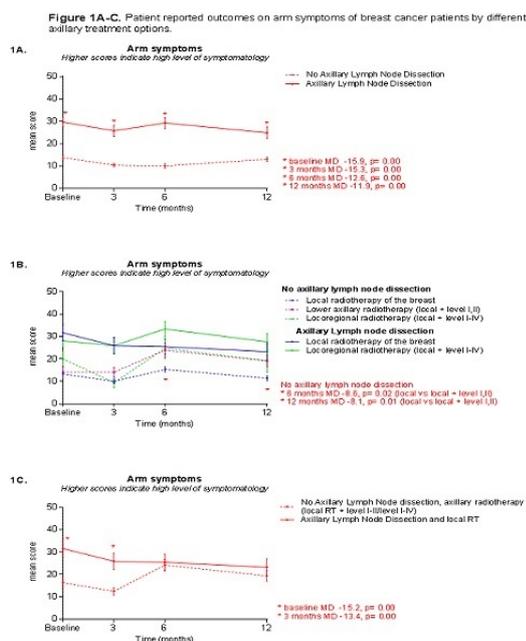

Table 1. Treatment and tumor characteristics of all analyzed breast cancer patients (n=521) stratified by different radiotherapy treatment options.

	Local RT (N=390)	Local RT + Lower axillary RT (N=53)	Local RT + Level I-IV RT (N=78)
Age in years (mean, SD)	58 (10.2)	59 (10.5)	54 (11.1)

Yes	152 (39.0)	36 (67.9)	57 (73.1)
No	238 (61.0)	17 (32.1)	21 (26.9)

Abbreviations: ALND, axillary lymph node dissection; RT, radiotherapy; SD, standard deviation; NA, not applicable

## Conclusion

Arm function in patients treated with ALND was worse compared to patients without ALND. Patients reported significant more arm symptomatology after ALND followed by local RT compared to non-ALND patients treated with local RT and axillary irradiation in the first 3 months after start of RT. Updated results on PROMs with increased patient numbers, longer follow-up and multivariable analyses will be available at the 36<sup>th</sup> ESTRO conference.

**Background:** Local cancer relapse rates after breast conservation surgery followed by radiotherapy have fallen sharply in many countries with risk influenced by patient age and clinico-pathological factors. In women at lower than average risk of local relapse, partial breast radiotherapy restricted to the vicinity of the original tumour is hypothesised to improve the balance of beneficial versus adverse effects compared with whole breast radiotherapy.

**Methods:** The IMPORT LOW trial (ISRCTN12852634) recruited women aged  $\geq 50$  years after breast conserving surgery for invasive ductal adenocarcinoma pT $\leq 3$ cm, pN0-3, G1-3 and  $\geq 2$ mm resection margins. Using 15 daily treatments, patients were randomly allocated (1:1:1) to 40 Gy whole breast radiotherapy (control), 36 Gy whole breast plus 40 Gy to partial breast (reduced dose) or 40 Gy partial breast only (partial breast). Primary endpoint was ipsilateral local relapse rate (80% power to exclude a +2.5% non-inferiority margin at 5 years for each test group).

**Findings:** Between May 2007 and October 2010, 2018 women were recruited (control n=675, reduced dose: n=674, partial breast: n=669). With a 72.2 month median follow-up (IQR 61.7-83.2), 5-year local relapse rates were 1.1% (95%CI 0.5-2.3), 0.2% (0.02-1.2) and 0.5% (0.2-1.4) in control, reduced dose and partial breast groups. Absolute differences in local relapse rate compared with the control group were -0.73% (-0.99, 0.22) for the reduced dose and -0.38% (-0.84, 0.90) for the partial breast groups, demonstrating non-inferiority for both test groups. Photographs, patients and clinicians reported similar or lower levels of adverse effects after reduced dose or partial breast radiotherapy compared with whole breast radiotherapy (see Table 1).

Table 1 Patient, photographic and clinician assessment of normal tissue effects at 5 years

Year 5 assessments		Whole breast n (%)	Reduced dose n (%)	Partial breast n (%)
Patient reported: change in appearance of breast	Number of assessments	295	325	331
	None/mild	215 (73)	259 (80)	282 (85)
	Moderate/marked	80 (27)	66 (20)	49 (15)
	P-value	-	0.047*	<0.001*
Photographs: Change in breast appearance (comparison with pre-RT baseline)	Number of assessments	262	264	279
	None	202 (77)	205 (78)	229 (82)
	Mild/Marked	60 (23)	59 (22)	50 (18)
	P-value	-	0.917*	0.165*
Clinician assessed: Worst grade of normal tissue event	Number of assessments	457	480	474
	None/mild	397 (87)	432 (90)	425 (90)
	Moderate/Marked	60 (13)	48 (10)	49 (10)
	P-value	-	0.152	0.221*

\*Fishers Exact test compared with whole breast RT

**Interpretation:** At 5 years, partial breast and reduced dose radiotherapy showed local relapse rates non-inferior to that observed following whole breast radiotherapy and

produced equivalent or milder late normal tissue side effects. This simple radiotherapy technique is implementable in radiotherapy centres worldwide. Funding: Cancer Research UK (CRUK/06/003).

<sup>8</sup>Copenhagen University Hospital- Rigshospitalet, DBCG, Copenhagen, Denmark

<sup>9</sup>Aarhus University Hospital, Dept Expt. Clin. Oncology, Aarhus C, Denmark

**Objective** The risk of local recurrence after adjuvant radiation therapy (RT) of early breast cancer (BC) is now so low that ESTRO and ASTRO have suggested guidelines to select patients who may be safely treated with partial breast (PBI) and not whole breast irradiation (WBI). In the Danish Breast Cancer Group (DBCG) the randomized DBCG PBI trial was initiated to safely introduce PBI as standard in DK.

**Material/Methods** Patients  $\geq 60$  years operated with breast conservation for early non-lobular breast cancer (BC) pT1 pN0, ER+, grade 1 or 2, HER2-, margin  $\geq 2$ mm were enrolled and randomized to PBI vs WBI, all cases based on 40Gy/15 fr. Strata were institution and endocrine therapy. The primary endpoint was breast induration 3 years after RT, secondary endpoints were other morbidities, genetic risk profile for RT-induced fibrosis and recurrences. ClinicalTrial NCT00892814.

**Results** In 6 RT departments in DK and D 882 pts were enrolled in 2009-16. At analysis 353 pts (40%) had  $\geq 3$  years follow up. At 3 years grade 2-3 induration was detected in 6.4% in the PBI arm and in 7.7% in the WBI arm (HR 0.76, 95% CI, 0.39-1.47). At 3 years, comparing the PBI with the WBI arm there were no differences in dyspigmentation (8.1% vs 11.0%), telangiectasia grade 2-3 (5.3% vs 8.9%), edema grade 2-3 (0.6% vs 0.6%), scar grade 2-3 (21.5% vs 17.1%), and global cosmetic outcome (excellent/good) was 84.3% vs 83.9%, respectively. At 3 years patients treated with PBI or WBI reported excellent/good satisfaction with the treated breast in 92.5% vs 91.2% of cases, and 83.2% vs 81.8% when reporting satisfaction with the treated breast compared with the non-treated breast. In the PBI / WBI arm local recurrence was reported in 1 pt / 2 pts, regional recurrences 0 pt / 0 pt, distant failure 1 pt / 2 pts, new contralateral BC / DCIS 2 pts / 2 pts and other malignancy 8 pts / 16 pts. One patient had died from BC, 7 from other malignancy, 7 from non-cancer causes. Updated results will be provided at ESTRO 36. **Conclusion** Using 40/15 fr for PBI in selected early node-negative BC patients results in few late RT induced morbidities with no difference compared with WBI. These results are in harmony with results from the large UK IMPORT LOW trial using the same RT technique. Thus 40 Gy/15 fr external beam PBI is now DBCG standard for breast RT in patients fulfilling the inclusion criteria for the DBCG PBI trial.

### OC-0316 Single dose external beam preoperative radiotherapy in breast cancer: experience and guidelines

K.R. Charaghvandi<sup>1</sup>, S. Yoo<sup>2</sup>, B. Van Asselen<sup>1</sup>, M.D. Den Hartogh<sup>1</sup>, H.J.G.D. Van den Bongard<sup>1</sup>, J.K. Horton<sup>2</sup>  
<sup>1</sup>University Medical Center Utrecht, Radiation Oncology Department, Utrecht, The Netherlands  
<sup>2</sup>Duke Cancer Center, Department of Radiation Oncology, Durham, USA

#### Purpose or Objective

In patients treated with breast-conserving surgery, suboptimal cosmetic results have been reported following post-operative 3D-conformal accelerated partial breast irradiation (APBI) [1]. The delivery of radiation (RT) preoperatively to the intact tumor enables better target visualization and reduction in treatment volumes, and thus, the potential for less normal tissue toxicity [2]. We compiled our clinical experience and dosimetric data to develop practical guidelines for this new treatment approach.

#### Material and Methods

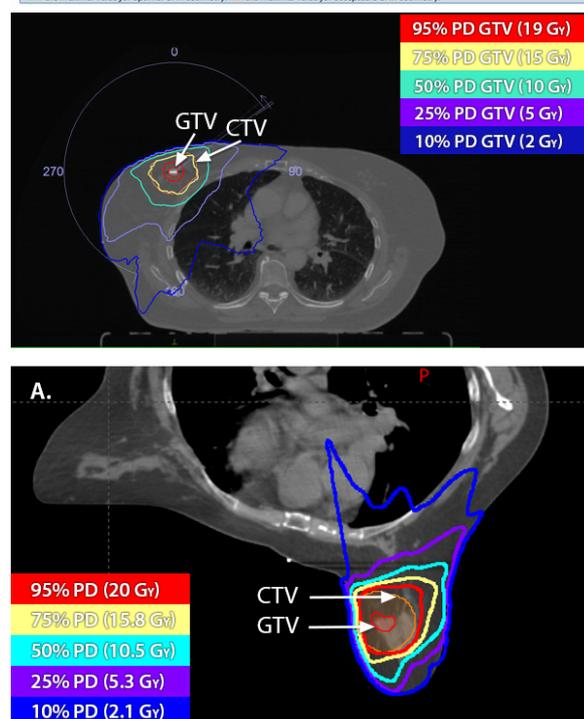

Dosimetry and toxicity data were pooled from 2 preoperative single dose APBI cohorts and 1 planning-study [table 1]. In an American dose escalation trial, patients  $\geq 55$  years, with non-lobular cT1N0Mx or DCIS received a single dose of 15, 18 or 21Gy (1.5cm CTV margin) using IMRT in the prone position (n=32) followed by lumpectomy within 10 days [fig 1A]. In the Netherlands, the feasibility of VMAT-based supine APBI (20 Gy to tumor, 15Gy to 20mm clinical target volume(CTV)) was evaluated initially in a planning study (n=20) and is currently ongoing in women  $\geq 50$  years with cT1-2(max. 3 cm)N0Mx non-lobular carcinoma (n=10) [fig. 1]. In this trial, lumpectomy is planned 6 months after RT. Acute toxicity was scored according to CTCAE version 4.03. Single dose APBI constraints were derived from pooled OAR estimates. The limit for optimal OAR dosimetry was set at the 75<sup>th</sup> percentile, whereas the 90<sup>th</sup> percentile represented non-optimal but acceptable dosimetry. Replanning of the US cohort was performed to check the adherence of these constraints for uniform single dose 21Gy APBI with a 20mm CTV margin (n=32).

#### Results

In the dose escalation cohort (n=32), grade 1 local radiation dermatitis, fibrosis and fatigue developed in 39%, 23% and 6% of the cases within 90 days after RT. At a median follow-up of 57 days in the 15/20Gy simultaneous boost cohort (n=10) grade 1 fatigue and local fibrosis was encountered in 90% and 80% of patients, without any radiation dermatitis. In both cohorts no acute  $\geq$ grade 3 toxicity developed. Based on pooled OAR estimates, optimal dosimetry was defined as a maximum value of 0.7Gy for the mean heart dose, 1.5Gy Dmax for contralateral breast, 1.3Gy for mean ipsilateral lung dose, and 12.3Gy as D20cc dose to chest wall [table 1]. All replanning plans adhered to these constraints. At least acceptable mean ipsilateral breast dose (max. 5.5Gy) was achieved in 97% of cases. Optimal skin dosimetry was set at Dmax  $\leq$ 100% prescription dose, D1cc  $\leq$ 13.2Gy and D10cc  $\leq$ 10.0Gy.

A. TREATMENT PLANNING	Cohorts 15, 18, 21 and 15/20 Gy median (IQR) [10 <sup>th</sup> -90 <sup>th</sup> percentile] (N=62)	Replanning cohort 21 Gy median (IQR) (N=32)

xxxx: the maximal value for optimal OAR dosimetry, xxx: the maximal value for acceptable OAR dosimetry.

#### Conclusion

Acute toxicity following single dose IMRT-based preoperative APBI appears to be mild. Clinically feasible optimal and acceptable OAR constraints were developed for future studies. Long-term follow-up is required for validation and the skin dosimetry constraints, in particular, may need additional modification based on long-term outcomes. Chronic toxicity will be available at the 36<sup>th</sup> ESTRO conference.

<sup>1</sup>Università Cattolica del Sacro Cuore -Policlinico A. Gemelli, Radiation Oncology Department, Rome, Italy

<sup>2</sup>Università Cattolica del Sacro Cuore -Policlinico A. Gemelli, Radiology Department, Rome, Italy

<sup>3</sup>Università Cattolica del Sacro Cuore -Policlinico A. Gemelli, Gynecology Department, Rome, Italy

#### Purpose or Objective

Standard treatment in cervical cancer (CC) is largely based on chemoradiation (CRT) for locally advanced stages. The role of surgery after a first time of CRT is limited to selected protocols. In such cases it is possible to assess the pathological complete response (PCR). A fractal is an object having geometric shape that can be divided into subparts, each of which is a reduced copy of the whole. This property, known as self-similarity, can be measured by the Fractal Dimension (FD). Aim of this study is finding an enhanced by FD radiomics signature detecting patients with PCR.

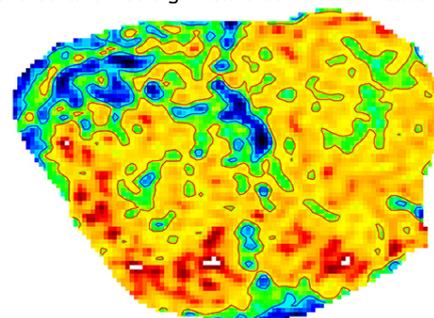

#### Material and Methods

Pathologically proven CC patients underwent to CRT after MR definition of the local stage. T2 High-Resolution images were used for delineating GTV. A home-made software was used for assessing radiomics features after pre-processing images by Laplacian of Gaussian (LoG) filter and tuning its  $\sigma$  parameter, and for extracting fractal dimension (FD) on raw images. FD was extracted at different threshold levels considering all deciles between 10% and 100% of signal intervals inside the GTV volume analyzed slice by slice by using the box-counting technique. Stepwise logistic regression (SLR) models were used for predicting PCR using FIGO Stage, 1<sup>st</sup> order features (skewness, kurtosis, entropy) and different thresholds for FD. AUC of ROC and calibration, were determined for internal validation.

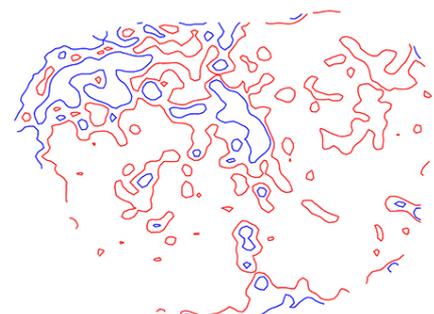

#### Results

177 patients were retrospectively recruited (FIGO stage Ib - IVb). FD was the only significant predictor for the whole dataset in SLR (MaxDF@10%: P-Value<0.001, MinDF@0-90%: P-Value<0.05, see fig. 1). AUC of ROC was 0.70 with not significant deviance at calibration. After selecting patients according to the MR pixel spacing (PS) the most numerous group was found in patients having PS=0.58mm (69 patients). A new SLR model showed significance of entropy ( $\sigma=2.36\text{mm}$ , P-Value<0.05), kurtosis ( $\sigma=1.23\text{mm}$ , P-Value<0.01) and MinDF@0-90% (P-Value<0.01), with AUC

of ROC=0.80 and not significant deviance in calibration.

Example of voxel thresholding for fractal dimension analysis: each color represents a decile in the 10% - 100% scale of voxel intensities.

The two levels significant in the analysis: **blue** is the 10% of the voxel intensities (DF10%), **red** are the limits of the 0-90% voxel intensities interval. (DF90%)

#### Conclusion

Radiomics can be an interesting perspective for detecting patients with CC who will show PCR and subsequently could result in better prognosis. Even considering that CRT followed by surgery is not a standard treatment this workflow gave us the chance to analyze the relationship between radiomics signature and pathological findings, not feasible in CRT alone. An external validation of the signature is planned to evaluate the stability of this model by using different MR scanners at diagnosis time.

#### OC-0318 Hematological toxicity during bowel sparing IMRT: Exploratory analysis from PARCER Phase III trial.

S. Lewis<sup>1</sup>, S. Chopra<sup>1</sup>, P. Naga<sup>1</sup>, N. Bharadwaj<sup>1</sup>, E. Dandapani<sup>1</sup>, U. Mahantshetty<sup>1</sup>, R. Engineer<sup>1</sup>, J. Swamidas<sup>1</sup>, J. Ghosh<sup>2</sup>, S. Gupta<sup>2</sup>, S. Shrivastava<sup>1</sup>

<sup>1</sup>Tata memorial centre, radiation oncology, Mumbai, India

<sup>2</sup>Tata memorial centre, medical oncology, Mumbai, India

#### Purpose or Objective

To report acute hematological toxicity (HT) and dose volume correlates in patients receiving postoperative bowel sparing intensity-modulated radiotherapy (IMRT) and cisplatin within a Phase III trial for late bowel toxicity reduction in patients with cervical cancer.

#### Material and Methods

Clinical database of Phase III trial (NCT01279135) that randomizes patients to IMRT (Tomotherapy) and 3DCRT was searched to select patient strata that received IMRT (50 Gy/25#/5 wks) and concurrent cisplatin (40 mg/m<sup>2</sup>) from Jan, 2011 to Jun, 2016. The IMRT planning aimed at restricting V15 and V40 Small Bowel to  $\leq 200$  and 100 cc respectively. No prospective bone marrow (BM) constraints were applied. The data base was reviewed to determine worst grade of HT toxicity. IMRT planning scans were dearchived and pelvic BM was delineated in 2 sets; whole bone (WB), and freehand (FH) inner cavity of bone from top of L3 vertebra to ischial tuberosity. Various BM sub-volumes namely whole pelvis + lumbar (WPL), lumbar vertebra, sacrum, ilium, ischium, femoral head and neck, whole pelvis (WP), lower pelvis(LP) were contoured and dose volume histograms (DVH) parameters (V<sub>5</sub>, V10, V20,

V30, and V40) were obtained. Receiver operating characteristic (ROC) curve identified DVH thresholds that predicted for grade  $\geq$  II HT toxicity with highest specificity. All data was dichotomized across these cut-offs. Univariate and multivariate analysis was performed with SPSS, version 20.

#### Results

Of the 94 patients randomized to IMRT arm, 74 received concurrent cisplatin (median cycles=4). Grades I-V HT was seen in 55.5%, 32.5%, 5%, 0% and 0% patients, respectively demonstrating low incidence of HT during bowel sparing IMRT. Leukopenia, neutropenia, anemia, and thrombocytopenia  $\geq$  grade II was observed in 24.3%, 5.3%, 17.6%, and 0%, respectively. None of the HT resulted in treatment break. On comparing BM delineation techniques the FH sub volumes were 25%-47% of WB sub-volumes. The mean V<sub>s</sub>, V10, V20, V30, and V40 for WP FH and WB were 99%, 93%, 77%, 60%, and 36%; and 99%, 94%, 80%, 60%, and 36%, respectively suggesting unintended desirable BM sparing. On univariate analysis WPL FH V30 > 55% (p=0.04) predicted for overall grade  $\geq$  II HT, WP V10 > 95% (p= 0.04) for grade  $\geq$  II leucopenia and ilium V20 > 90% (p=0.04) for hemoglobin toxicity. On multivariate analysis, only WP FH V10 > 95% (p value 0.04, OR 3.3 (1-11.5) was statistically significant for grade  $\geq$  II leucopenia.

#### Conclusion

The IMRT arm of NCT01279135 (PARCER study) that employed strict bowel constraints also had unintentional dosimetrically desirable BM sparing. This was associated with low absolute rates of HT. Within the setting of bowel sparing IMRT WP FH V10 should be restricted to  $\leq$ 95% for simultaneous bowel and BM sparing. However as none of the other dosimetric variables predicted for HT, WB marrow contours could serve as a resource sparing strategy while planning pelvic IMRT.

#### OC-0319 Cervix cancer: dose-volume effects in pathologic lymph nodes

W. Bacorro<sup>1</sup>, R. Mazon<sup>2</sup>, I. Dumas<sup>3</sup>, A. Escande<sup>2</sup>, A. Huertas<sup>2</sup>, R. Sun<sup>2</sup>, P. Castelnau-Marchand<sup>2</sup>, C. Haie-Meder<sup>2</sup>, C. Chargari<sup>2</sup>

<sup>1</sup>Benavides Cancer Institute- UST Hospital, Radiation Oncology, Manila, Philippines

<sup>2</sup>Gustave Roussy, Radiation Oncology, Villejuif, France

<sup>3</sup>Gustave Roussy, Medical Physics, Villejuif, France

#### Purpose or Objective

Whereas clear dose-volume relationships have been demonstrated for the tumor and organs at risk in locally advanced cervix cancer, the optimal threshold to reach for pathologic lymph nodes remains uncertain. The objective was to identify planning aim for pathologic nodes.

#### Material and Methods

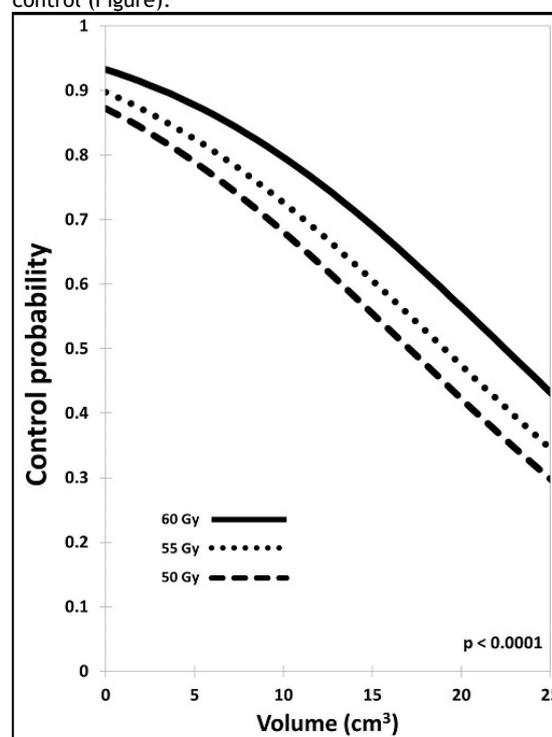

Patients treated with curative intent for a cervical cancer with nodal involvement were identified. Their treatment combined external beam radiotherapy (EBRT) and image-guided brachytherapy (IGABT). Nodal boosts were performed sequentially or using the simultaneous integrated boost (SIB) technique depending on the EBRT technique used. The contributions of EBRT, IGABT (D<sub>98</sub>) and nodal boosts were converted in 2-Gy equivalent ( $\alpha/\beta=10$  Gy) and summed. Each node was considered individually, and followed from diagnosis to relapse. Resected nodes during para-aortic node surgical staging were not considered. Statistical analyses comprised log-rank tests (univariate analyses), Cox proportional model (factors with p  $\leq$  0.1 in univariate) and probit analyses.

#### Results

One hundred and fifteen patients were included, with a total number of nodes of 288 (2.5 per patient). PET-CT was performed in 90.6% of the patients; para-aortic dissection in 53.8%. Histologic subtypes comprised squamous cell carcinomas (SCC) in 88.9%, adenocarcinomas in 8.5% and adenosquamous in 2.6%. The

mean pathologic node volume at diagnosis was 3.4 $\pm$ 5.8 cm<sup>3</sup>. The mean EBRT and nodal boost doses were 44.3 $\pm$ 0.9 Gy and 10.0 $\pm$ 2.9 Gy respectively. The mean IGABT contribution to pelvic nodes was 4.2 $\pm$ 2.6 Gy. Finally the mean total dose to lymphadenopathies was 55.3 $\pm$ 5.6 Gy. Concomitant chemotherapy was administered in 96.5% of the patients. After a median follow-up of 33.5 months, 20 patients (17.4%) experienced relapses in nodes initially considered pathologic at diagnosis (local relapse). Among them recurrences were observed in a total of 44 nodes (15.3%). The mean time from treatment completion to relapse was 9.0 $\pm$ 11.8 months.

There was no significant relationship between the dose delivered to pathologic nodes and local control probability (p=0.38). Univariate analyses tested various factors: subtypes (SCC versus others, p=0.35), concomitant chemotherapy (p=0.39), use of SIB (p=0.07), volume at diagnosis (threshold: 3 cm<sup>3</sup>, p<0.0001) and dose ( $\geq$  57.5 Gy, p=0.039). The last three factors were entered in a multivariate analysis. Volume (HR=8.2, 4.0-16.6, p<0.0001) and dose (HR=2, 1.05-3.9, P=0.034) remained independent, whereas SIB was not (p=0.99). Subsequent Probit analysis combining dose and volume showed significant relationships with the probability of local control (Figure).

#### Conclusion

The initial volume was the main prognostic factor of control in pathologic lymph nodes. A dose superior to 57.5 Gy was also associated with a better local control probability. Further studies are required to refine these findings.

#### PV-0320 Stereotactic body radiotherapy for liver metastases based on functional treatment planning

M.M. Fode<sup>1</sup>, J. Petersen<sup>2</sup>, E. Worm<sup>2</sup>, M. Sørensen<sup>3</sup>, K. Bak-Fredslund<sup>3</sup>, S. Keiding<sup>3</sup>, M. Høyer<sup>4</sup>

<sup>1</sup>Aarhus University Hospital, Department of Oncology, Aarhus C, Denmark

<sup>2</sup>Aarhus University Hospital, Department of Medical Physics, Aarhus C, Denmark

<sup>3</sup>Aarhus University Hospital, Department of Nuclear Medicine & PET Centre and Department of Hepatology and Gastroenterology, Aarhus C, Denmark

<sup>4</sup>Aarhus University Hospital, Danish Centre for Particle Therapy, Aarhus C, Denmark

#### Purpose or Objective

<sup>218</sup>F]fluoro-2-deoxy-D-galactose (FDGal) is a hepatocyte-specific positron emission tomography (PET) tracer. It was used as a marker for hepatocyte function for applying functional treatment planning (FTP) to minimize the radiation dose to the normal liver tissue. We report the results of a cohort of patients treated with FTP-stereotactic body radiotherapy (SBRT) for liver metastases.

#### Material and Methods

Fourteen patients referred for SBRT for liver metastases from colorectal cancer were included in the study between December 2013 and August 2016. Nine patients were irradiated for a solitary metastasis and five patients for two (n=4) or three (n=1) metastases. The mean cumulated CTV was 70.3 cc (range 2.0 - 189.7 cc). FDGal PET/CT was performed at baseline and one month post-treatment. The liver was divided into nine iso-functioning volumes based on radioactivity concentration SUV of FDGal on the baseline FDGal PET/CT and transferred to the planning CT using deformable co-registration. The prescribed mean dose to the CTV was 45-60 Gy in 3-6 fractions. The post-treatment FDGal PET/CT was used for evaluation of radiation dose-response for the normal liver tissue.

#### Results

FTPs were created and applied for all patients and all plans met the predefined dose-volume constraints with the exception of a soft constraint of mean dose to the liver-CTV that was not met in three patients. Eight patients (57%) were treated with local therapy for liver metastases before inclusion in the present study (surgery n=1; SBRT n=1; combined local therapy n=6. No severe (CTCAE 4.0 grade 3-5) acute morbidity was registered. Ten grade 1 gastrointestinal and six grade 1-2 non-gastrointestinal acute morbidities were registered. No patients had liver-related morbidity. Analysis of the post-treatment FDGal PET/CT revealed a dose-dependent depression in hepatocyte function measured in SUV of FDGal uptake in the irradiated normal liver tissue.

#### Conclusion

The study shows feasibility for FTP in patients with colorectal liver metastases referred for SBRT using FDGal PET/CT as a marker for hepatocyte function and the radiation dose to the normal liver tissue was minimized without compromising the organs at risk. The acute morbidity was minimal.

may lead to better palliation and possibly increase survival with the advantage of a short overall treatment time. The superior soft tissue contrast of MRI might improve tumour contouring and MRI is capable of tumour motion quantification. We want to investigate the technical feasibility and safety of MRI-guided SBRT for LAPC.

#### Material and Methods

From July 2013 to January 2016, 20 patients with LAPC or medically unresectable pancreatic cancer without distant metastasis were included in this study (Table). A custom made abdominal corset was manufactured to reduce breathing induced tumour motion. Contouring of the gross tumour volume (GTV) and organs at risk (OARs) was performed on 4D treatment planning CT and multiparametric MRI. A GTV-to-PTV margin of 3 mm was applied. We quantified tumour motion with cine MRI. After treatment planning, the static dose distribution was convolved with the cine MRI based motion trajectory to simulate and evaluate the delivered dose to the GTV, PTV, and OARs. SBRT was carried out up to a dose of 24 Gray in 3 fractions in one week. Online position verification was performed with 4D CBCTs, with 4D matching based on gold fiducial markers at the midventilation position.

#### Results

All patients underwent uncomplicated endoscopic fiducial marker placement. Tumours and OARs were clearly visible with contrast enhanced CT and multiparametric MRI (Figure). On the 4D planning CT and on the 4D CBCT scans, the fiducial markers were clearly visible. The corset decreased peak-to-peak tumour motion in craniocaudal direction on average from 11.3 to 7.2 mm. With incorporation of the tumour motion trajectory, the dose distribution was blurred and, in this way, the actual delivered dose was simulated. In all patients, an adequate dose distribution was achieved with acceptable dose in the OARs (Table). Position verification based on 4D marker matching was feasible. No grade 3 or higher treatment related toxicity was observed in these patients to date.

## Conclusion

MRI-guided SBRT for pancreatic cancer with individually evaluated margins is technical feasible and safe, with no treatment related grade  $\geq 3$  toxicity. New strategies are applied, including an individual corset to reduce breathing motion, MRI based contouring and simulation of motion-integrated dose distributions.

## PV-0322 Rapid Early Response of Gastroesophageal Junction Tumors During Real-time MRI-Guided Radiotherapy

H. Musunuru<sup>1</sup>, S. Rosenberg<sup>1</sup>, J. Bayouth<sup>1</sup>, K. Mitteur<sup>1</sup>, M. Ritter<sup>1</sup>, B. Paliwal<sup>1</sup>, M. Witek<sup>1</sup>, A. Baschnagel<sup>1</sup>, N. Uboha<sup>2</sup>, S. Lubner<sup>2</sup>, N. Loconte<sup>2</sup>, P. Harari<sup>1</sup>, M. Bassetti<sup>1</sup>  
<sup>1</sup>University of Wisconsin Hospital and Clinics, Radiation Oncology, madison, USA  
<sup>2</sup>University of Wisconsin Hospital and Clinics, Medical Oncology, Madison, USA

## Purpose or Objective

Multimodality comprehensive therapy has become the standard of care for locally advanced esophageal and gastroesophageal junction tumors. Tumor response to chemoradiation correlates with outcomes, however full response information generally awaits esophagectomy. Intra treatment predictors of response may allow improved personalization of therapy. Daily MRI allows direct quantification of GEJ tumor size. The aim of this study is to evaluate volumetric changes in gross tumor volume (GTV) for gastroesophageal junction (GEJ) cancer patients undergoing MRI-guided radiation therapy, as part of neoadjuvant chemoradiotherapy

## Material and Methods

Five GEJ adenocarcinoma patients underwent MRI during simulation and with each treatment fraction immediately prior to radiation delivery. The GTV primary was contoured on MRI scans at fractions 5, 10, 15, 20 and 23 and compared to the baseline GTV (Fig 1). Change in GTV across time was expressed as percentage difference (between baseline and different fractions and between individual fractions) and in terms of absolute volume(cc).

## Results

Median age and follow-up period for this cohort were 68 years and 46.5 days. The treatment regimen consisted of weekly carboplatin (AUC 2mg/ml/min) and paclitaxel (50mg/m<sup>2</sup>) with concurrent radiotherapy, 50.4Gy in 28 fractions in three patients and 41.4Gy in 23 fractions in the remaining two patients. The earliest decrease in GTV (% change) was noted at fraction 10 when compared to baseline (Mean -52%, SD 4.6%; Fig 2A). Evaluation of percentage change in the GTV between different fractions (i.e. fraction 5 and fraction 10 etc.) also showed that the earliest change occurred between fractions 5-10 (Table 1). Mean (SD) of GTV at baseline and at fractions 5, 10, 15, 20 and 23 were 94.7cc(15.4), 93.9cc(14.8), 46.3cc(7.8), 39.7cc(6), 33.2cc(4.7) and 33.2cc(4.7), respectively.

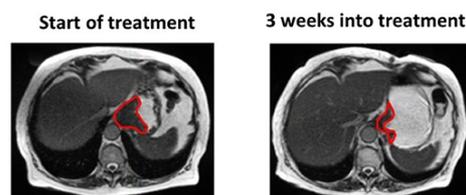

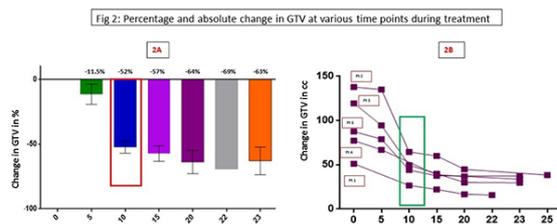

Fig 1  
GTV on Axial  
TRUFI MRI

Time Points Mean(SD) of change in GTV expressed as percentage

Baseline and different fractions

Fractions 0 and 5 -11.5%(7.8)

Fractions 0 and 10 -52.0%(4.6)

Fractions 0 and 15 -57.0%(6.0)

Fractions 0 and 20 -64.0%(9.0)

Fractions 0 and last fraction -66.0%(9.0)

Baseline different fractions

Fractions 0 and 5 -11.5%(7.8)

Fractions 5 and 10 -48.0%(3.9)

Fractions 10 and 15 -14.5%(5.5)

Fractions 15 and 20 -16.0%(12.2)

Fractions 20 and the last fraction -6.0%(5.9)

#### Conclusion

Real-time MRI-guided radiation provides previously unavailable data on tumor response during neoadjuvant chemoradiation. In this study, the most significant volumetric change in the GTV was observed earlier than expected, between fractions 5 and 10. Correlation of early volumetric response changes with clinical and/or pathological outcomes may prove highly valuable. Daily MRI during radiation provides a unique opportunity to tailor individual treatment based on early response to chemoradiation, and suggests that functional imaging correlates are likely best undertaken early during chemoradiation. Additional patients are being recruited into this study to correlate imaging response with clinical and pathological outcomes.

#### PV-0323 Development of a prognostic model incorporating PET texture analysis in oesophageal cancer patients

K. Foley<sup>1</sup>, R. Hills<sup>1</sup>, B. Berthon<sup>2</sup>, C. Marshall<sup>2</sup>, W. Lewis<sup>3</sup>, T. Crosby<sup>1</sup>, E. Spezi<sup>5</sup>, A. Roberts<sup>6</sup>

<sup>4</sup>Velindre Cancer Centre, Oncology, Cardiff, United Kingdom

<sup>5</sup>Cardiff University, School of Engineering, Cardiff, United Kingdom

<sup>6</sup>University Hospital of Wales, Clinical Radiology, Cardiff, United Kingdom

#### Purpose or Objective

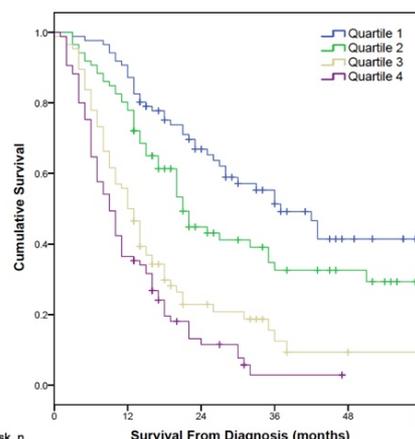

Texture analysis provides additional quantitative data extracted from radiological staging investigations. This exploratory study investigates the prognostic significance of PET texture variables when incorporated into a model predicting overall survival (OS) in patients with oesophageal cancer (OC).

#### Material and Methods

This retrospective cohort study includes consecutive OC patients staged with PET/CT between October 2010 and December 2014. PET-defined tumour variables and texture metrics were obtained using ATLAS, a machine learning algorithm for optimised automatic segmentation. A Cox regression model including age, radiological stage, treatment and 12 novel texture variables was developed and a prognostic score stratifying patients into quartiles was calculated. Primary outcome was OS and a p-value <0.1 was considered statistically significant.

#### Results

Three hundred and forty-three consecutive patients [median age=67 (range=24-83), adenocarcinoma=258] were included. Median survival was 17 months (95% CI 14.685-19.315). Multivariate analysis demonstrated 7 variables that were significantly and independently associated with OS; age [HR=1.024 (95% CI 1.010-1.038), p<0.001], radiological stage [HR=1.492 (1.221-1.823), p<0.001], treatment [HR=2.855 (2.038-3.998), p<0.001], standard deviation [HR=0.898 (0.815-0.989), p=0.029], log(coarseness) [HR=1.774 (0.918-3.43), p=0.088], dissimilarity [HR=1.136 (1.007-1.281), p=0.038] and zone percentage [HR=0.938 (0.897-0.980), p=0.005]. A prognostic score derived from the model equation showed significant differences in OS between quartiles ( $\chi^2=90.13$ , df=3, p<0.001).

Patients at Risk, n	Survival From Diagnosis (months)					
	0	12	24	36	48	60
Total	343	216	87	44	22	8
Quartile 1	86	75	42	24	12	6
Quartile 2	86	67	26	15	10	2
Quartile 3	86	43	12	4	0	0
Quartile 4	85	31	7	1	0	0

#### Conclusion

This study demonstrates the additional benefit of PET texture analysis in OC staging, over and above the current TNM system. Our prognostic model requires further validation, but highlights the potential of texture analysis to predict survival in OC.

#### PV-0324 FDG-PET based pelvic bone marrow dose predicts for blood cell nadirs in CT-RT for anal cancer

### Purpose or Objective

To test the proof of principle that irradiated volume of pelvic active bone marrow (<sup>act</sup>BM), as detected by <sup>18</sup>FDG-PET, may be a predictor of decreased blood cell nadirs in anal cancer patients undergoing concurrent chemo-radiation and to identify subregions within the pelvis potentially more involved in the occurrence of acute hematologic toxicity.

### Material and Methods

Forty four patients submitted to IMRT and concurrent chemotherapy were analyzed. Several bony structures were defined: pelvic and lumbar-sacral (LSBM), lower pelvis (LPBM) and iliac (IBM) bone marrow. <sup>act</sup>BM was characterized employing <sup>18</sup>FDG-PET and defined as all subregions within pelvic bone marrow having Standard Uptake Values (SUVs) higher than SUV<sub>mean</sub>. All other regions were defined as inactive BM (<sup>inact</sup>BM) (Figure 1). On dose-volume histograms, dosimetric parameters were taken. Endpoints included white blood-cell-count (WBC), absolute-neutrophil-count (ANC), hemoglobin (Hb) and platelet (Plt) nadirs. Acute toxicity was scored according to RTOG scoring scale. Generalized linear and logistic regression models were used to find correlations between dosimetric variables and blood cell toxicity.

### Results

<sup>act</sup>BM mean dose had a statistically significant correlation with WBC ( $\beta = -1.338$ ; 95%CI:  $-2.455/-0.221$ ;  $p = 0.020$ ), ANC ( $\beta = -1.651$ ; 95%CI:  $-3.284/-0.183$ ;  $p = 0.048$ ) and Plt ( $\beta = -0.031$ ; 95%CI:  $-0.057/-0.004$ ;  $p = 0.024$ ) nadirs. On the contrary, no correlation was found between <sup>inact</sup>BM mean dose and any blood cell nadir (Table 1). <sup>act</sup>BM V<sub>10</sub> had a significant correlation with WBC ( $\beta = -0.062$ ; 95%CI:  $-0.104/-0.021$ ;  $p = 0.004$ ) and ANC ( $\beta = -0.038$ ; 95%CI:  $-0.067/-0.007$ ;  $p = 0.015$ ) nadirs. <sup>act</sup>BM V<sub>20</sub> was significantly correlated to WBC ( $\beta = -0.044$ ; 95%CI:  $-0.080/-0.008$ ;  $p = 0.017$ ), ANC ( $\beta = -0.027$ ; 95%CI:  $-0.052/-0.001$ ;  $p = 0.039$ ) and Plt ( $\beta = -1.570$ ; 95%CI:  $-3.140/-0.002$ ;  $p = 0.050$ ) nadirs. <sup>act</sup>BM V<sub>30</sub> had a significant correlation with WBC ( $\beta = -0.033$ ; 95%CI:  $-0.064/-0.002$ ;  $p = 0.036$ ) and Plt ( $\beta = -1.720$ ; 95%CI:  $-2.990/-0.450$ ;  $p = 0.010$ ) nadirs. <sup>act</sup>BM V<sub>40</sub> was significantly correlated to WBC ( $\beta = -1.490$ ; 95%CI:  $-2.900/-0.072$ ;  $p = 0.040$ ) nadir. With respect to subregions within the pelvis, WBC nadir was significantly correlated to <sup>act</sup>LSBM mean dose ( $\beta = -1.852$ ; 95%CI:  $-3.205/-0.500$ ;  $p = 0.009$ ), V<sub>10</sub> ( $\beta = -2.153$ ; 95%CI:  $-4.263/-0.043$ ;  $p = 0.002$ ), V<sub>20</sub> ( $\beta = -2.081$ ; 95%CI:  $-4.880/-0.112$ ;  $p = 0.003$ ), V<sub>30</sub> ( $\beta = -1.971$ ; 95%CI:  $-4.748/-0.090$ ;  $p = 0.023$ ) and to <sup>act</sup>IBM V<sub>10</sub> ( $\beta = -0.073$ ; 95%CI:  $-0.106/-0.023$ ;  $p = 0.016$ ). ANC nadir found to be significantly associated to <sup>act</sup>LSBM V<sub>10</sub> ( $\beta = -1.878$ ; 95%CI:  $-4.799/-0.643$ ;  $p = 0.025$ ), V<sub>20</sub> ( $\beta = -1.765$ ; 95%CI:  $-4.050/-0.613$ ;  $p = 0.030$ ). No significant correlation were found between dosimetric parameters and > G3 hematologic toxicity, even if borderline significance was found for <sup>act</sup>LSBM mean dose and WBC nadir.

	<sup>act</sup> BM - Mean dose (Gy)				<sup>inact</sup> BM - Mean Dose (Gy)				<sup>act</sup> IBM - Mean Dose (Gy)						
	$\beta$	R <sup>2</sup>	95% CI	t	p	$\beta$	R <sup>2</sup>	95% CI	t	p	$\beta$	R <sup>2</sup>	95% CI	t	p

Hb (g/dl)	-0.646	0.039	-1.354/0.020	-1.15	0.324	-0.719	0.042	-1.878/0.439	-1.26	0.216	-0.587	0.044	-1.558/-0.333	-1.23	0.204

Legend: <sup>act</sup>BM: active bone marrow; <sup>inact</sup>BM: inactive bone marrow; WBC: white blood cells; ANC: absolute neutrophil count; Plt: platelets; Hb: hemoglobin; t: t;  $\beta$ : coefficient; R<sup>2</sup>: R-squared; CI: confidence interval; t: t; p: p-value.

### Conclusion

<sup>18</sup>FDG-PET is able to define active bone marrow within pelvic osseous structures. <sup>act</sup>BM is a predictor of decreased blood cells nadirs in anal cancer patients undergoing concurrent chemo-radiation. Lumbar-sacral bone marrow dose seems to be the strongest predictor.

### PV-0325 Tumor Regression Grading in the CAO/ARO/AIO-04 phase 3 trial in locally advanced rectal carcinoma

<sup>6</sup>University of Erlangen, Department of Radiation Oncology, Erlangen, Germany

<sup>7</sup>University of Zurich, Epidemiology- Biostatistics and Prevention Institute, Zurich, Switzerland

<sup>8</sup>University of Leipzig, Institute of Pathology, Leipzig, Germany

### Purpose or Objective

We examined the prognostic value of tumor regression grading (TRG) in 1208 patients with locally advanced rectal carcinoma treated within the CAO/ARO/AIO-04 trial after a median follow-up of 50 months.

### Material and Methods

TRG and clinicopathologic parameters were correlated to clinical outcome. Statistical differences between groups were calculated by the Log-rank test, and incidence curves were plotted using the Kaplan-Meier method. The Cox regression and the Fine-Gray models were used for the multivariate analysis. We used the four Prentice criteria (PC1-4) to assess the surrogacy of TRG for disease-free survival (DFS).

### Results

The 3-year cumulative incidence of DFS, distant metastases, local recurrence and overall survival (OS) were 64.6%, 25.4%, 6.9% and 76.8% for patients with TRG 0+1 (poor regression), 77.6%, 18.3%, 3.3% and 89.2% for TRG 2+3 (intermediate regression), and 92.3%, 4.1%, 0% and 96.2% for TRG 4 (complete regression), respectively ( $P < .001$ , for all four endpoints). Due to multicollinearity, TRG 4 and pathologic stage was not assessed within the same model. TRG 2+3 vs TRG 0+1 after preoperative CRT remained an independent prognostic factor for DFS (HR, 0.677;  $P = .007$ ), the cumulative incidence of local recurrence (HR, 0.504;  $P = .028$ ) and OS (HR, 0.582;  $P < .001$ ). Notably, TRG satisfied PC1-3 for individual-level surrogacy ( $P = .037$ ,  $P < .001$  and  $P < .001$ , respectively). The treatment effect on DFS was captured by TRG and therefore PC4 satisfaction is plausible.

### Conclusion

TRG following preoperative chemoradiotherapy predicted for a favorable long-term outcome in multivariate analysis. In the era of personalized medicine, TRG might constitute an attractive option to validate molecular biomarkers, facilitate successful clinical testing of new

biological agents and tailor treatment-adaptive strategies based on initial response in early phase trials in the era of personalized medicine. Further examination and validation of TRG as surrogate for DFS based on large independent phase III trials is needed and should be enhanced for its implementation in the regular pathologic work-up.

#### Purpose or Objective

Population based electronic health records, provide a means of obtaining information on patient characteristics and outcomes that can then be compared with the more selected populations recruited within randomized controlled trials. Aim of this analysis was to retrospectively evaluate the difference in terms of pathologic complete response (pCR) according to time elapsed between chemoradiation (CRT) and surgery on a large unselected real-life dataset of locally advanced rectal cancer (LARC) patients.

#### Material and Methods

A multicentre retrospective cohort study of LARC patients among 21 Italian Radiotherapy Institutions was performed. 3D conformal or intensity-modulated radiation treatment was required as inclusion criteria. Surgery was performed according to the principles of total mesorectal excision (TME). Patients were stratified according to 3 different

time intervals. The 1<sup>st</sup> group included 305 patients undergone TME within 6 weeks, the 2<sup>nd</sup> group included 1610 patients undergone TME within 7-12 weeks, and the 3<sup>rd</sup> group included 198 patients undergone TME within 13 or more weeks after CRT, respectively.

#### Results

Data on 2113 patients treated between 1997 and 2016 were retrieved from the historical database of gastrointestinal radiation oncologists joined into the study. Recruitment in the period investigated by the study took place as follows: 183 patients from 1997 to 2002, 550 from 2003 to 2008, and the majority, 1380, from 2009 to 2016. Five hundred and eighty two patients had stage II (T3-4, N0) and 1531 had stage III (any T, N1-2) histological proven invasive rectal adenocarcinoma. A CRT schedule with one (1600 pts) or 2-drugs was administered (513 pts). Overall, pCR were 468 (22%). Among the 2113 assessable patients the proportion of patients achieving a pCR increased according with time interval, as follows: 12.4% (1<sup>st</sup> group), 22.9% (2<sup>nd</sup> group), and 30.8% (3<sup>rd</sup> group) (p<0.001, ANOVA test), respectively. The 1<sup>st</sup> group had a pCR odds ratio of 0.47 compared to 2<sup>nd</sup> group, while the latter had a pCR odds ratio of 0.66 compared to 3<sup>rd</sup> group. Moreover, 1<sup>st</sup> group had a pCR odds ratio of 0.31 compared to 3<sup>rd</sup> group. The rate of complete response increments for each week of waiting was 1.5% (about 0.2%/die). At univariate analysis, time interval (p<0.001), radiotherapy dose (>5040 cGy; p=0.013), and clinical tumor stage (p=0.029) were significantly correlated to pCR. The positive impact of time interval (p<0.001) and clinical tumor stage (p=0.038) were confirmed by multivariate analysis, in agreement with the literature data (Table 1).

Table 1. Univariate and multivariate analyses for pathologic complete response (pCR) according to the patient and treatment variables.

Variable	pCR	
	Univariate pvalue <sup>a</sup>	Multivariate pvalue <sup>b</sup>
Gender		
Male	P=0.90	-
Female		
Stage		
II	P=0.03	P=0.01
III		
Dose		
≤5040cGy	P=0.01	-
>5040 cGy		
Chemotherapy schedule		
1 drug	P=0.68	-
2-drugs		
Time interval <sup>c</sup>	P<0.001	P<0.001

<sup>a</sup>Significant p values (p value < 0.05) are in bold; <sup>b</sup> Only variables with a p value ≤ 0.10 in the univariate analysis were included in the multivariate model; <sup>c</sup> Considered as a continuous variable in the logistic regression analysis

#### Conclusion

We confirmed on a population-level that lengthening the interval (>13 weeks) from CRT to surgery improves the pCR in comparison to historic data, possibly due to technical improvement of radiotherapy such as the ability of high-precision dose delivery and real-time knowledge of the target volume location.

#### PV-0327 The effect of postoperative complications on Quality of Life in elderly rectal cancer patients

A.M. Couwenberg<sup>1</sup>, F.S.A. De Beer<sup>1</sup>, M.P.W. Intven<sup>1</sup>, M.E. Hamaker<sup>2</sup>, W.M.U. Van Grevenstein<sup>3</sup>, H.M. Verkoijen<sup>4</sup>  
<sup>1</sup>UMC Utrecht, Radiotherapy, Utrecht, The Netherlands  
<sup>2</sup>Diakonessenhuis, Geriatrics, Utrecht, The Netherlands  
<sup>3</sup>UMC Utrecht, Surgery, Utrecht, The Netherlands  
<sup>4</sup>UMC Utrecht, Imaging Division, Utrecht, The Netherlands

### Purpose or Objective

As result of the aging population, increasing life expectancy and increasing rectal cancer incidence, more elderly patients will undergo treatment for rectal cancer. Neoadjuvant (chemo)radiotherapy and surgery are associated with considerable morbidity and mortality. In this study we compared treatment course, postoperative complications and quality of life (QoL) in older versus younger rectal cancer patients.

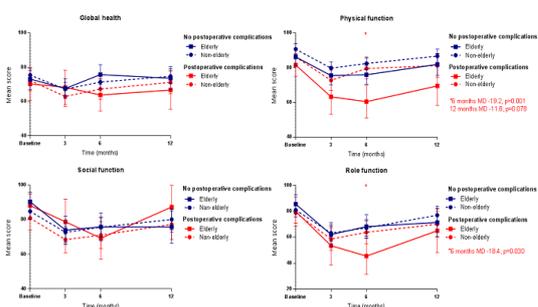

### Material and Methods

All patients within the Dutch prospective colorectal cancer cohort with primary rectal cancer referred for Radiotherapy at the UMC Utrecht between February 2013 and January 2016 were selected. QoL was assessed with the EORTC-C30 questionnaire before start of neoadjuvant treatment and at 3, 6 and 12 months afterwards. Patients were divided into elderly ( $\geq 70$  years) and non-elderly ( $< 70$  years). Differences in QoL were analyzed with generalized estimation equations, adjusted for baseline score, and stratified according to presence of postoperative complications.

### Results

A total of 115 elderly (33.3%) and 230 non-elderly (66.6%) patients were included. Compared to non-elderly, elderly patients were less often male (62.6% vs. 75.2%), had more often previous abdominal surgery (40.9% vs. 30.0%) and presence of comorbidities (80.0% vs. 59.1%). Elderly were more likely to undergo short-course radiation with delayed surgery and less likely to undergo chemoradiation (resp. 19.1% and 39.1% vs. 6.1% and 62.6% in non-elderly,  $p < .001$ ). Surgery was performed equally in both groups (83.5% in elderly vs. 87.8% in non-elderly,  $p = .318$ ). The reasons for no surgical treatment, included disease progression and poor performance status in elderly, and disease progression or a wait-and-see policy in non-elderly. No differences were observed in postoperative complications between elderly and non-elderly (surgical- and non-surgical complication rate 36.5% vs. 34.7%,  $p = .780$ ), neither when stratified for type of neoadjuvant therapy or surgical procedure. Trends of functional QoL domains were similar between elderly and non-elderly during the first year after diagnosis with lowest scores at 3 and/or 6 months. In elderly, postoperative complications had a stronger impact on physical- and role functioning (at 6 months resp. MD -19.2 and -18.4, relative to non-elderly with postoperative complications) (Figure 1). In a sensitivity analysis, comparing patients  $> 80$  years with younger patients, comparable results were observed.

Figure 1. Functional Quality of Life domains in elderly ( $\geq 70$ ) and non-elderly ( $< 70$ ) stratified by presence of postoperative complications.

### Conclusion

Elderly are more often treated by less invasive treatments, which deviates from the standard treatment. Compared with younger patients, elderly have similar postoperative complication rates. Nevertheless, the impact of postoperative complications on physical- and role functioning is stronger in elderly than in younger patients. These results suggest a need to predict the frailest elderly patients who are at risk for postoperative morbidity and hereby an impaired quality of life.

### PV-0328 Factors associated with complete response after brachytherapy for rectal cancer; the HERBERT study.

E.C. Rijkmans<sup>1</sup>, R.A. Nout<sup>1</sup>, E.M. Kerkhof<sup>1</sup>, A. Cats<sup>2</sup>, B. Van Triest<sup>3</sup>, A. Inderson<sup>4</sup>, R.P.J. Van den Ende<sup>1</sup>, M.S. Laman<sup>1</sup>, M. Ketelaars<sup>1</sup>, C.A.M. Marijnen<sup>1</sup>

<sup>1</sup>Leiden University Medical Center LUMC, Department of Radiotherapy, Leiden, The Netherlands

<sup>2</sup>The Netherlands Cancer Institute, Department of Gastroenterology and Hepatology, Amsterdam, The Netherlands

<sup>3</sup>The Netherlands Cancer Institute, Department of Radiotherapy, Amsterdam, The Netherlands

<sup>4</sup>Leiden University Medical Center LUMC, Department of Gastroenterology and Hepatology, Leiden, The Netherlands

### Purpose or Objective

The HERBERT study was performed to examine the feasibility of a high dose rate endorectal brachytherapy (HDREBT) boost after external beam radiotherapy (EBRT) in elderly patients with rectal cancer who were unfit for surgery. The primary results and long term clinical outcomes have been presented at ESTRO 2014 and 2016. With rising interest for organ preservation, the role of definitive (chemo)radiotherapy becomes increasingly important. This current analysis evaluates factors that are associated with a complete response to treatment.

### Material and Methods

A dose finding feasibility study was performed from 2007 to 2013 in inoperable rectal cancer patients. Patients received 13x3 Gy EBRT followed by three weekly applications HDREBT of 5 to 8 Gy per fraction. Clinical target volume (CTV) for HDREBT was defined as residual scarring or tumor after EBRT. Clinical tumor response was evaluated based on digital rectal examination and endoscopy (MRI or biopsy was not routinely performed). Complete response was determined after serial assessments. Patient, tumor and treatment characteristics of complete responders (CR) were compared to non-complete responders (nCR) using Chi-square test and the independent samples t-test.

### Results

Of the 38 patients included in the study 33 were evaluable for response evaluation. Seven were treated with 5 Gy per fraction, four with 6 Gy, 12 with 7 Gy and 10 with 8 Gy per fraction. In total 20 patients achieved a complete response. Baseline patient characteristics (age, ASA, WHO and co-morbidity) and tumor-characteristics (T-stage, N-stage, cranio-caudal length of the tumor and distance from anal verge) were not associated with response to treatment. A trend was observed in complete response between dose levels; 2/7 treated with 5 Gy per fraction; 1/4 with 6 Gy; 9/12 with 7 Gy and 8/10 with 8 Gy per fraction ( $p = 0.05$ ). The actual planned D98 (dose to 98% of the CTV) was however not significantly different between patient with a complete response and no complete response: 6.25 Gy (range 3.8-8.3 Gy) vs. 5.98 Gy (range 1.2-8.8 Gy) respectively ( $p = 0.63$ ).

Endoscopic evaluation of response after EBRT was significantly associated with the overall response rate. Seven patients already had a CR after EBRT, whereas 13/21 patients (62%) with a partial response after EBRT achieved a CR. None of the five patients with stable disease achieved a complete response ( $p = 0.002$ ). Mean residual volume and thickness of residual scarring or tumor after EBRT were significantly lower in complete responders (see Figure). In addition, tumors encompassing less than 1/3 of the circumference were more likely to achieve a complete response than larger tumors (70% vs 17% respectively,  $p = 0.025$ ).

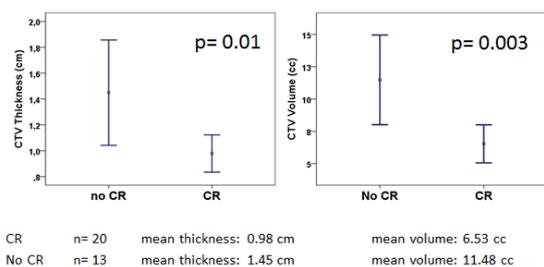

Figure: Association of thickness and volume of the HDREBT CTV with complete clinical response. Lines denote 95% confidence interval.

### Conclusion

Endoscopic response after EBRT and residual tumor thickness, circumference and volume at time of HDREBT were significantly associated with achieving a complete response. This demonstrates that careful selection of patients for organ preserving strategies can result in a very high success rate.

### Proffered Papers: Head and Neck

#### OC-0329 Does margin matter? Distribution of loco-regional failures after primary IMRT for Head & Neck cancer

<sup>2</sup>Aarhus University Hospital, Department of Oncology, Aarhus, Denmark

<sup>3</sup>Herlev Hospital, Department of Oncology, Copenhagen, Denmark

<sup>4</sup>Aarhus University Hospital, Department of Experimental Clinical Oncology, Aarhus, Denmark

#### Purpose or Objective

Head and neck squamous cell carcinoma (HNSCC) often presents as a local or loco-regional disease. Margins are often added around the gross tumour volume (GTV) during the planning of curative radiotherapy to cover microscopic disease. However, there is little evidence available for the optimal size of the high dose clinical target volume (CTV1) margin. Until 2013, different margins from GTV to CTV1 were allowed according to the national treatment guidelines in Denmark, varying from 0 to up to 10 mm. The objective of this study was to analyse loco-regional recurrence pattern in a large cohort of patients with HNSCC treated with curatively intended IMRT. We aimed at evaluating how the location of CT verified loco-regional recurrences (LRR) were influenced by different CTV1 margins.

#### Material and Methods

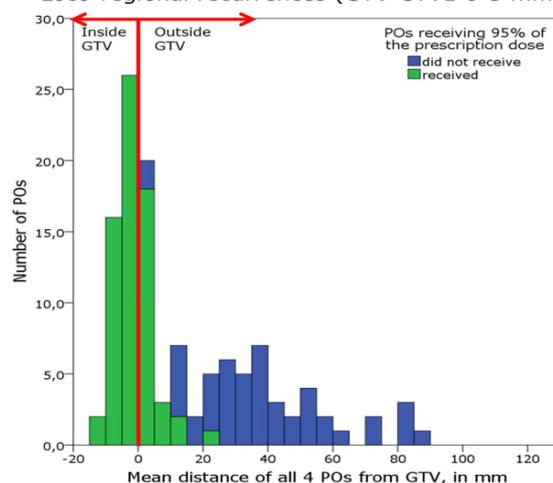

Patients with larynx, oro-/hypopharynx or oral cavity HNSCC treated with primary IMRT during 2006-2012 in three centres were retrospectively identified from national database. Treatment was given according to DAHANCA guidelines, primarily 66-68 Gy in 6 fractions/week with concomitant Nimorazole and weekly cisplatin in loco-regionally advanced cases. The GTV-CTV1 margin was primarily produced by volumetric expansion that varied from 0-10 mm and eventually modified according to anatomy. The origin of recurrence was estimated for all loco-regional treatment failures with diagnostic CT or PET/CT images available. Assuming that loco-regional recurrences arise from a few surviving cancer cells, the possible points of LRR origin (PO) were identified on diagnostic scans by two independent observers, and calculated as mass mid-point (MMP) and a

point with maximal surface distance (MSD). A validated deformable image registration (DIR) propagated the POs from recurrence-CT to planning-CT. The distance from POs to the surface of the GTV was calculated and presented as mean distance from all four POs to the GTV. The patient specific GTV-CTV1 margin was calculated as median surface distance from GTV to CTV1. Difference between LRR distribution in groups with small and large CTV margins was evaluated using Kolmogorov-Smirnov test ( $p < 0.05$ ).

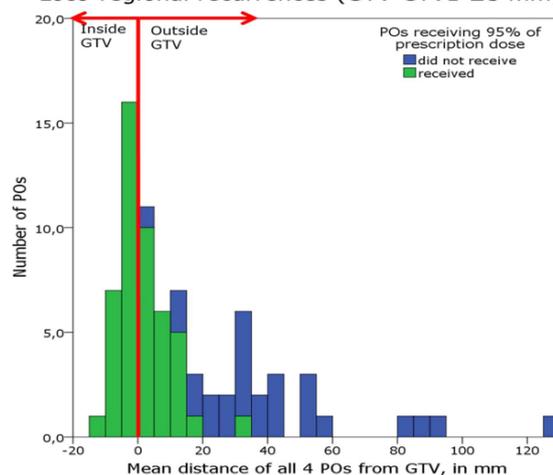

#### Results

In total 1,581 patients were identified and 297 had LRR within the first 3 years of follow-up; of those, 172 patients had CT-verified recurrent disease. Among them, 50% had GTV-CTV1 margin less than 5 mm and 50% larger than 5 mm. There was no difference in sex, tumour site, stage, tumour differentiation and p16-status between these two groups. After successful DIR, in total 192 recurrences were further analysed in the two margin groups; no significant difference in LRR distribution was found ( $p = 0.6$ ). Of the POs in the first and the second groups, 58% and 64% received 95% of the prescription dose, respectively (Figure 1).

#### Loco-regional recurrences (GTV-CTV1 0-5 mm)

#### Loco-regional recurrences (GTV-CTV1 ≥ 5 mm)

#### Conclusion

The presented data do not suggest any difference in distribution of loco-regional recurrences in relation to CTV margins. Such a difference could be expected if the CTV margin was a key component for loco-regional recurrence probability.

### OC-0330 Locoregionally Recurrent Head and Neck Squamous Cell Carcinoma

S.Y. Wu<sup>1</sup>

<sup>1</sup>Taipei Medical University Hospital, No.111- Section 3  
Department of Radiation Oncology, Taipei, Chinese Taipei

#### Purpose or Objective

For locoregionally recurrent head and neck squamous cell carcinoma (HNSCC), appropriate therapeutic decisions and prognostic factors remain unclear.

#### Material and Methods

The enrolled 4,839 patients were categorized into four groups: Group 1 comprised those undergoing chemotherapy (CT) alone; Group 2 comprised those receiving reirradiation (re-RT) alone (total radiation dose  $\geq 60$  Gy through intensity modulation radiation therapy [IMRT]); Group 3 comprised those receiving concurrent chemoradiotherapy (CCRT) alone (irradiation total dose  $\geq 60$  Gy through IMRT); and Group 4 comprised those receiving salvage surgery with or without RT or CT.

#### Results

Age  $\geq 65$  years, Charlson comorbidity index (CCI) score  $> 6$ , clinical stage III-IV at first diagnosis, and recurrence-free interval  $< 1$  year were significant independent prognostic risk factors for overall survival as per univariate and multivariate Cox regression analyses. After adjusting, adjusted hazard ratios (aHRs; 95% confidence intervals [CIs]) for overall mortality in recurrent clinical stages I and II were 0.63 (0.45-0.89,  $p = 0.009$ ), 0.65 (0.52-0.83,  $p < 0.001$ ), and 0.32 (0.26-0.40,  $p < 0.001$ ) in Groups 2, 3, and 4, respectively, whereas they were 1.23 (0.99-1.52,  $p = 0.062$ ), 0.69 (0.60-0.79,  $p < 0.001$ ), and 0.39 (0.34-0.44,  $p < 0.001$ ) for Groups 2, 3, and 4, respectively, for overall mortality in recurrent clinical stage III and IV.

#### Conclusion

Salvage surgery is the recommended first treatment choice for recurrent oral cavity and pharyngeal cancers. Re-RT alone and CCRT are more suitable for inoperable recurrent stage I-II oral and nonoral cavity recurrent HNSCCs, respectively.

### OC-0331 Cetuximab versus Platinum-based Chemoradiation in Locally Advanced p16 Positive Oropharyngeal Cancer

C. Barney<sup>1</sup>, S. Walston<sup>1</sup>, P. Zamora<sup>1</sup>, N. Nolan<sup>1</sup>, V. Diavolitsis<sup>1</sup>, D. Blakaj<sup>1</sup>, J. Wobb<sup>1</sup>, D. Mitchell<sup>1</sup>, J. Grecula<sup>1</sup>, P. Savvides<sup>2</sup>, A. Bhatt<sup>1</sup>

<sup>1</sup>The Ohio State University, Radiation Oncology, Columbus- Ohio, USA

<sup>2</sup>The University of Arizona Cancer Center at Dignity Health St. Joseph's Hospital, Medical Oncology, Phoenix, USA

#### Purpose or Objective

Randomized trials evaluating intensity modulated radiation therapy (IMRT) concurrent with platinum-based chemotherapy (PBC) versus cetuximab (C225) in treating oropharyngeal cancer (OPC) are underway but have yet to report preliminary data. Meanwhile, as a would-be step toward morbidity reduction, the off-trial use of C225 in p16+ patients is increasing in frequency, even in those who could potentially tolerate PBC. The purpose of this study was to retrospectively compare the efficacy of PBC versus C225 concurrent with IMRT in the treatment of locally advanced p16+ OPC.

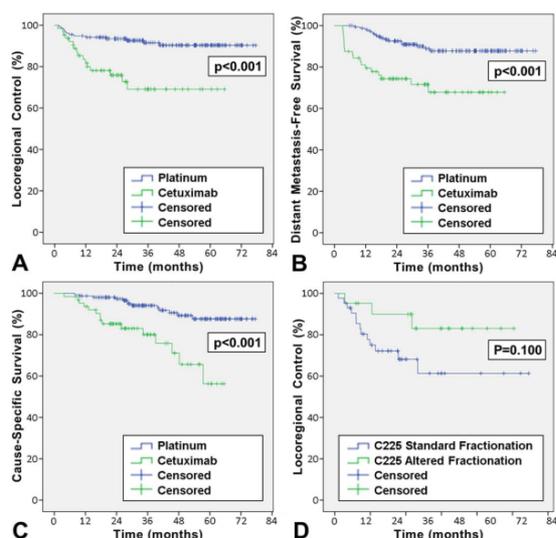

#### Material and Methods

From 2010 to 2014, 219 patients with stage III-IVB p16+ OPC were treated definitively (n=188, 6996-7000 cGy) or postoperatively (n=31,  $\geq 6600$  cGy) with IMRT plus concurrent PBC (n=155, Cisplatin-136 and Carboplatin-19) or weekly C225 (n=64). Log-rank/Kaplan-Meier analysis and Cox Regression modeling were used for univariate and multivariate analysis (MVA) respectively.

#### Results

Tumor and patient characteristics were well balanced - PBC patients had increased median follow-up time and time to complete chemoradiation (CRT), and were more likely to receive standard fractionation vs BID or concomitant boost (see table). With a median follow-up of 35.7 months, PBC improved 3yr locoregional control (LRC) [91.6 vs 69.1%], distant metastasis-free survival (DMFS) [88.9 vs 71.6%], and cause-specific survival (CSS) [94.1 vs 80.0%] compared to C225 [all  $p < 0.001$  - see A-C on figure]. Median time to distant failure (DF) was shorter for the C225 group (7.1 vs 17.2 months,  $p = 0.006$ ). On MVA the use of C225 increased the risk of locoregional failure (LRF) [HR 4.099, 95%CI 1.949-8.621,  $p < 0.001$ ], DF [HR 3.438, 95%CI 1.684-7.016,  $p = 0.001$ ], and cause-specific mortality (CSM) [HR 4.076, 95%CI 1.894-8.771,  $p < 0.001$ ]. On subgroup analysis the use of carboplatin trended toward decreased DF ( $p = 0.100$ ) compared to C225, although the rates of LRF were similar. When including only the C225 patients, UVA showed a strong trend toward increased LRF associated with  $\geq T3$  tumors [ $p = 0.066$ ] and standard fractionation [ $p = 0.100$  - see D on figure 1]; additionally, advanced nodal stage ( $\geq N2b-N3$ ) predicted for increased DF [ $p = 0.029$ ] and CSM [ $p = 0.035$ ]. On MVA of this subgroup, standard fractionation [HR 2.994,  $p = 0.09$ ] and  $\geq T3$  tumors [HR 2.633,  $p = 0.056$ ] continued to trend strongly in predicting for LRF as did advanced nodal stage for DF [HR 5.917,  $p = 0.064$ ] and CSM [HR 6.586,  $p = 0.077$ ].

	PBC (n=155)	C225 (n=64)	p-value

RPA Class			0.438
I	89 (58)	40 (63)	
II	65 (42)	23 (37)	

### Conclusion

Our findings strongly favor use of cisplatin in CRT treatment of locally advanced p16+ OPC. Until results of randomized trials evaluating cisplatin versus cetuximab are available, off-trial use of C225 in this population as an effort to reduce morbidity should be discouraged, especially in patients with advanced tumor and nodal stage disease. In cases where cisplatin is contraindicated, the use of carboplatin as an alternative option may reduce DF compared to C225. When C225 is used, altered fractionation radiotherapy may be beneficial for LRC.

### OC-0332 Impact of HPV on effect of chemotherapy in SCCHN : results of the GORTEC 2007-01 randomized trial

<sup>12</sup>CHUV, radiation oncology, Lausanne, Switzerland

### Purpose or Objective

Chemo-radiotherapy (CT/RT) and cetuximab-RT (cetux-RT) were established as standard treatments in non-operated locally advanced (LA) SCCHN. The GORTEC 2007-01 randomized trial was restricted to patients (pts) with no or limited nodal spread (N0-N2a and non palpable N2b). The results showed that the addition of concomitant CT with cetux-RT backbone markedly improved both PFS and LRC (Bourhis *et al* ASCO 2016) with no significant benefit on overall survival. The impact of p16 expression on the treatment effect of these patients was not available at the time of the first presentation.

### Material and Methods

The 1:1 randomization between cetux-RT (arm A) and cetux-CT/RT (arm B) was done by minimization on centers, N and T stages. Cetuximab was given as a loading dose of 400 mg/m<sup>2</sup> followed by weekly 250 mg/m<sup>2</sup> during

RT. RT total dose was 70 Gy (2 Gy/day, 5 days/week). Concurrent CT was 3 cycles of carboplatin 70mg/m<sup>2</sup>/d + 5FU 600mg/m<sup>2</sup>/d, D1-4. About 2/3 of the patients had oropharyngeal cancers (OPC) and HPV status was determined in these patients using p16 expression as a surrogate (immunohistochemistry). Smoking status was also collected. Primary endpoint was progression free survival (PFS).

### Results

Between Feb 2008 and Feb 2014, 406 pts were randomized with 265 (65%) OPC. The median follow-up was 4.4 years. Overall, p16 was assessed in 236 OPC (89%) patients (115 pts in arm A and 121 in arm B), and p16+ was found in 21% of each arm (24 patients in arm A and 25 arm B). 15 out of the 49 (31%) p16+ patients were non-smokers, while 5/187 (3%) p16- patients were non-smokers. A significant improvement in PFS was found in p16+ compared to p16- OPC (p= 0.0002). A significantly improved PFS was observed with cetux-CT/RT (arm B) compared with cetux-RT (arm A) in p16- OPC (HR: 0.63, 95% CI: 0.44 - 0.91) as well as in p16+ (HR: 0.23, 95% CI: 0.07 - 0.73), and the interaction between p16 and treatment modality was not significant (p=0.13). For loco-regional control, a similar effect was found in both p16- and p16+ OPC in favor of arm B (HR= 0.33 [95%CI 0.19 - 0.56] and 0.16 [95%CI 0.02 - 1.36] respectively; interaction test p=0.51).

### Conclusion

The large majority of OPC patients randomized in this trial were p16- and smokers. The addition of concomitant chemotherapy to cetux-RT markedly improved PFS and LRC in patients with OPC regardless of p16 status.

### OC-0333 Prognostic impact of HPV and smoking in RT of oropharyngeal cancer: the MARCH-HPV project

<sup>6</sup>Gustave-Roussy Paris-Saclay University, Radiotherapy Department- INSERM-U1018-CESP, Villejuif, France

### Purpose or Objective

HPV is a favorable prognostic factor in radiotherapy (RT) of HNSCC but whether HPV is predictive of response to altered fractionated RT remains controversial. We aimed to assess the potential prognostic and predictive impact of HPV in altered fractionated RT and moreover to evaluate the combined prognostic impact of HPV and smoking.

### Material and Methods

The MARCH-HPV project is based on the first update of the Meta-Analysis of Radiotherapy in HNSCC (MARCH), which included 33 trials and 11833 patients. HPV status was determined according to p16 immunohistochemistry. The HPV analysis was restricted to oropharyngeal cancer (OPC) and performed using a Cox model stratified by trial and adjusted on gender, age, T-stage, N-stage, type of RT schedule, p16 (positive, negative) and smoking status (never/former, current). The potential prognostic and predictive effects of HPV-status were estimated for progression-free survival (PFS) and overall survival (OS). Moreover, the combined prognostic impact of HPV and smoking were assessed for PFS and OS.

### Results

Data and tumor tissue from 815 patients enrolled in 4 trials (DAHANCA 6-7, RTOG 9003, ARTSCAN, RTOG 0129) was available for analysis: 350 (43%) HPV-neg and 465 (57%) HPV-pos. Patients with HPV-pos tumors were significantly younger (mean: 56 vs 59 years,  $p=0.0002$ ), in better performance status (PS=0: 74% vs 50%,  $p<0.0001$ ), had smaller tumors (T1-2: 46% versus 33%,  $p<0.0001$ ) and more advanced N-stage (N+: 87% versus 76%,  $p<0.0001$ ) compared with the HPV-neg subgroup. HPV-status significantly influenced prognosis and HPV-pos patients had favorable PFS (HR=0.42 [95% CI: 0.34-0.51] with a 42% absolute increase at 10 years) and OS (HR=0.40 [0.32-0.49] with a 40% absolute increase at 10 years) compared to the HPV-neg subgroup. Smoking independently influenced outcome and never/former smokers had better prognosis than current smokers with HR of 0.61 [0.50-0.75] and 0.58 [0.47-0.72] for PFS and OS, respectively. A further analysis of the impact of smoking was performed classifying smoking as former/current vs never smokers. This consequently led to the exclusion of 166 patients from the ARTSCAN trial where this information was not available. Compared to the HPV-neg smoking subgroup, HPV-pos never smokers were found to have significantly better outcomes (PFS: HR: 0.20 [0.14-0.31] and OS: HR: 0.20 [0.13-0.31]). Similar, although less pronounced, survival benefits were observed for HPV-pos smokers (PFS: HR: 0.41 [0.33-0.51] and OS: HR: 0.38 [0.30-0.47]) when compared with HPV-neg smokers. There was no significant interaction between HPV-status and fractionation effect, whatever the coding for smoking.

#### Conclusion

HPV status was not found to be predictive of outcome after altered fractionated RT in this pooled analysis of OPC. However, the strong prognostic impact of HPV was confirmed and especially HPV-pos never smoking patients have superior outcome after RT.

Supported by the French Ministry of Health (PHRC)

#### OC-0334 Prospective MR assessment of dose-response kinetics of non-target muscles in head and neck cancer

A.S.R. Mohamed<sup>1</sup>, R. Davuluri<sup>1</sup>, S. Frank<sup>1</sup>, Y. Ding<sup>1</sup>, S. Lai<sup>1</sup>, J. Wang<sup>1</sup>, C. Fuller<sup>1</sup>, K. Hutcherson<sup>1</sup>

<sup>1</sup>The University of Texas- MD Anderson Cancer Center, Radiation Oncology, Houston, USA

#### Purpose or Objective

We have recently demonstrated the role of Magnetic Resonance Imaging (MRI) in characterizing radiotherapy (RT)-induced changes in non-target swallowing related musculature in a retrospective head and neck cancer cohort treated with definitive RT. We aim to validate the longitudinal dose-response changes of normal-muscle quantitative MRI signal kinetics in a prospective and well curated institutional dataset.

#### Material and Methods

A total of 39 patients were enrolled as part of an ongoing prospective clinical trial after obtaining study specific signed consent. All patients underwent three MRI studies: pre-, mid-, and post-RT. The mean T1, T1+ contrast (T1+C), and T2-weighted signal intensities (SI) for superior pharyngeal constrictors (SPC), middle pharyngeal constrictors (MPC), intrinsic tongue muscles (ITM), geniohyoid (GH), genioglossus (GG), mylohyoid (MH), masseters, medial/lateral pterygoids, anterior/posterior digastrics (ADM, PDM), and buccinators were recorded in the three time points and delta SI changes were calculated. Trapezius muscle was segment as a control due to negligible dose received. The SI changes were correlated to RT dose to the segmented structures after deformable image registration to planning CT and dose.

#### Results

All patients were stage III-IV HPV-positive oropharyngeal cancer. Median age was 58 years (range 39-80), 35 (90%) were men, and 35 (90%) were white race. Tonsillar fossa was the area of tumor origin in 20 patients (51%) and base

of tongue in 19 (49%). Prescription dose was 70 Gy in 33 fractions. At mid-RT; significant increase in mean T1+C SI was noted in the following muscles: ADM, ITM, GHM, and MPC ( $p=0.005$ , 0.01, 0.04, and 0.002, respectively) and significant increase in mean T2 SI was noted only in MPC ( $p=0.0005$ ). At post-RT; significant increase in mean T1+C SI was detected in all studied muscles ( $p<0.05$  for all). After Bonferroni correction for multiple comparisons, all remained significant except buccinators, pterygoids, and masseter. Post-RT increase in T2 SI was detected only in pharyngeal constrictors and medial pterygoids ( $p<0.05$ ) and remained significant after Bonferroni correction for pharyngeal constrictors. No significant changes in mean T1 SI was detected in all tested muscles in both time points. There were no dose-parameter relationship in all muscles with increased T1+C and T2 SIs in all studied time points. Mean dose to muscle groups with significant increase in T1+C after Bonferroni correction was significantly higher compared to other muscle groups (52.7 vs. 37.5 Gy,  $p<0.0001$ ). Simultaneously, mean dose to pharyngeal constrictors that showed significant T2 increase was significantly higher compared to other muscle groups (63.2 vs. 41.2 Gy,  $p<0.0001$ ).

#### Conclusion

Significant dose-dependent increase in mid-RT and post-RT T1+C and T2 signal intensities is noted in non-target swallowing muscles particularly in pharyngeal constrictors due to higher beam-path dose to these muscles.

#### Symposium: GTFRC

#### SP-0335 GTFRC: where to go from here?

Y. Lievens<sup>1</sup>

<sup>1</sup>University Hospital Ghent,

Department of Radiation Oncology, Gent, Belgium

The Global Task Force on Radiotherapy for Cancer Control (GTFRC) has not only highlighted the urgent need for addressing the inequity gap in access to radiotherapy globally, it has also demonstrated that judicious investment in radiotherapy infrastructure and training is both effective and cost-effective. Indeed, in addition to preventing millions of cancer deaths in the decades to come, investing in radiotherapy has also been shown to bring value for money and a positive return on investment to the societies involved. The GTFRC has articulated five calls-to-action in order to remedy the radiotherapy shortage and to make sure that radiotherapy is included into the multidisciplinary approach to cancer care. To ascertain a global impact by 2035, the time is now to build upon the GTFRC results. ESTRO and the stakeholders involved in the GTFRC have decided to join forces by establishing a new collaborative group with the aim of identifying timely, effective, and achievable responses to the GTFRC's calls-to-action, and of positioning radiotherapy as an essential component of effective cancer care globally. It is our pleasure to launch this initiative at ESTRO 36!

#### SP-0336 Costs and needs of radiotherapy: a regional perspective

E.H. Zubizarreta - zubi<sup>1</sup>

<sup>1</sup>IAEA, Applied Radiation Biology and Radiotherapy, Wien, Austria

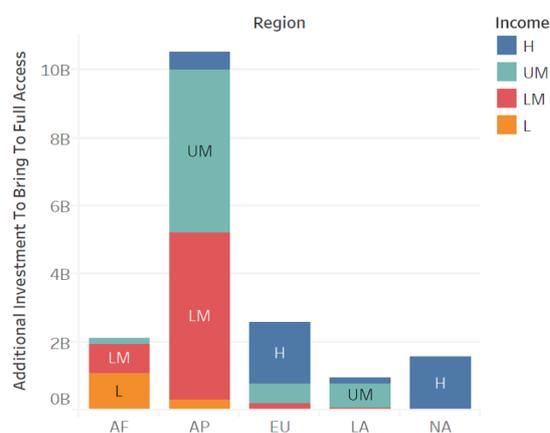

This analysis presents the resources needed and costs at the present time globally and by region to give full access to RT. The variables and methodology were the same used by the GTFRC. The GTFRC reported the resources needed and costs to reach full access to RT in 2035 by income group, but not per region (Atun R et al. Expanding global access to radiotherapy. Lancet Oncol 2015; 16(10)). The division in regions adopted by the IAEA was used: Africa (AF), North America (NA) only includes USA and

Canada, Latin America and the Caribbean (LAC) includes Mexico, Asia-Pacific (AP) includes Australia, New Zealand, and the Pacific islands, and all the post-Soviet states are included in Europe (EU). AP is bigger than all the other regions together in terms of population and also in terms of additional resources needed. The weighted GNI per capita is US\$ 2,086 for AF, US\$ 6,343 for AP, US\$ 9,863 for LAC, US\$ 25,225 for EU, and US\$ 54,140 for NA. This is an important observation, as the scale of salaries and training costs used by the GTFRC was fixed for each income group, but the reality shows that there are big differences between the same income group in different regions (Zubizarreta E et al. Analysis of global radiotherapy needs and costs by geographic region and income level. Clinical Oncology 2017, 29). According to IAEA-DIRAC there are 13,133 megavoltage machines worldwide, of which cobalt machines represent 15%, and the total number required is 16,666, but NA has near the double of machines needed. Assuming working days of 12 hs. AF covers 34% of its needs, AP 61%, EU 92%, and LAC 88%. Globally, 73% of the needs are covered worldwide. The table below summarises the main findings of the analysis. Around 40,000 additional professionals would be needed if the additional equipment needed would be installed: 8,732 RO, 6,122 MP, 21,100 RTT, and 3,787 dosimetrists. 70.5% of these correspond to AP. Operating costs will increase 23% globally, but the cost per patient will decrease 10%. By region, AF requires 239% (percent extra needs) additional investment (new or upgraded Mv machines, staff), AP 54%, EU 13%, LAC 23%, and NA 6%. The figure below shows the additional investment to obtain full access to RT in 2016, a total of US\$ 17.6 billion. 12% correspond to AF, 59.4% to AP, 14.6% to EU, 5.2% to LAC, and 8.8% to NA. The main conclusion is that an additional investment of 25% is needed today worldwide to obtain full access to RT, US\$ 17.6 billion, and that a separate analysis of each region provides a clearer picture, as the situation is totally different in all of them.

Summary of actual status and total needs to provide full access to radiotherapy in the different regions of the world

	Africa	Asia Pacific	Europe	Latin America	North America
<b>Population and courses</b>					
Population (million)	1070	4108	893	601	350
Actual radiotherapy courses	148 600	1 914 454	1 712 000	503 000	934 746
Total radiotherapy courses	437 624	3 277 387	1 884 893	573 385	934 746
<b>Resources</b>					
Actual radiotherapy centres	140	2585	1431	620	2787
Total radiotherapy centres needed (for full access (working 12 h/day))	407	3503	1449	624	1200
Actual megavoltage machines	277	3894	3751	968	4243
Percentage cobalt machines	30.0%	19.8%	16.0%	30.1%	3.6%
Total megavoltage machines needed (for full access (working 12 h/day))	813	6406	4098	1106	2175
Actual coverage of the needs	34%	61%	92%	88%	195%
<b>Costs</b>					
Capital - training costs needed to bring to full access (million US\$)	2118	10 497	2573	918	1558
Actual operational costs/year (million US\$)	182	4638	5868	975	6151
Total operational costs/year (million US\$), assuming full access	571	6968	6573	1192	6588
Actual cost per radiotherapy course (US\$)	1226	2423	3428	1939	6581
Total cost per radiotherapy course (US\$), assuming full access	1306	2126	3487	2079	7048

### Add investment per region

### SP-0337 "From the ground up" - tackling challenges at the country level

M.L. Yap<sup>1</sup>

<sup>1</sup>Liverpool Cancer Therapy Centre, Ingham Institute for Applied Medical Research, Liverpool, Australia

The global incidence of cancer is rising rapidly, particularly in low and middle-income countries (LMICs). Radiotherapy is a core component of cancer care and has been demonstrated to be cost effective. Despite this, there is a significant shortfall of services in LMICs, with 65% of low-income countries having no radiotherapy services available. Recently, an evidence-based case for investment in radiotherapy services in LMICs has been developed. The Collaboration for Cancer Outcomes, Research and Evaluation (CCORE) group have demonstrated that if the gap in radiotherapy services in LMICs were closed by 2035, millions of patients would derive local control and/or survival benefits as a result of radiotherapy. In addition, the Global Task Force for Radiotherapy in Cancer Control (GTFRC)'s Lancet Oncology Commission paper demonstrated that although initial outlays are required to start up a radiotherapy service, economic net gains can be achieved in LMICs over a 20-year period. IT has been estimated that >5500 megavoltage machines would be required to meet the gap in radiotherapy services in LMICs.

However the challenges pertaining to radiotherapy in LMICs are not just limited to the supply of radiotherapy machines, but also concern the safe and effective running of new and established radiotherapy departments. The breakdown of the solitary radiotherapy machine in Uganda was publicised in the mainstream media last year, as a stark image of the challenges facing LMIC radiotherapy departments. There is a severe shortage of trained radiotherapy and oncology staff in LMICs, with the GTFRC report estimating that over 30 000 radiation oncologists, 22 000 medical physicists and 78 000 radiation therapists will need to be trained in LMICs by 2035 in order to meet the projected radiotherapy demand. Regional organisations such as RANZCR-FRO's Asia Pacific Radiation Oncology Special Interest Group (APROSIG) aim to support LMIC radiotherapy departments in this endeavour, alongside international initiatives such as the International Cancer Experts Corp, and Medical Physicists without Borders.

As well as regional/international support, the key factors on a local level imperative to success will be discussed, with examples such as Cambodia and Botswana used to illustrate these. With regards to technology use in these countries, the approach has been stratified to the needs and expertise on a local level. Collaboration between these local, regional and international initiatives, as well as the IAEA, PACT, ESTRO, ASTRO and other organisations is crucial to the safe and effective delivery of radiotherapy in LMICs.

<sup>6</sup>IBA Dosimetry GmbH, Schwarzenbruck, Germany

### Purpose or Objective

The main application of calorimeters in standards laboratories is as primary standard of absorbed dose to water against which ionisation chambers (ICs) are calibrated. At present, no calorimeter is established as a primary standard instrument in proton beams.

Based on the absorbed dose-formalism of IAEA TRS-398, this work describes a direct comparison between a water calorimeter (WCal) and plane-parallel ICs in clinical pulsed pencil beam scanning (PBS) proton beams, delivered by a synchrocyclotron. The temporal beam characteristics and the absence of a dosimetry protocol for such beams create significant challenges in absorbed dose determination. The aim of this work is to demonstrate the feasibility a water calorimetry in pulsed PBS beams.

### Material and Methods

The method consisted in comparing the response of WCal and ICs (PPC40 and PPC05) in the same reference conditions. Measurements have been performed at a depth of 3.1 cm using two mono-layers maps of proton beams ( $10 \times 10 \text{ cm}^2$ ), with incident beam energies of 96.17 MeV (range in water =  $6.8 \text{ g/cm}^2$ ) and 226.08 MeV (range in water =  $31.7 \text{ g/cm}^2$ ), respectively. The response of the WCal is corrected for heat transfer (calculated using numerical simulations based on finite element method) and non-water material inside the WCal (using experimentally derived factors). Using hydrogen-saturated high-purity water in the WCal, the chemical heat defect is assumed to be zero. Classical correction factors are applied to the response of ICs: temperature and pressure, polarity and recombination ( $k_s$ ).  $k_s$  was studied in detail due to the very high beam dose rate used with the delivery method.

### Results

Table 1 shows preliminary relative differences of  $D_w$  measured with WCal and IC, during two independent experimental campaigns, for both energies. A small positioning uncertainty could explain that the ratios obtained during campaign B are higher for the low energy beam. For campaign A, however, ratios are higher for the high energy beam, which cannot be explained by a positioning uncertainty. A new campaign is planned to repeat the measurement of correction factors to improve the statistics of the results.

	Experimental campaign A		Experimental campaign B	
	WCal		WCal	
	96.17 MeV	226.08 MeV	96.17 MeV	226.08 MeV
PPC40	-1.2%	-1.9%	1.5%	-0.1%
PPC05	-1.0%	-1.2%	1.0%	0.3%

Table 1. Preliminary relative differences between  $D_w$  measured with WCal and  $D_w$  measured with IC obtained during two experimental campaigns, for two energies.

### Conclusion

The preliminary results are very encouraging and demonstrate that water calorimetry is feasible in a clinical pulsed PBS proton beam. The absolute relative differences between  $D_w$  derived from WCal and IC are inferior to 2%, which is within the tolerance of the IAEA TRS-398 protocol. Due to the depth-dose distribution, a depth inferior to 3.1 cm (e.g. 2 cm where the gradient is lower) would be more suitable to minimise the uncertainty in positioning. Further numerical and experimental investigations are

planned to confirm and consolidate correction factors and determine the overall uncertainty on absorbed dose-to-water obtained using each system. The next experimental step is to perform the same experimental comparison for a real clinical situation: a dose cube of  $10 \times 10 \times 10 \text{ cm}^3$ , created by a superposition of mono-energetic layers.

### OC-0340 Validation of HU to mass density conversion curve: Proton range measurements in animal tissues

J. Góra<sup>1</sup>, G. Kragl<sup>1</sup>, S. Vatnitsky<sup>1</sup>, T. Böhlen<sup>1</sup>, M.

Teichmeister<sup>1</sup>, M. Stock<sup>1</sup>

<sup>1</sup>EBG MedAustron GmbH, Medical Physics, Wiener Neustadt, Austria

### Purpose or Objective

Proton dose calculation in the treatment planning system (TPS) is based on HU information taken from the CT scans and its relation to the relative stopping powers (RSP). However, tissue equivalent substitutes commonly used in the process of conversion curve definition may not reflect precisely the properties of real, human tissues. Therefore, various animal tissues were used for validation of the CT number to mass density (MD) conversion curves implemented in the TPS (RayStation v5.0.2).

### Material and Methods

10 animal tissue samples (pig) were used in this study (muscle, brain, bone, blood, liver, spleen, lung, fat, kidney and heart). Each sample was prepared and wrapped separately. 3-4 tissues were placed in dedicated phantoms (head and pelvis) at a time and CT scans were taken in the clinically accepted planning protocols. Specially designed PMMA phantoms were composed of two parts: a) an internal box, which could fit the animal tissues inside, b) the outer PMMA cover, designed to simulate pelvis (see fig.1c) and head during CT scan. The design of the phantoms not only helped to reduce imaging artefacts but also allowed to apply a slight pressure on the tissues in order to remove unwanted air. Subsequently, the tissue phantom was attached to the front of the water phantom, where with the use of 2 Bragg peak chambers, range measurements were performed. All measurements were performed within 24h after the animal was slaughtered with the use of one, central, 160.3 MeV pencil beam. For each sample, multiple irradiation positions were chosen in a very precise matter, as it was extremely important to choose the most homogeneous path through which the proton beam would pass. Acquired CT data was used to read out the HU, correlate them with the measured RSP and validate against implemented CT number to MD conversion curves.

### Results

Figure 1, shows the comparison between measured RSP and HU for real tissue samples and implemented conversion curve in the TPS a), CT scan of the adult, abdomen protocol b), and measurement set-up c). The measured data for all soft tissues were found to be within 1% agreement with the calculated data. Only for lung tissue the deviations were up to 3.5%. For bone, both the difficulty in assessing the actual thickness of the part where the beam was passing through, as well as the inhomogeneous nature of this tissue, prevented us from the accurate RSP assessment. However, for 2 measurements out of 3, the measured RSP were within 3.5% uncertainty.

### Conclusion

The experimental validation of the conversion curve resulted in good agreement between measured and calculated data, therefore we can use it in the clinical set-up with confidence. There is a number of uncertainty sources related to these measurements, starting from HU to RSP model, real tissue heterogeneities or uncertainties related to acquisition of the CT data due to beam hardening. The last one, we tried to minimize by using especially dedicated phantom.

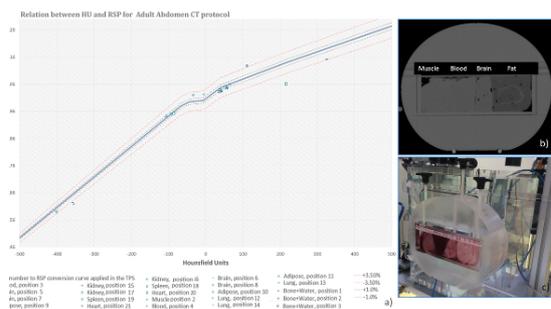

Figure 1 Validation of the adult, abdomen CT protocol; a) relationship between HU and RSP; b) CT scan of the phantom containing animal tissue samples; c) measurements set-up of the water phantom and animal tissue phantom

### OC-0341 Monte Carlo dose calculations using different dual energy CT scanners for proton range verification I.P. Almeida<sup>1</sup>

<sup>1</sup>Maastricht Radiation Oncology MAASTRO clinic, Physics Research, Maastricht, The Netherlands

#### Purpose or Objective

To simulate the dose profile for proton range verification by means of Monte Carlo calculations and to quantify the difference in dose using extracted values of relative electron densities ( $\rho_e$ ) and effective atomic numbers ( $Z_{eff}$ ) for three commercial dual-energy computed tomography (DECT) scanners from the same vendor: a novel single-source split-filter (i.e. twin-beam), a novel single-source dual-spiral and a dual source device. This study aims also to provide a comparison between the use of different DECT modalities and the conventional single-energy CT (SECT) technique in terms of dose distributions and proton range.

#### Material and Methods

Measurements were made with three third generation DECT scanners: a novel dual spiral at 80/140 kVp, a novel twin-beam at 120 kVp with gold and tin filters, and a dual-source scanner at 90/150kVp with tin filtration in the high energy tube. Images were acquired with equivalent CTDI<sub>vol</sub> of approximately 20 mGy and reconstructed with equivalent iterative reconstruction algorithms. Two phantoms with tissue mimicking inserts were used for calibration and validation. Monte Carlo proton dose calculations were performed with GEANT4, in which the materials and densities were assigned using the DECT extracted values of  $\rho_e$  and  $Z_{eff}$  for both phantoms. Simulations were done with monoenergetic proton beams impinging under directions to the cylindrical phantoms, covering different tissue-equivalent inserts. Dose calculations were also performed on images from a third generation SECT scanner at 120 kVp. Simulations based on DECT and SECT images were compared to a reference phantom.

#### Results

Range shifts on the 80% distal dose fall-off (R80) were quantified and compared for the different beam directions and media involved to a reference phantom. Maximum R80 range shifts from the reference values for the calibration phantoms based on DECT images were 3.5 mm for the twin-beam, 2.1 mm for the dual-spiral and for the dual-source. For the same phantom, simulations based on SECT images had a maximum range shift of 4.9 mm. 2D stopping power maps were computed and compared for the different techniques.

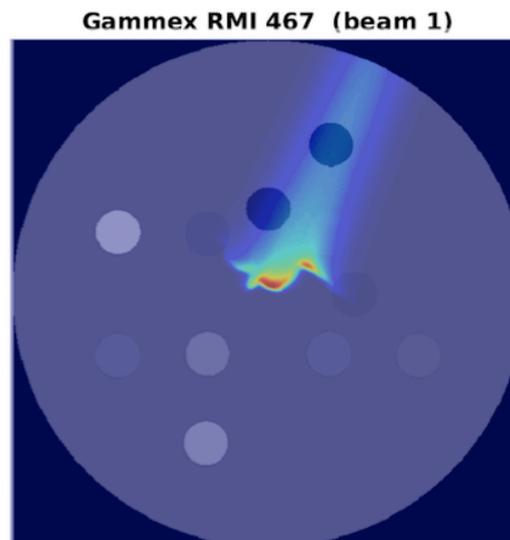

Figure 1. Illustration of the beam 1 direction in the calibration phantom with different tissue-equivalent inserts.

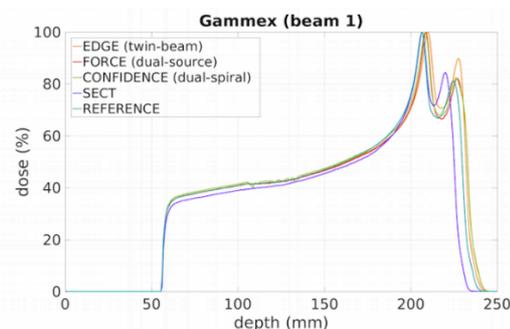

Figure 2: Dose to water profile for one beam direction in the Gammex RMI 467 phantom. The dose is laterally integrated and the R80 is measured.

#### Conclusion

A comparison study between the use of SECT and DECT images for proton dose distribution is performed to understand the differences and potential benefit of DECT for proton therapy treatment planning, using different CT scanners. The final aim is to decrease uncertainty in dose delivery, possibly allowing narrower treatment margin than currently used. In most scenarios, the different modalities of DECT produced results closer to the reference, when compared with the SECT based simulations. Small differences were found for the different DECT scanners.

### OC-0342 Monte Carlo simulations of a low energy proton beam and estimation of LET distributions

T.J. Dahle<sup>1</sup>, A.M. Rykkeli<sup>2</sup>, C.H. Stokkevåg<sup>3</sup>, A. Gørgen<sup>2</sup>, N.J. Edin<sup>2</sup>, E. Malinen<sup>2,4</sup>, K.S. Ytre-Hauge<sup>1</sup>

<sup>2</sup>University of Oslo, Department of Physics, Oslo, Norway

<sup>3</sup>Haukeland University Hospital, Department of Oncology and Medical Physics, Bergen, Norway

<sup>4</sup>Oslo University Hospital, Department of Medical Physics, Oslo, Norway

#### Purpose or Objective

The physical advantage of protons in radiotherapy is mainly due to the 'Bragg peak' of the proton depth dose distribution. However, there is still a controversy on the biological effects of protons, in particular around the Bragg peak. This relates both to the variability of

biological systems and endpoints studied, but also to the actual linear energy transfer (LET) in the biological systems. To provide accurate estimates of the relative biological effects of protons, high precision cell experiments are needed together with detailed knowledge of the LET at a given measurement depth. The objective of this study was to estimate the LET distribution along the depth dose profiles from a low energy proton beam, using Monte Carlo (MC) simulations adjusted to match measured dose profiles.

#### Material and Methods

Dose measurements were performed at the experimental proton beam line at the Oslo Cyclotron Laboratory (OCL) employing 17 MeV protons. A Markus ionization chamber and GafChromic films were used to measure the dose distribution at 28, 88 and 110 cm from the beam exit window. At each position, measurements were performed along the depth dose profile (using increasing thickness of paraffin- and Nylon6 sheets). A transmission chamber was used for monitoring beam intensity. The geometry of the experimental setup was reproduced in the FLUKA MC code. The dose profiles were calculated using FLUKA, and MC parameters relating to beam energy and beam line components were optimized based on comparisons with measured doses. LET-spectra and dose-averaged LET ( $LET_d$ ) were also scored using FLUKA.

#### Results

The measured pristine Bragg peak from the OCL cyclotron covered about 200  $\mu\text{m}$  (Figure 1a). The MC simulations of the beam line were validated by comparing simulated dose profiles with measured data (Figure 1a). The simulated  $LET_d$  increased with depth, also beyond the Bragg peak (Figure 1a and Table 1). Also,  $LET_d$  at target entrance increased with distance from the beam exit window due to the presence of air (Table 1). The LET spectrum was narrow at the target entrance, and considerably broadened at BP depth (Figure 1b).

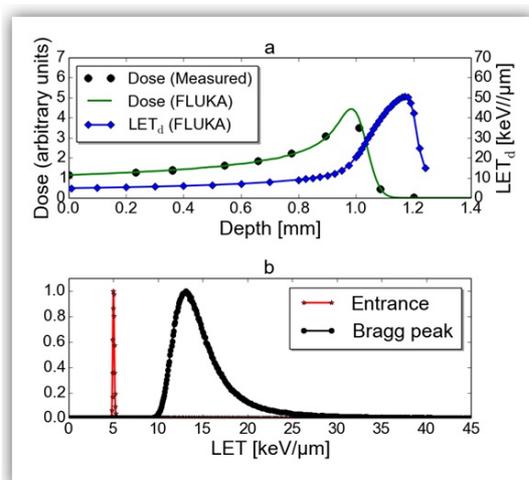

Figure 1: (a) Simulated and measured depth dose profile together with simulated  $LET_d$ , and (b) LET spectra at entrance to target and at Bragg peak, normalized to 1. Measurements were performed at a distance of 88 cm from beam exit window.

Table 1:  $LET_d$  values at three locations along the depth dose profiles (target entrance, Bragg peak and distal dose falloff, i.e. the distal margin of the Bragg peak, given by the distance between the locations corresponding to 80% and 20% dose levels), for three measurement distances from the beam exit window.

Distance to beam exit window [cm]	Entrance [keV/ $\mu\text{m}$ ]	Bragg peak [keV/ $\mu\text{m}$ ]	Distal dose falloff [keV/ $\mu\text{m}$ ]
28	4.1	17.7	23.8-37.9
88	5.0	16.9	24.6-36.5
110	6.3	17.2	25.0-36.9

#### Conclusion

MC simulations accurately modelled the dose distribution around the Bragg peak and can be used to estimate the LET at any given position of the proton beam with optimized parameters. The LET spectrum varied considerably with depth and such LET estimates are highly valuable for future studies of relative biological effectiveness of protons.

#### OC-0343 Experimental setup to measure magnetic field effects of proton dose distributions: simulation study

Department of Radiation Oncology, Dresden, Germany

#### Purpose or Objective

As a first step towards proof-of-concept for MR-integrated proton therapy, the dose deposited by a slowing down proton pencil beam in tissue-equivalent material is assessed within a realistic magnet assembly. Furthermore, radiation-induced activation and demagnetization effects of the magnet are studied.

#### Material and Methods

The dose distributions of proton pencil beams (energy range 70-180 MeV) passing through a transverse magnetic field of a permanent C-shaped NdFeB dipole magnet (maximum magnetic flux density  $B_{\text{max}} = 0.95$  T) while being stopped inside a tissue-equivalent slab phantom of PMMA were simulated (Figure 1). The beam was collimated to a diameter of 10 mm. A radiochromic EBT3 film dosimeter was placed centrally between the two phantom slabs parallel to the beam's central axis. 3D magnetic field data was calculated using finite-element modelling (COMSOL Multiphysics) and experimentally validated using Hall-probe based magnetometry. A Monte Carlo model was designed using the simulation toolkit Geant4.10.2.p02 and validated by reference measurements of depth-dose distributions and beam profiles obtained with Giraffe and Lynx detectors (IBA Dosimetry), respectively. The beam trajectory and lateral deflection were extracted from the film's planar dose distribution. Demagnetization was assessed by calculating the dose deposited in the magnet elements, and by relating this to radiation hardness data from literature. A worst-case estimate of the radioactivation of the magnet was obtained by taking into account the most common produced mother nuclides and their corresponding daughter nuclides.

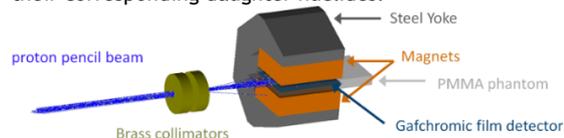

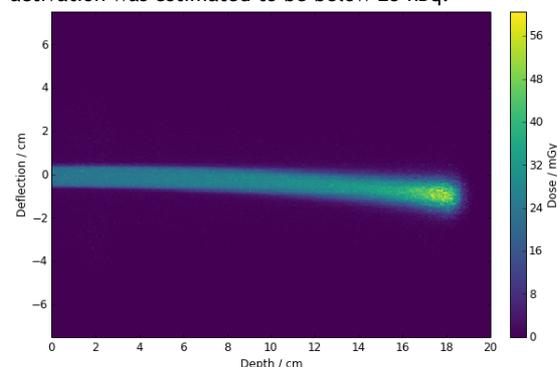

Figure 1: Simulation geometry.

#### Results

The Monte Carlo model showed excellent agreement with the reference measurements (mean absolute range difference below 0.2 mm). The predicted planar dose distribution clearly showed the magnetic field induced beam deflection (Figure 2). The estimated in-plane

deflection of the Bragg peak ranged from 0 cm for 70 MeV to 1 cm for 180 MeV in comparison to no magnetic field. No out-of-plane beam deflection was observed. Exposing the film to 2 Gy at the Bragg peak was estimated to cause a mean dose to the magnets of 20  $\mu$ Gy, which is expected to produce negligible magnetic flux loss. The initial activation was estimated to be below 25 kBq.

**Figure 2:** Simulated dose distribution of a deflected proton beam (180 MeV,  $10^7$  primary particles) on a film dosimeter.

#### Conclusion

A first experimental setup capable of measuring the trajectory of a proton pencil beam slowing down in a tissue-equivalent material within a realistic magnetic field has been designed and built. Monte Carlo simulations of the design show that magnetic field induced lateral beam deflections are measurable at the energies studied and radiation-induced magnet damage is expected to be manageable. These results have been validated by irradiation experiments, as reported in a separate abstract.

#### OC-0344 Experimental validation of TOPAS neutron dose for normal tissue dosimetry in proton therapy patients

G. Kuzmin<sup>1</sup>, A. Thompson<sup>2</sup>, M. Mille<sup>1</sup>, C. Lee<sup>1</sup>

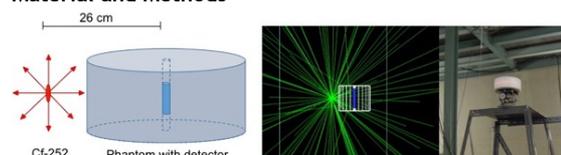

<sup>1</sup>National Cancer Institute, Division of Cancer Epidemiology and Genetics, Rockville, USA

<sup>2</sup>National Institute of Standards and Technology, Radiation Physics Division, Gaithersburg, USA

#### Purpose or Objective

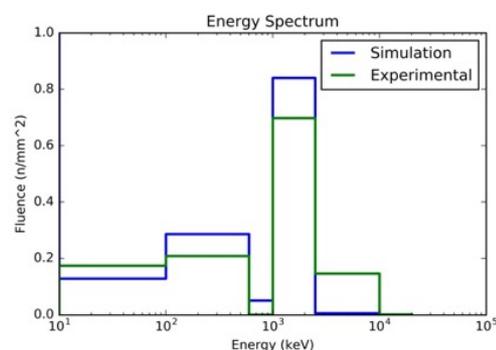

In the last several years, the popularity and use of proton therapy has been increasing due to its promise of a dosimetric advantage over conventional photon therapy. This is especially of great importance in pediatric patients who have a higher risk of developing late effects. During proton therapy 90% of scatter dose is from neutrons, which can travel out of the treatment field and can be highly biologically effective. In order to conduct epidemiological investigations of the risk of long term adverse health effect in proton therapy patients, it is imperative to accurately assess radiation dose to normal tissue. Tool for Particle Simulation (TOPAS) based on the GEANT4 Simulation Toolkit may be a computational option for normal tissue dosimetry to support large scale epidemiological investigations of proton therapy patients. While previous works have benchmarked TOPAS for proton dosimetry within treatment fields, there is a lack of validation for neutron scatter and energy spectrum. In the current study, we measured the energy spectrum of scattered neutrons using a simple physical phantom coupled with a series of Bubble Detectors irradiated by Californium-252 neutron source.

#### Material and Methods

We conducted the neutron measurement under the collaboration with National Institute of Standards and Technology (NIST). We employed Bubble detectors (BTI, Canada) to measure the neutron dose and energy spectrum with good spatial resolution. The detectors provide six energy thresholds from 10 keV to 10 MeV allowing to validate dose and the neutron energy spectrum. To simulate neutron scatter, a polyethylene cylindrical phantom was milled and the bubble detectors were placed inside. The phantom was then irradiated with a Californium-252 neutron source to simulate the secondary neutrons. We also simulated the experiment in TOPAS to compute the neutron dose and energy spectrum for comparison (Figure 1).

#### Results

The measured spectrum was unfolded and shows to be in good agreement with the simulation. On average, the percent difference in the spectrum was less than 31% (Graph 1) and the percent difference of dose was under 23%. The agreement was best at the neutron energies 10 keV - 100 keV (19 %) and worst at 2.5-10 MeV (91 %). Better statistics are needed for the higher energy spectrum region. We plan to conduct the measurement three times to minimize statistical errors and plan to extend the validation to anthropomorphic physical phantoms.

#### Conclusion

We validated the dose and energy spectrum of scattered neutrons computed from TOPAS Monte Carlo code by the measurements using Bubble Detector. We plan to utilize TOPAS dose calculation system coupled with patient-specific proton therapy data for normal dose calculations to support epidemiological studies of proton therapy patients.

### Purpose or Objective

The craniospinal irradiation (CSI) is challenging due to the long target volume and the need of field junctions. The conventional 3D-CRT technique (two lateral opposed cranial fields matched to a posterior field) is still widely adopted. Modern techniques (MT) like IMRT, VMAT, Tomotherapy and proton pencil beam (PBS) are used in a limited number of centres.

A multicentre dosimetric analysis of five techniques for CSI is performed using the same patient, set of delineations and dose prescription. We aimed to address two questions: Is the use of 3D-CRT still justifiable in the modern radiotherapy era? Is one technique superior?

### Material and Methods

One 14 year-old patient with medulloblastoma underwent a CT-simulation in supine position. The CTV and OARs were delineated in one centre. A margin for PTV was added to CTV: 5 mm around the brain and spinal levels C1-L2, 8 mm for levels L3-S3. Fifteen SIOP-E linked institutes, applying 3D-CRT, IMRT, VMAT, Tomotherapy, or PBS (three centres per technique), were asked to return the best plan applicable for their technique: high weighting for PTV coverage (at least 95% of PTV should receive 95% of the prescribed dose) and low weighting for OAR sparing. Plans for a prescription dose of 36 Gy were compared within and between techniques, using a number of dose metrics: Paddick conformity (range 0-1, with 1 being highly conformal), and heterogeneity (range 0-1, with 1 being highly heterogeneous) indices for brain and spine PTVs, OAR mean doses and non-PTV integral doses.

### Results

Conformity- (range 0.75-0.90) and homogeneity (range 0.06-0.08) indices of brain PTV were similar among all techniques. However for the spinal PTV inferior indices (CI: 0.30 vs 0.61 HI: 0.18 vs 0.08) are observed for 3D-CRT with respect to modern techniques (Figure 1). Compared to more advanced photon techniques, 3D-CRT increased mean dose to the heart (13Gy vs 8Gy), thyroid (28Gy vs 15Gy), and pancreas (17Gy vs 12Gy) but decreased dose to both kidneys (4Gy vs 6Gy) and lungs (6Gy vs 8Gy) (Figure 2). PBS reduced the mean dose to the OARs compared to all photon techniques: a decrease of more than 10Gy was found for parotid glands, thyroid and pancreas; between

5-10Gy for lenses, submandibular glands, larynx, heart, lungs, intestine and stomach; smaller than 5Gy for scalp and kidneys (Figure 2). Moreover, protons provide the smallest non-PTV integral doses (V1Gy: 53% 3D-CRT, 69% photons MT, 15% PBS; V5Gy: 23% 3D-CRT, 43% photons MT, 12% PBS). A considerable variation in PTV and OAR dosimetry was observed within a certain technique.

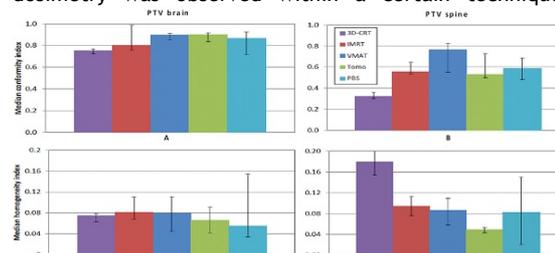

Figure 1 A&B: Median conformity index for PTV brain and spine. C&D: Median homogeneity index for PTV brain and spine. Error-bars show the range (min, max) per technique. (Tomo: Tomotherapy; PBS: pencil beam scanning protons).

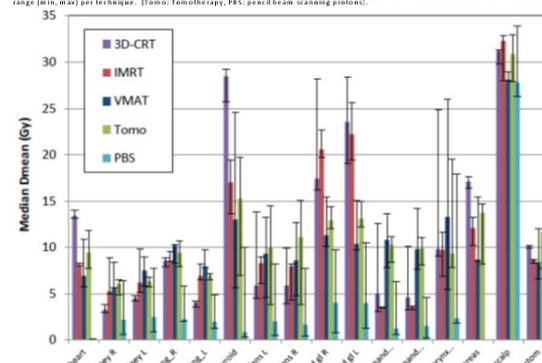

Figure 2 Median mean doses delivered to OAR's. Errorbars show the range (min,max) per technique. (Tomo: Tomotherapy; PBS: pencil beam scanning protons).

### Conclusion

Modern radiotherapy techniques demonstrate superior conformity and homogeneity, and reduced mean dose the OARs compared to 3D-CRT.

PBS produced the case with the lowest mean dose for each OAR and integral doses. However, the variability among centres using the same technique means it is not possible to clearly identify the best technique from this data. Efforts should be made to improve inter-centre consistency for each technique.

### OC-0346 Multicentre audit of SBRT oligometastases plan quality

J. Lee<sup>1</sup>, R. Patel<sup>1</sup>, C. Dean<sup>2</sup>, G. Webster<sup>3</sup>, D.J. Eaton<sup>1</sup>

<sup>1</sup>Mount Vernon Cancer Centre, National Radiotherapy Trials QA RTTQA Group, Northwood, United Kingdom

<sup>2</sup>Barts Health NHS Trust, Radiotherapy Physics, London, United Kingdom

<sup>3</sup>Worcestershire Oncology Centre, Radiotherapy Physics, Worcester, United Kingdom

### Purpose or Objective

SBRT for oligometastases is currently being used to treat patients at 17 centres in England, as part of the NHS England "Commissioning through Evaluation" programme. The national trials QA group conducted QA for the programme, which included establishing appropriate clinical plan quality metrics for auditing submitted SBRT plans. The purpose of the audit was to inform future guidance on plan quality metric tolerances and help centres determine whether a given plan is optimal.

### Material and Methods

Plans included were either benchmark plans using pre-delineated CT images planned by all centres prior to patient recruitment; or plans of initial patients reviewed prior to treatment. VODCA software (Medical Software Solutions) was used for independent plan review. Lung plans were analysed separately due to the inherent

differences in scatter conditions around the tumour. Initial analysis showed a high proportion of plans where PTV coverage was compromised. Plan quality metrics were therefore developed which were independent of PTV coverage. These metrics are defined in eqn1 and eqn2:

$$\text{Spillage} = \frac{\text{Body } V_{100\%}}{\text{PTV } V_{100\%}} \quad \text{eqn. 1}$$

$$\text{Modified Gradient Index} = \frac{\text{Body } V_{50\%}}{\text{PTV } V_{100\%}} \quad \text{eqn. 2}$$

where  $V_{100\%}$  and  $V_{50\%}$  are the volumes covered by 100% and 50% of the prescription dose (the dose intended to cover the target) respectively. The mean, median and standard deviation are reported for both metrics, split into PTV  $V_{100\%}$  volume ranges of 0-20cc, 20-40cc and >40cc.

### Results

38 lung and 77 non-lung (lymph node, liver, adrenal and bone) plans were reviewed, produced for treatment using Cyberknife (29), Tomotherapy (7), VMAT (71), fixed gantry angle IMRT (5) or 3D conformal (3) modalities. 11% of lung patients and 29% of non-lung patients had significantly compromised PTV coverage (PTV  $V_{100\%} < 90\%$ ). The spillage results for lung and non-lung sites were similar. Modified Gradient Index (MGI) values were higher for lung than non-lung sites and decreased with increased treated volume (see table 1). No clinically significant differences were seen between treatment platform or modality.

Lung	Spillage			Modified Gradient Index			n
	Mean	Median	S.D.	Mean	Median	S.D.	
PTV $V_{100\%}$ Vol (cc)							
<20	1.19	1.22	0.07	6.99	6.80	1.66	7
20-40	1.11	1.10	0.07	5.50	5.34	1.00	26
>40	1.12	1.12	0.07	4.83	4.44	0.86	5

Non-lung	Spillage			Modified Gradient Index			n
	Mean	Median	S.D.	Mean	Median	S.D.	
PTV $V_{100\%}$ Vol (cc)							
<20	1.20	1.15	0.15	6.22	5.61	1.35	11
20-40	1.13	1.12	0.07	4.66	4.08	1.43	15
>40	1.11	1.09	0.07	4.53	4.49	0.75	51

Table 1. The mean, median and standard deviation of the "Spillage" and "Modified Gradient Index" plan quality metrics for lung and non-lung oligometastatic SBRT plans.

### Conclusion

The high proportion of non-lung patient plans with compromised target coverage suggests that future guidance documents should use plan quality metrics which are independent of coverage, such as those proposed here. The similar spillage results for lung and non-lung sites suggest that for this metric, site specific tolerances are not required. The MGI is higher for lung plans, as expected with the increased scatter in low density surroundings. MGI lung and non-lung results are similar in absolute terms and so equivalent planning tolerances could be applied to both groups. These data provide evidence of what plan quality is achievable across multiple treatment platforms, modalities and clinical sites. These are particularly useful for non-lung oligometastatic SBRT plans where there is currently a lack of data in the literature.

### OC-0347 Key factors for SBRT planning of spinal metastasis: Indications from a large scale multicentre study

### Purpose or Objective

SBRT planning for spinal metastases is particularly challenging due to the high dose required for covering the PTV complex shape, and to the steep dose gradient mandatory for sparing the spinal cord. Many combinations of delivery systems and TPSs are clinically available in different institutions. Aim of this study was to investigate the dosimetric variability in planning spine SBRT among a large number of centers.

### Material and Methods

Two spinal cases were planned by 38 centers (48 TPS) with different technologies (table 1): a single dorsal metastasis, and double cervical metastases. The required dose prescription (DP) was 30 Gy in 3 fractions. Ideal PTV coverage request was:  $V_{DP}>90\%$  (minimum request:  $V_{DP}>80\%$ ). Constraints on the organs at risk (OAR) were: PRV spinal cord:  $V_{18Gy}<0.35\text{cm}^3$ ,  $V_{21.9Gy}<0.03\text{cm}^3$ ; oesophagus:  $V_{17.7Gy}<5\text{cm}^3$ ,  $V_{25.2Gy}<0.03\text{cm}^3$ .

As a last option, planners were allowed to downgrade DP to 27 Gy to fulfil OAR constraints. 3D dose matrices were analyzed. DVH were generated and analyzed with MIM 6.5 (MIM Software Inc. Cleveland US). Homogeneity index (HI) was computed for each PTV as  $HI = (D_{2\%} - D_{98\%}) / DP$ . Planners did not meet the protocol constraints or PTV dose coverage were asked to re-plan the wrong case. Multivariate statistical analysis was performed to assess correlations between dosimetric results and planning parameters.

Table1: Linac, TPS, delivery technique and kind of inverse optimization used in the intercomparison.

### Results

14/96 plans did not meet the protocol requests. After the re-planning, still 6/96 plans with different technologies did not respect at least one constraint with differences >0.5 Gy. For the dorsal case, 3 minimum (<0.5Gy) deviations (1 VMAT, 1 IMRT, 1 Tomo), and 2 reduced DP (1 VMAT and 1 Tomo) occurred. For the cervical case, 3 minimum deviation (1VMAT 1IMRT 1Tomo), and 2 reduced

DP (1 VMAT and 1Tomo) were observed. Multivariate analysis showed, for both cases, a significant correlation ( $p < 0.05$ ) between Homogeneity Index (HI) and both OAR dose sparing and PTV coverage. Irradiation techniques correlated with spinal cord sparing; however institutions using similar/same delivery/TPS techniques produced quite different dose distributions, highlighting the influence of the planner experience on the optimization process (figure 1).

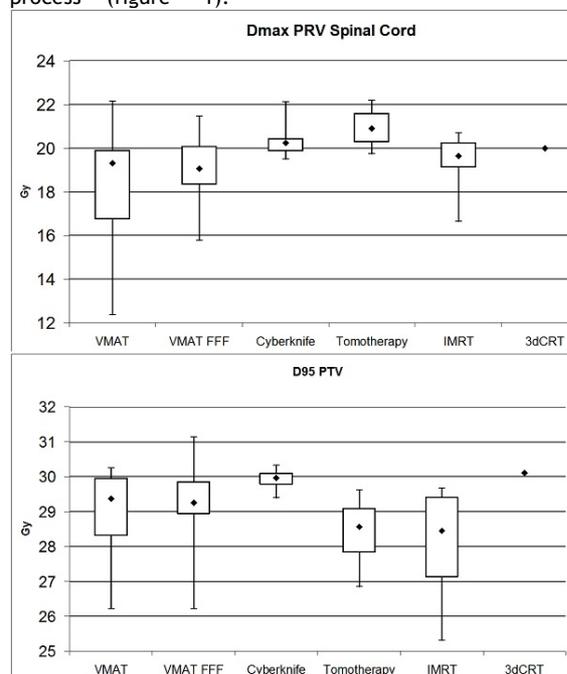

Fig1 Box plot relative to the single metastasis case. 18 plans were computed using VMAT, 8 VMAT FFF (linac Free of Flattering Filter), 6 Cyberknife, 5 Tomotherapy, 7 IMRT, 1 3dCRT.

#### Conclusion

At our knowledge, this is the largest non-sponsored multicentre planning comparison. Differences in DVH binning among centres could explain minor violations. HI is a key factor for planning optimization: prescribing to lower isodose generally leads to better OAR sparing and higher PTV coverage. Results have a dependence on the irradiation technique, although the planner's experience plays a not negligible role. A multicentre analysis as proposed in this study can have an impact on the standardization of plan quality for spinal SBRT.

#### OC-0348 Reducing the dosimetric impact of variable gas volume in the abdomen during RT of esophageal cancer

P. Jin<sup>1</sup>, J. Visser<sup>1</sup>, K.F. Crama<sup>1</sup>, N. Van Wieringen<sup>1</sup>, A. Bel<sup>1</sup>, M.C.C.M. Hulshof<sup>1</sup>, T. Alderliesten<sup>1</sup>  
<sup>1</sup>Academic Medical Center, Radiation Oncology, Amsterdam, The Netherlands

#### Purpose or Objective

For middle/distal esophageal tumors, a varying gas volume in the upper abdomen could induce changes in the dosimetry of RT. In this study, we investigated the dosimetric impact of abdominal gas pockets as well as a density override (DO) strategy to mitigate dosimetric effects.

#### Material and Methods

We retrospectively included 1 patient with middle and 8 patients with distal esophageal cancer. For these patients, it was unclear whether re-planning was needed due to the varying gas volume during treatment. For each patient, we measured gas volumes in the planning CT (pCT) and 8-28 (median: 14) CBCTs to assess possible time trends.

Further, we made IMRT and VMAT plans with a prescription of 41.4Gy (preoperative RT) or 50.4Gy (definitive RT). For IMRT/VMAT, a DO strategy (i.e., assigning mass density to gas pockets in the pCT) with three settings was used: no DO (denoted as DO=0), DO=0.5, and DO=1 (equivalent to an adipose-muscle mixture), resulting in 6 plans per patient. Next, by copying the gas pockets derived from the available CBCT to the pCT, a fractional CT was simulated to calculate the fractional doses using all 6 plans. DVH parameters of the CTV and organs at risk (OARs) were compared between 1) the three DO settings, 2) IMRT and VMAT, and 3) fractional and planned dose. Dose distribution difference in the CTV between fractional and planned dose was also compared.

#### Results

The range of initial gas volume measured in the pCT was 56-732ml. The gas volume fluctuated over the treatment course with no time trend (range of mean: 33-519ml, range of standard deviation: 20-162ml). For the fractional dose,  $V_{95\%}$  of the CTV was always  $>98\%$  for VMAT but not for IMRT with DO=0 (Fig.1). For both IMRT and VMAT, DVH parameters of the CTV were significantly larger for DO=1 than for DO=0 and 0.5 ( $p < 0.05$ , Wilcoxon signed-rank test). For an increasing gas volume, an overdose ( $>3.5\%$  higher than the planned dose) in the CTV was found in 72-88%/64-77% cases for IMRT/VMAT with all three DO settings. The amount of overdose increased as the gas volume increased relative to the initial volume and was  $>5\%$  when the increase was  $>100\text{ml}$  (Fig.2). For a decreasing gas volume, an underdose ( $>3.5\%$  lower than the planned dose) in the CTV was found for IMRT/VMAT in 34%/23% cases with DO=0, 7%/0% cases with DO=0.5, and 0%/0% cases with DO=1. The underdose became more severe as the gas volume decreased for DO=0 and 0.5. An overdose ( $>3.5\%$ ) still existed in up to 28% cases for DO=1 when the gas volume decreased. DVH parameters of OARs in the fractional dose were almost the same as in the planned dose and below the clinical constraints for all scenarios.

#### Conclusion

For esophageal cancer RT, the use of VMAT with DO=0.5 in treatment planning is preferable to avoid an overdose/underdose in the CTV when the abdominal gas volume decreases during treatment. However, when the gas volume increases with  $>100\text{ml}$ , a DO strategy would result in an overdose  $>5\%$ . Therefore, in that case re-planning may be a better solution.

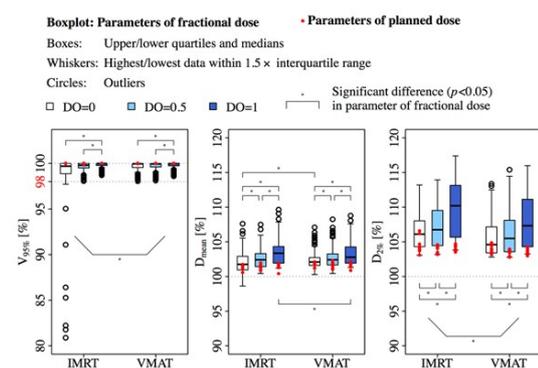

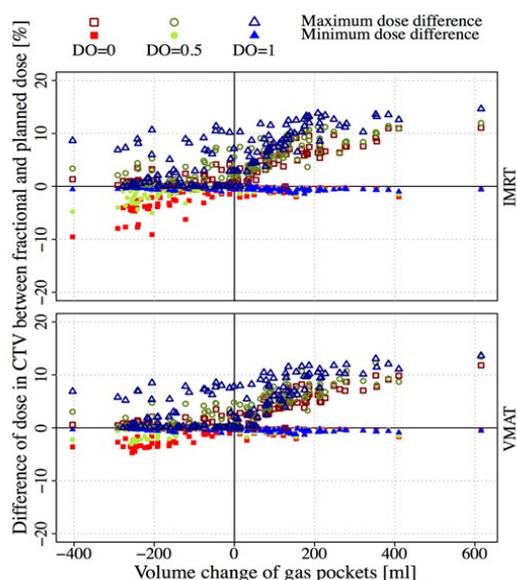

Fig. 1 For IMRT and VMAT, the  $V_{95\%}$ ,  $D_{max}$ , and  $D_{2\%}$  of the clinical target volume (CTV) for the planned and fractional dose in the scenarios of the three density override (DO) settings (DO=0, DO=0.5, and DO=1).

**Fig. 2** The maximum and minimum values (a pair of filled/open symbols in same shape) of the dose difference in CTV between the fractional and planned dose against the gas volume changes for both IMRT and VMAT (upper and lower panels) with all three DO settings (different colors). A positive value in the horizontal axis means the gas volume increased and a negative value means a decrease relative to the initial volume measured in the pCT. A positive value in the vertical axis means an overdose and a negative value means an underdose.

#### OC-0349 Prediction of GTV median dose differences benefit Monte Carlo re-prescription in lung SBRT

D. Dechambre<sup>1</sup>, Z.L. January<sup>1</sup>, N. Jansen<sup>1</sup>, C. Mievis<sup>1</sup>, P. Berkovic<sup>1</sup>, S. Cucchiari<sup>1</sup>, V. Baart<sup>1</sup>, C. Ernst<sup>1</sup>, P. Coucke<sup>1</sup>, A. Gulyban<sup>1</sup>

<sup>1</sup>C.H.U. - Sart Tilman, Radiotherapy department, Liège, Belgium

#### Purpose or Objective

The use of Monte Carlo (MC) dose calculation algorithm for lung patients treated with stereotactic body radiotherapy (SBRT) can be challenging. Prescription in low density media and time-consuming optimization conducted CyberKnife centers to propose an equivalent path length (EPL)-to-Monte Carlo re-prescription method, for example on GTV median dose (Lacornerie T, et al. *Radiat Oncol* 2014;9:223). The aim of this study was to evaluate the differences between the two calculation algorithms and their impact on organs at risk (OAR) and to create a predictive model for the re-prescription.

#### Material and Methods

One hundred and twenty seven patients (with 149 lesions) were treated with CyberKnife (CK; Accuray, Sunnyvale, US) between 2010 and 2012. A high-resolution grid (512<sup>3</sup>) was used for the EPL and MC calculations (2% variance). All re-calculation from EPL to MC maintained the number of beams and their monitor units. Relative differences in GTV D50 between the two algorithms were assessed and uni/multivariate linear regression was performed using prescription dose (Gy), tracking (ITV concept if not available), location (peripheral or central) and volume (in cc) of the lesion as input parameters. Statistical significance was determined using F-test at p-value<0.05. OARs volumetric dose constraints were applied from Timmerman RD et al. (*Semin Radiat Oncol* 2008;18:215-22). As tolerance limits were defined based on simple heterogeneity correction algorithm (e.g. EPL), correlation between EPL and MC OARs dose values was assessed following the work from the Rotterdam team (van der Voort van Zyp NC, et al. *Radiother Oncol* 2010;96:55-60).

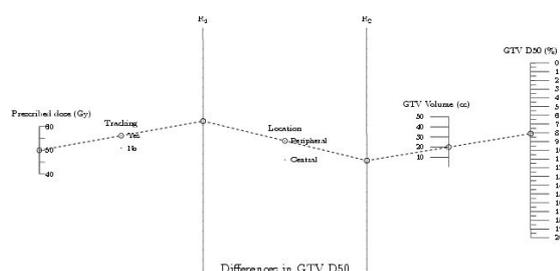

#### Results

The observed difference (MC compared to EPL) varied from 0 % to 48% (median = 10%, standard deviation = 9%).

The uni- and multi-variate analysis showed statistical significance for all parameters except lesion location (table 1).

	Differences in D50 (%)			
	Univariate		Multivariate	
	Coeff.	p-value	Coeff.	p-value
Dose	0.55	<0.001	0.27	0.045
Tracking	-2.80	0.062	-2.81	0.029
Location	9.17	<0.001	4.32	0.054
Volume	-0.33	<0.001	-0.23	<0.001

The high coefficient associated to the peripheral character is probably due to the EPL un-modelled lateral electron equilibrium caused by the prevalent presence of low density lung tissues surrounding the peripheral lesion, thus greatly impacting dose calculation differences. Based on the multivariate analysis predictive nomogram was generated ( $R^2=0.58$ , Figure 1).

Dose to OARs calculated with EPL and MC showed strong linear correlation ( $R^2=0.99-1.00$ ). The dose constraints decreased by 1% in the heart (D10cc), great vessels (D10cc) and spinal cord (D0.25cc), 2% in the oesophagus (D5cc), 5% in the ribs (D5cc) and 16% in the trachea (D4cc).

#### Conclusion

The differences between MC and EPL are significantly impacted by dose, tracking, location and the volume of the lesion. Predictive nomogram helps to estimate the differences on GTV D50. EPL to MC OAR dose tolerance limit proved to have a strong linear correlation with conversion factors ranging from 0.84 to 0.99. Based on our model, re-prescription value can be estimated and, if required, used to further restrict the constraints on the OARs during EPL optimization.

#### OC-0350 ExacTrac®-based Fractionated Radiosurgery (fRS) of Choroidal Melanoma (CM)

M. Wöslle<sup>1</sup>, P. Goldschmidt<sup>1</sup>, G. Lohm<sup>1</sup>, L. Grajewski<sup>2</sup>, L. Krause<sup>2</sup>, I. Ciernik<sup>1</sup>

<sup>1</sup>Dessau City Hospital, Radiation Oncology, Dessau, Germany

<sup>2</sup>Dessau City Hospital, Ophthalmology, Dessau, Germany

#### Purpose or Objective

Proton therapy (PT) has been a standard for treating choroidal melanomas for the last three decades. However, PT is not easily available for the majority of patients. Advances in photon therapy allow highly conformal dose delivery while sparing normal tissue. However, fRS for small moving target volumes, such as CM, has remained a challenge.

#### Material and Methods

Since December 2014, we treated 40 patients with central choroidal tumors with fRS. Radiotherapy plans were obtained with iPlan® RT (Version 4.5.3, Brainlab, Feldkirchen, D) after placement of 4 Tantalum clips (Altomed Ltd., U.K.) a week prior the planning CT/MRT. Thirteen cases have been reanalysed: ten treated with 10 Gy x 5 for CM, one case of haemangioma treated with 14,5 Gy in one fraction, and 2 cases of breast cancer metastasis treated with 6 Gy x 5 and 4. iPlan® RT uses HybridArc™ as field configuration with three to six dynamic conformal arcs complemented with five to seven dynamic IMRT

fields. Treatment was delivered with a Novalis-TrueBeam™ STx Linac (Palo Alto, CA, USA). IGRT was achieved with ExacTrac® (version 6.0). ExacTrac® documented the eye position before and after each irradiation field.

#### Results

No local failure and no case of enucleation have been seen at a median follow-up time of 329 days (range 98 - 678). Complications observed so far were impairment of visual acuity in half of the cases, intraocular haemorrhage (1 pts.), xerophthalmia (2 pts.), or keratitis (2 pts.). The minimal, mean, and maximal doses within the target volumes were 86.3 ( $\pm$  5.2)%, corresponding to  $V_{95\%} = 98.3$  ( $\pm$  1.4)%, 100.0 ( $\pm$  0.4)%, and 103.4 ( $\pm$  1.1)%, respectively. The conformity index was  $1.23 \pm 0.16$  and the homogeneity index was  $0.04 \pm 0.01$ . Mean dose applied to the ipsilateral eye lens, cornea, normal tissue of the involved eye, and the lacrimal gland were 12.1 ( $\pm$  17.7) Gy, 6.8 ( $\pm$  11.5) Gy, 18.1 ( $\pm$  9.2) Gy, and 10.7 ( $\pm$  7.6) Gy, respectively. Maximal dose of the ipsilateral optic nerve was 31.7 ( $\pm$  15.9) Gy. Doses delivered to the contralateral eye, lens, optic nerve, and lacrimal gland were less than 0.6 ( $\pm$  0.7) Gy, 0.2 ( $\pm$  0.1) Gy, 1.3 ( $\pm$  1.6) Gy, and 0.2 ( $\pm$  0.1) Gy, respectively. The doses given to the chiasma did not exceed 1.3 ( $\pm$  1.5) Gy; the pituitary gland 0.9 ( $\pm$  1.4) Gy, and the maximal dose to the brain did not exceed 11.1 ( $\pm$  4.9) Gy. The ITV did not exceed 2mm.

#### Conclusion

HybridArc® in combination with peritumoral tissue markers for image-guidance provides highly conformal and homogenous doses distributions for the treatment of small and moving target volumes.

### Proffered Papers: Adaptive strategies

#### OC-0351 Analysis of concordance in multicentre adaptive bladder trials quality assurance

E. Parsons<sup>1</sup>, D. Megias<sup>1</sup>, A. Baker<sup>1</sup>, S. Hafeez<sup>2</sup>, E. Hall<sup>2</sup>, H. McNair<sup>3</sup>, Y. Tsang<sup>1</sup>, R. Huddart<sup>3</sup>

<sup>1</sup>Mount Vernon Hospital, National Radiotherapy Trials Quality Assurance Group, Northwood- Middlesex, United Kingdom

<sup>2</sup>The Institute of Cancer Research, Clinical Trials Unit, Sutton- Surrey, United Kingdom

<sup>3</sup>Royal Marsden Hospital, Radiotherapy, Sutton- Surrey, United Kingdom

#### Purpose or Objective

HYBRID (CRUK/12/055) and RAIDER (CRUK/14/016) are two randomised phase II multi-centre clinical trials investigating the use of adaptive 'Plan of the day' (POD) bladder radiotherapy. In order to promote accurate POD selection across multiple recruiting centres, a pre-accrual assessment for adaptive plan selection was developed as part of an IGRT QA credentialing programme (3<sup>rd</sup> ESTRO Forum 2015-OC0564). The purpose of this study was to establish whether the pre-accrual POD assessment is a feasible QA process and investigate whether the POD can be consistently selected by individuals across all recruiting centres.

#### Material and Methods

Twelve bladder CT/CBCT image pairs were made available to individuals to register according to protocol. Individuals recorded the most appropriate POD selection from a library of three possible plans and submitted to a central QA group for review. In order to receive QA approval to select the POD for HYBRID/RAIDER, individuals were required to achieve an assessment score of  $\geq 83\%$  (10/12) agreement with the expert consensus answers.

It was a pre-requisite of HYBRID and RAIDER that centres already have an appropriate IGRT competency framework for bladder CBCT in place prior to trial recruitment. The assessment was first piloted for 10 centres recruiting to

the HYBRID trial in November 2013 and then utilised for a further 14 RAIDER centres in June 2015. The Mann-Whitney U test and Kruskal-Wallis test were used to investigate if there were any significant difference in assessment scores between the two trials and individual staff grading respectively.

#### Results

The POD assessment was completed by 244 individuals (HYBRID=73, RAIDER=171) from 24 recruiting centres. The median assessment score was 92% (range: 25-100%) and 86% of individuals achieved the score required for QA approval on their first attempt. The distribution of assessment scores in RAIDER was found to be significantly different to HYBRID ( $p=0.034$ ). Individuals would be more likely to achieve a score  $\geq 83\%$  for RAIDER (90%) than HYBRID (77%). Each centre had an average of 10.2 (Range 3-23) individuals complete the POD assessment. There was no statistically significant difference in assessment scores between different staff grades ( $p=0.713$ ). The median assessment scores varied between recruiting centres, with a range between 83% and 100%.

#### Conclusion

A high median score was achieved by the individuals that completed the assessment indicating consistent POD selection with the expert consensus answers across individuals and centres. The POD assessment proved to be a feasible way of credentialing multiple individuals across all recruiting centres. Differences in assessment scores between HYBRID and RAIDER trials likely reflect the increased experience with pelvis CBCT in UK centres between 2013 and 2015. Individuals of all grades were able to successfully complete the assessment indicating the importance of appropriate local IGRT training rather than staff seniority when choosing the POD.

#### OC-0352 CBCT-guided evolutive library for cervix adaptive IMRT

B. Rigaud<sup>1,2</sup>, A. Simon<sup>1,2</sup>, M. Gobeli<sup>3</sup>, C. Lafond<sup>1,3</sup>, D. Guillaume<sup>3</sup>, J. Leseur<sup>3</sup>, J. Castelli<sup>1,2,3</sup>, P. Haigrón<sup>1,2</sup>, R. De Crevoisier<sup>1,2,3</sup>

<sup>1</sup>INSERM, U1099, Rennes, France

<sup>2</sup>Université de Rennes 1, LTSI, Rennes, France

<sup>3</sup>Centre Eugene Marquis, Radiotherapy Department, Rennes, France

#### Purpose or Objective

In the context of locally advanced cervix carcinoma adaptive radiation therapy (ART), this study aimed to simulate five treatment strategies, including an original CBCT-guided evolutive library. We compared geometrically the strategies by considering the coverage by the simulated PTVs for both CTV and OARs.

#### Material and Methods

Sixteen patients having received a total dose of 45 Gy by IMRT for locally advanced cervix carcinoma were included. Each patient had: three planning CTs corresponding to three bladder volumes (empty (EB), intermediate (IB) and full (FB)), a CT scan at 20 Gy and bi-weekly CBCTs for 5 weeks. The CTV and the OARs were manually delineated on each CT and CBCT. Five radiotherapy (RT) strategies were investigated (Figure 1): (1) "Standard RT" based on one planning CT with IB and considered as reference, (2) "ITV-based RT" with an ITV built from the three planning CT scans, (3) "RT with one midtreatment replanning" corresponding to the standard RT with replanning at 20 Gy, (4) "Pretreatment library ART" using the three planning CTs (EB, IB, FB) to define the plan of the day by a CTV overlapping criteria, and (5) "Evolutive library RT" corresponding to the 4<sup>th</sup> strategy enriched by including CBCTs anatomy in the pretreatment library if the daily CTV shape was highly different (overlap scores between the library and the daily CTV). For each strategy, two PTV margins were used (7 and 10 mm). All the strategies were geometrically compared by considering, on the CBCTs, the percentage of coverage of the CTV or the OAR by the

strategy PTVs. The under-coverage of the CTV by the PTV was investigated using elastic registration.

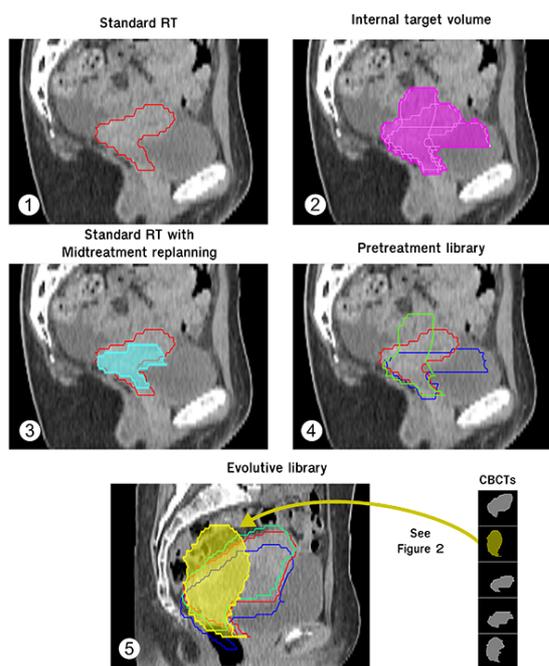

Figure 1: Five tested RT strategies in cervix IMRT

**Results**

The “Evolutive library RT” corresponded to a mean number of one per-treatment replanning (up to 3). For 50% of the cohort, no per-treatment replanning was needed. The table shows the CTV and OARs coverage by the PTV for all strategies. The evolutive library strategy provided the highest CTV coverage compared to the other strategies corresponding to a mean CTV coverage (min - max) of 98.3 % (96.4 - 100%) with 10mm margins and to 96.0 (93.0 - 99.7) with 7mm margins (p<0.05). Moreover, this strategy significant decreased the bowel-PTV overlapping.

RT strategies	PTV margin (mm)	Coverage by the PTV (%) mean (min - max)			
		CTV	Bladder	Rectum	Bowel
Standard RT	7	89.7 (63.6 - 99.9)	20.7 (1.9 - 46.3)	22.3 (2.5 - 46.8)	7.5 (1.9 - 15.0)
	10	93.9 (70.9 - 100)	29.5 (6.8 - 60.5)	37.0 (5.0 - 69.8)	10.2 (3.0 - 18.9)
ITV-based RT	7	95.0 (72.8 - 100)	30.9 (3.1 - 52.5)	38.3 (4.5 - 76.7)	10.6 (2.8 - 21.1)
	10	97.1 (78.6 - 100)	40.9 (9.2 - 66.5)	53.1 (10.7 - 87.8)	13.7 (4.1 - 26.1)
MidTtReplan	7	91.4 (79.5 - 98.7)	18.7 (4.6 - 41.1)	25.1 (11.8 - 47.0)	5.7 (1.8 - 13.4)
	10	95.2 (84.7 - 99.9)	27.6 (10.5 - 57.4)	40.9 (21.9 - 72.3)	8.1 (2.8 - 17.9)
Pretreatment library	7	93.0 (64.9 - 99.7)	20.2 (1.7 - 41.2)	25.9 (2.8 - 63.1)	6.5 (1.8 - 13.5)
	10	96.1 (72.4 - 100)	29.6 (6.1 - 55.7)	39.7 (7.9 - 75.1)	9.1 (3.0 - 17.6)
Evolutive library	7	96.0 (93.0 - 99.7)	19.4 (8.5 - 41.2)	28.3 (9.2 - 65.2)	5.6 (1.8 - 10.1)
	10	98.3 (96.4 - 100)	29.3 (15.4 - 55.7)	43.2 (18.2 - 76.8)	8.1 (3.0 - 14.2)

Table: CTV and OARs geometric coverage by the PTV for all strategies

PTV: Planning target volume; CTV: Clinical target volume; ITV: Internal target volume.

**Conclusion**

The “Evolutive library RT” strategy increased the CTV to PTV coverage, while not increasing the PTV bladder overlapping and even decreasing the bowel to PTV overlapping.

**OC-0353 Implementation of RTT led ‘plan of the day’ adaptive radiotherapy in cervical cancer**

A. Baker<sup>1</sup>, T. Hague<sup>2</sup>, Y. Tsang<sup>1</sup>, P.J. Hoskin<sup>1</sup>  
<sup>1</sup>Mount Vernon Hospital, Department of Radiotherapy, Northwood Middlesex, United Kingdom  
<sup>2</sup>Mount Vernon Hospital, Department of Radiotherapy Physics, Northwood Middlesex, United Kingdom

**Purpose or Objective**

Plan of the day (PoD) ART for cervical cancer patients can potentially reduce toxicity and the risk of geometrical miss but may be resource intensive. In order to implement accurate PoD for these patients this study aimed to assess the accuracy of adaptive online plan selection and linac resource impact.

**Material and Methods**

An initial patient cohort had planning CTs acquired with an empty and full bladder and an intermediate MRI. CTVs were outlined on each of the datasets to include uterus and proximal vagina, from which an ITV and PTV were defined with further nodal volumes as required. VMAT plans were created depending on the amount of uterine movement, with a further plan using the previous standard technique as a backup.

Online daily CBCT was performed for all patients with additional kV planar images used for nodal positioning in one patient and for pelvic tilt in another. Plan selection following online registration using a combination of bony anatomy and soft tissue was performed by 2 members of the project team (observers) who had attended an anatomical training session and had a range of experience with female pelvic CBCT analysis. A 3mm margin between the visible target anatomy and the PTV contour was allowed for intrafraction motion. This was assessed through the addition of weekly post-treatment CBCTs. In-room time (patient enter to exit) was recorded at each session and patients were booked into the departmental 20 minutes time slot for ART.

A consensus standard PoD was agreed offline by an experienced clinician and RTT. Offline analysis was performed to measure concordance with the consensus standard PoD and the online decision.

**Results**

A total of 100 online PoD evaluations plus 600 offline evaluations, by 6 observers, were used for the analysis. The median concordance between the consensus standard PoD and the online plan selection was 98%. Where poor concordance was observed between online plan selection and the consensus standard PoD, a safe larger volume option was chosen online. Post-treatment CBCT’s showed target anatomy was covered in all but 1 case. In-room timing ranged from 10 - 30mins with a median time of 19mins. The median score of the 4 observers offline compared to the consensus standard was 86%. The range between individuals was 76%- 96% and between patients was 78 - 96%.

Concordance	patient 1	patient 2	patient 3	patient 4	median
CS and online	100%	92%	100%	96%	98%
CS and observer 1	96%	92%	84%	84%	88%
CS and observer 2	96%	88%	64%	64%	76%
CS and observer 3	92%	76%	84%	72%	80%
CS and observer 4	100%	84%	96%	96%	96%
median by patient	96%	86%	84%	78%	

CS = consensus standard

**Conclusion**

High online concordance of 98% with the consensus standard PoD demonstrates that the initial training equipped the team with appropriate knowledge to perform accurate plan selection. A combination of 2 observers online achieve closer results to the consensus standard rather than individually. The joint decision making can be performed within the standard departmental ART time slot of 20 minutes. The CBCT data, consensus standard PoD and anatomy training can be used as part of the assessment programme for future RTT observers. Greater confidence in choosing smaller volume

plans needs to be built to achieve the full potential of ART.

#### OC-0354 Dosimetric impact of anatomical changes in photon and particle therapy for pancreatic cancer

K. Crama<sup>1</sup>, A.C. Houweling<sup>1</sup>, J. Visser<sup>1</sup>, K. Fukata<sup>2</sup>, C.R.N. Rasch<sup>1</sup>, T. Ohno<sup>2</sup>, A. Bel<sup>1</sup>, A. Van der Horst<sup>1</sup>

<sup>1</sup>Academic Medical Center, Department of Radiation Oncology, Amsterdam, The Netherlands

<sup>2</sup>Gunma University, Gunma University Heavy Ion Medical Center, Maebashi, Japan

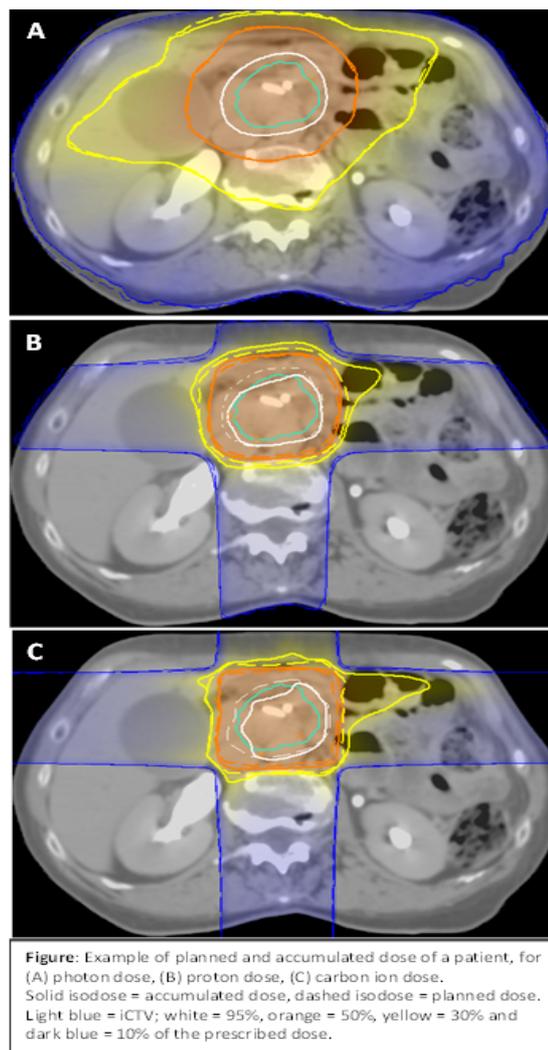

##### Purpose or Objective

Radiotherapy of pancreatic tumors is toxic due to the high dose to surrounding organs-at-risk (OARs). Irradiation with charged particles is characterized by a sharp dose fall-off around the target area. Compared to photon therapy, OARs can be further spared while delivering a high dose to the tumor. Treatment planning studies in pancreatic cancer patients have shown this benefit of charged particle therapy over photon therapy. However, intra- and interfractional changes may greatly affect the robustness of particle therapy. Past studies only investigated differences in planned dose; studies comparing the robustness of different modalities have not been published yet.

We compared the dosimetric impact of interfractional anatomical changes (i.e. body contour differences, gastrointestinal gas volume changes and setup errors) in photon, proton and carbon ion therapy for pancreatic cancer patients. Intrafractional changes were not taken into account in this study.

##### Material and Methods

Photon, proton and carbon ion treatment plans (36 Gy, 12 fractions) were created for 9 patients. For the particle therapy plans, the relative radiobiological effectiveness was taken into account. To simulate daily online setup correction, the CBCTs were rigidly registered (only translations) to the planning CT using fiducial markers. Fraction dose calculation was then made possible by deformable registering the planning CT to each of the 12 CBCTs. Gastrointestinal gas was delineated on each CBCT and copied to the deformed CT, a relative density override was applied for dose calculation (0.01). Fraction doses were accumulated rigidly. To compare planned and accumulated dose, for each radiotherapy modality, dose volume histogram (DVH) parameters of the planned and accumulated dose were determined for the internal gross tumor volume (iGTV), internal clinical target volume (iCTV) and OARs (duodenum, stomach, kidneys, liver and spinal cord).

##### Results

Photon plans were highly robust against interfractional anatomical changes. The difference between planned and accumulated DVH parameters for the photon plans was  $\leq 0.5\%$  for the target and OARs. For proton therapy, coverage of the iCTV was considerably reduced for the accumulated compared to the planned dose: the mean near-minimum dose (D98%) of the iCTV reduced from 98.1% to 90.3% [79.4%-95.3%] (Figure). For carbon ion therapy it was even worse; D98% was reduced with 10%, from 98.6% to 88.6% [80.7%-92.7%]. The DVH parameters of the OARs differed  $\leq 3\%$  between both particle modalities. For all modalities the near-maximum dose (D2%) did not differ.

##### Conclusion

Photon therapy is highly robust against interfractional anatomical changes and setup errors in pancreatic cancer patients. However, in particle therapy with either protons or carbon ions, severe reductions in target dose coverage were observed. Implementation of particle therapy for pancreatic cancer patients should be done with great care and interfractional anatomical changes must be accounted for.

#### OC-0355 Which anatomical changes in Head&Neck cancer lead to Repeat CT/planning?

S. Van Beek<sup>1</sup>, O. Hamming-Vrieze<sup>1</sup>, A. Al Mamgani<sup>1</sup>, A. Navran<sup>1</sup>, J. Van de Kamer<sup>1</sup>, P. Remeijer<sup>1</sup>

<sup>1</sup>The Netherlands Cancer Institute, Department of Radiation Oncology, Amsterdam, The Netherlands

##### Purpose or Objective

During a course of radiotherapy for head and neck (H&N) cancer, non-rigid anatomical changes can occur. For example, changes in volume of the target, changes in neck diameter (contour) due to edema or weight loss, shifts of hyoid or thyroid bone or other localized soft tissue deformations. These anatomical changes cannot be corrected for by a couch shift, but they can be observed on daily Cone Beam CT (CBCT) and are scored digitally by RTTs according to a traffic light protocol (TLP)(green: no action, orange: evaluation of dose consequences before the next fraction, red: immediate evaluation of dose consequences). Orange and red scores can lead to a new radiation plan, either on the original planning CT scans (O-pCT) with local adjustment of target volumes or on a new pCT scans (N-pCT) with complete re-delineation. In this work, we evaluated how often re-planning was done for non-rigid anatomical changes and which anatomical changes lead to which new plan actions during the 7 weeks of treatment.

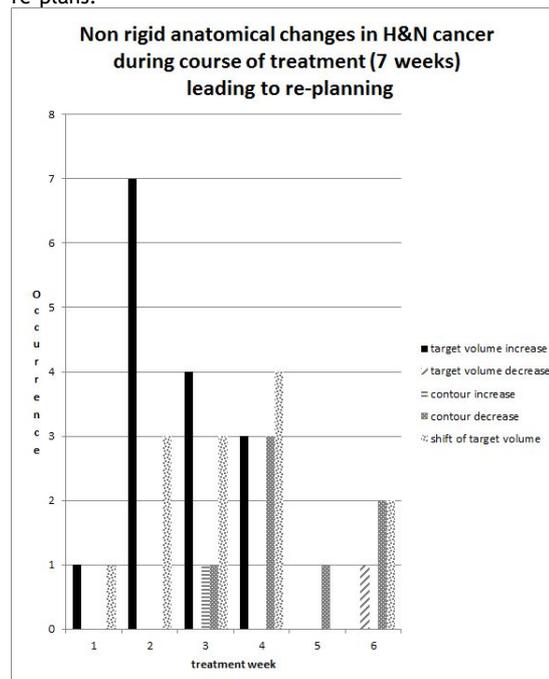

#### Material and Methods

A consecutive series of H&N cancer patients (416) treated from January 2015 until September 2016 were retrospectively selected using the digital log of CBCT scans (10862 H&N logs). These digital logs were analysed for the number of new treatment plans on an O-pCT or a N-pCT. Reasons for re-planning were categorized into: target volume increase, target volume decrease, contour decrease, contour increase and shift of target volume. To evaluate the timing of re-planning, the week in which delivery of the new plan started was scored as well.

#### Results

In 9% (37/416) of the H&N patients included in this analyses, the treatment plan was adapted due to anatomical changes detected during radiation treatment on CBCT. Re-planning on a N-pCT with complete re-delineation was done 22 times. In fifteen cases a new plan was created after adjustment of contours on the O-pCT. For 4 patients, two actions were taken, first a new plan on the O-pCT and secondly (further in the treatment) a new plan on a N-pCT. Figure 1 shows the anatomical changes observed at the time of re-planning, as well as the time of occurrence during treatment. In the early weeks of treatment, the most observed reason for re-planning was a target volume increase, both on a N-pCT as well as on the O-pCT. In the last part of treatment, re-planning on a N-pCT was mainly done because of contour decrease, while re-planning on the O-pCT was chosen in the event of local shifts of target volume. The majority of adaptive treatment plans were made in the second, third and fourth week of treatment for relatively 10, 9 and 10

re-plans.

#### Conclusion

Visual detection of anatomical changes on CBCT during treatment of head and neck cancer, without pre-defined adaptive radiotherapy protocol, results in re-planning in 1 out of 11 patients.

#### OC-0356 Adaptive strategy for rectal cancer: evaluation of plan selection of the first 20 clinical patients

R. De Jong<sup>1</sup>, N. Van Wieringen<sup>1</sup>, J. Visser<sup>1</sup>, J. Wiersma<sup>1</sup>, K. Crama<sup>1</sup>, D. Geijsen<sup>1</sup>, L. Lutkenhaus<sup>1</sup>, A. Bel<sup>1</sup>  
<sup>1</sup>Academic Medical Center, Department of radiation oncology, Amsterdam, The Netherlands

#### Purpose or Objective

For rectal cancer, sparing the organs at risk with the use of state-of-the-art planning techniques (IMRT/VMAT) is compromised by the large margins that are necessary to compensate for daily shape changes. In our clinic we implemented a plan selection strategy with multiple plans made prior to treatment. For each fraction, the best fitting plan is selected based on daily cone beam CT (CBCT) scans. The aim of this study is to assess the plan selection strategy for the first 20 clinical patients with respect to available plans, selected plans and safety.

#### Material and Methods

Multiple plans for plan selection were created for each patient based on a single CT scan. For 20 patients, 3 PTVs were created with different anterior margins for the upper mesorectum. Margins could be either 25 mm, 15 mm, 0 mm, or -15 mm, with choice of margins based on the anatomy as captured on the CT scan (fig. 1). Patients were treated with either a long or short treatment schedule (25x2 Gy, and 5x5 Gy, respectively). All plans were delivered with VMAT. Plan selection was based on daily CBCT. Selection was performed by 1 trained radiotherapist (RTT), a physician and a physicist for all fractions of the first week, and from the second week onwards by 2 RTTs, one of whom trained in plan selection. Once a week a post-treatment CBCT scan was acquired to assess the validation of the selected plan at the end of treatment. An expert IGRT RTT performed a weekly review, inspecting all plan selections retrospectively, as well as consistency between selected plans in the imaging system

and the radiotherapy management system, as the two systems are not linked.

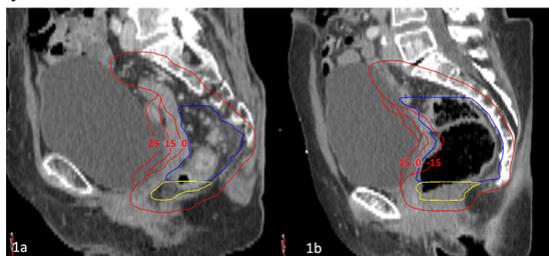

Fig. 1. Margin sets based on anatomy as captured on planning CT. (1a) shows full rectum with a set of 25 mm, 15 mm, and 0 mm anterior margins (red) for upper mesorectum (blue). (1b) shows empty rectum with a set of 15 mm, 0 mm, and -15 mm anterior margins (red) for upper mesorectum (blue).

### Results

In total, 10 patients were treated with the long treatment schedule, and 10 with the short treatment schedule, resulting in 300 plan selections. Margin sets of 25 mm, 15 mm, 0 mm were created for 6 patients, and margin sets of 15 mm, 0 mm, -15 mm for 13 patients. One patient had a set of only two margins available (0 mm, 15 mm), due to insufficient time at treatment planning. Overall, the -15 mm, 0 mm, 15 mm and 25 mm plans were selected in 2%, 45%, 39% and 14% of fractions, respectively. For distributions per patient, see figure 2. The largest available margin was always sufficient. Treatment was delayed a total of 7 times (of which 5 times in 1 patient) to obtain a more favorable anatomy in case of a very full rectum, usually caused by gas pockets. Evaluation of the post-treatment CBCT scans showed for 1 fraction the selected plan was no longer suitable due to a moving gas pocket. The weekly review showed that a plan with a smaller margin could have been selected in 20% of fractions, and a larger margin in 2% of fractions. No inconsistencies were found in selected plans between the imaging system and radiotherapy management system.

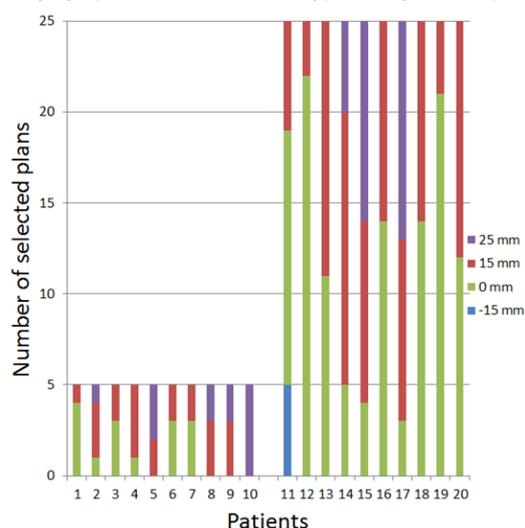

Fig. 2. Number of selected plans per patient for the first 20 patients, sorted on short (5x5 Gy) and long (25x2 Gy) treatment schedule.

### Conclusion

A plan selection strategy for rectum cancer patients was successfully and safely implemented. Next we will quantify the dosimetric impact of plan selection to the dose of the organs at risk in this dataset.

### Proffered Papers: Physics Dosimetry

#### OC-0357 Treatment planning dosimetry accuracy in $^{192}\text{Ir}$ HDR brachytherapy of lip carcinoma

P. Papagiannis<sup>1</sup>, V. Peppas<sup>1</sup>, T. Major<sup>2</sup>

<sup>1</sup>National and Kapodistrian University of Athens, Medical Physics Lab.- Medical School, Athens, Greece

<sup>2</sup>National Institute of Oncology, Department of Radiotherapy, Budapest, Hungary

#### Purpose or Objective

Advanced dose calculation algorithms have become clinically available for  $^{192}\text{Ir}$  HDR brachytherapy to account for the effects disregarded by TG43 based dosimetry algorithms (heterogeneities, applicators and patient specific scatter conditions).

The aim of this work is to study the effect of improved dosimetric accuracy in HDR brachytherapy of squamous carcinoma of the lip.

**Material and Methods**  
Three anonymized patient cases were studied (treatments using the  $^{192}\text{Ir}$  microSelectron-HDR v2 source, 27 Gy planning aim delivered in 3 Gy fractions b.d.).

The plans were imported to OncentraBrachy v4.5 and dosimetry was repeated using both the TG43 and the Advanced Collapsed Cone Engine (ACE) TPS algorithms. The same TRAK was used with both algorithms for the same patient case. ACE calculations were performed using the high accuracy option taking into account individual voxel densities and assuming the elemental composition of water, average skin and cortical bone for the PTV and soft tissue, the skin, and the mandible, respectively. The spatial resolution of TPS dosimetry results was 1 mm, isotropic.

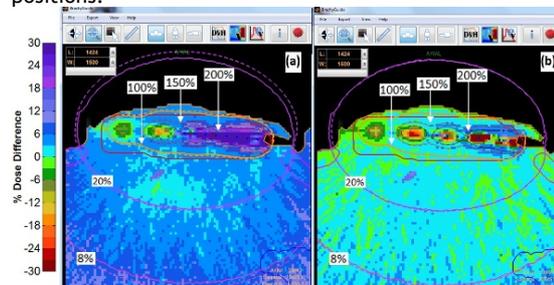

Corresponding reference data were obtained from patient specific Monte Carlo (MC) simulations using the MCNP6 code with input files prepared from the parsing of dicom RT data with the BrachyGuide software tool.

The TPS HU calibration was imported to BrachyGuide to ensure identical density input to ACE and MC. Dose was approximated by collision Kerma and kerma to medium in medium was scored using the F6 tally.

BrachyGuide was also used for the comparison of the three RT dose files for each patient case (TG43, ACE, and MC).

#### Results

TG43 clearly overestimates results for all cases as shown in the left side of Figure 1 for an indicative case. This cannot be attributed solely to the difference between patient scatter conditions and TG43 assumptions since large differences are also observed close to the source dwell positions. The corresponding comparison between ACE and MC (right side of figure 1) shows agreement within MC type A uncertainty up to 5 cm from the implant. While ACE improves dosimetric accuracy, considerable differences are still observed close to the source dwell positions.

Results from the comparison of median DVH parameters in the Table show large differences between TPS calculations and MC for high dose PTV volumes (V150 and V200) in accordance with the above findings. Large differences between TPS calculations and MC are also observed for OAR parameters. These differences however correspond

to low dose while the low value of V85 does not raise particular concern for tissue necrosis.

Dosimetric characteristic	TG43 Median	ACE Median	MC Median	TG43 - MC %	ACE - MC %
<b>Coverage (%)</b>					
D90	80.07	77.20	77.81	2.91	-0.79

<b>Skin (%)</b>					
D0.1cc	71.23	68.63	69.55	2.41	-1.33
D1cc	41.21	38.90	39.33	4.78	-1.08
D10cc	14.29	13.01	12.92	10.63	0.66
Dmax	80.48	78.14	78.95	1.93	-1.04
<b>Soft Tissue (cc)</b>					
V85	12.59	11.76	11.95	5.31	-1.58

### Conclusion

Considerable differences between TG43 and MC dosimetry indicate that plan quality of HDR brachytherapy for lip carcinoma may be compromised.

The ACE algorithm was found to improve dosimetric accuracy at clinically relevant distances.

TPS dosimetric accuracy close to the source dwell positions warrants further investigation.

### OC-0358 Evaluation of the Advanced Collapsed-cone Engine dose calculation algorithm for COMS eye plaques

H. Morrison<sup>1,2</sup>, G. Menon<sup>1,2</sup>, M. Larocque<sup>1,2</sup>, E. Weis<sup>3,4</sup>, R. Sloboda<sup>1,2</sup>

<sup>1</sup>University of Alberta, Oncology, Edmonton, Canada

<sup>2</sup>Cross Cancer Institute, Medical Physics, Edmonton, Canada

<sup>3</sup>University of Alberta, Ophthalmology, Edmonton, Canada

<sup>4</sup>University of Calgary, Surgery, Calgary, Canada

### Purpose or Objective

The current dosimetry protocol for ocular brachytherapy involves augmenting TG-43 dose calculations with correction factors or using look-up tables to account for plaque materials, as the water-based TG-43 calculation alone overestimates the dose in front of gold eye plaques by >20%. This work investigates the accuracy with which the Advanced Collapsed-cone Engine (ACE) algorithm (Oncentra Brachy (OcB) v4.6.0, Elekta, Sweden) can account for the ophthalmic applicator materials (gold backing and Silastic insert) for three different sizes of COMS eye plaques in a water phantom.

### Material and Methods

The 12, 16, and 20 mm COMS eye plaques were introduced into the applicator library for OcB by creating 3D CAD models of the plaques and Silastic inserts with virtual catheter lines along each seed slot. The Nucletron selectSeed 130.002 I-125 source model for ACE was created using primary-scatter separated kernel data (generated by the CLRP (Carleton Laboratory for Radiotherapy Physics) group) and AAPM consensus TG-43 dosimetry data. Treatment plans were created in OcB for a single seed in water, a single seed loaded in the central slot of the 12 and 20 mm COMS plaques (the 16 mm COMS plaque does not have a central slot), and fully loaded 12, 16, and 20 mm COMS plaques. ACE dose calculations were performed in high accuracy mode on a high resolution 0.5 mm<sup>3</sup> calculation grid. The resulting dose data was

compared to Monte Carlo (MC) simulated data using MCNP6, replicating the OcB treatment plans.

### Results

The ACE doses for the single seed in water agree with MC simulations on average within  $4.4 \pm 2.1\%$  in a 60x60x60 mm<sup>3</sup> cube centered on the seed, with the largest differences near the end-welds of the seed. Percent differences between ACE and MC doses along the plaque central axes (CAX) for all eye plaque plans are shown in Figure 1. The agreement improves beyond ~3 mm from the outer scleral surface, and is generally better for the fully loaded plaques than the single seed plaques, due to more overlapping dose from each seed washing out ray effects caused by the ACE calculation. Compared to using the previous minimum calculation grid size of 1 mm<sup>3</sup>, the smaller 0.5 mm<sup>3</sup> grid size results in less voxel averaging, and therefore more accurate doses immediately adjacent to the plaques, though both agree well with MC in the eye region (Figure 2).

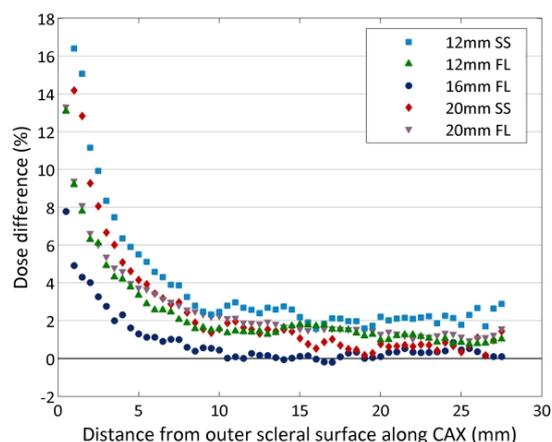

Figure 1: Percent dose differences along the plaque CAX between ACE and MC (reference standard) for the 12, 16, and 20 mm plaques with single seed (SS), and fully loaded (FL) configurations (0.5 mm<sup>3</sup> calculation grid).

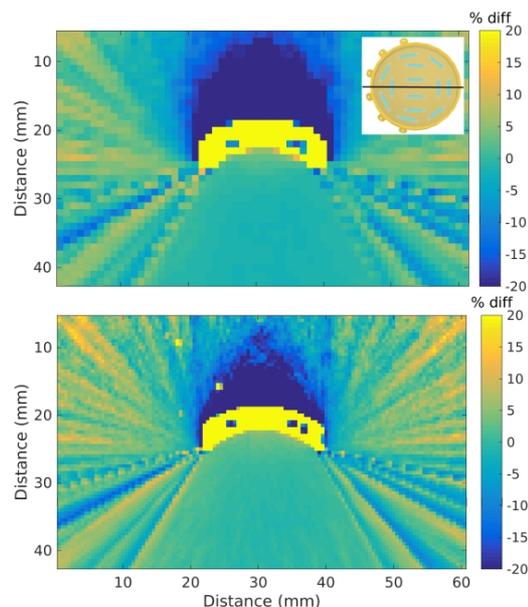

Figure 2: Percent dose differences between ACE and MC (reference standard) in the central plane of the fully loaded 16 mm COMS plaque using 1 mm<sup>3</sup> (top) and 0.5 mm<sup>3</sup> (bottom) calculation voxel size. Inset: front view of the plaque showing the orientation of the central dose calculation plane.

## Conclusion

Overall, good agreement is found between ACE and MC dose calculations in front of the eye plaques in water. The consistent difference of -3-4% observed for all comparisons with MC simulations is potentially due to differences in the MC simulation codes used to generate the data, and scaling of the ACE dose distribution in water to match TG-43 data in OcB. Updated seed models will be used to investigate this discrepancy. The good level of agreement indicates that further investigation of ACE in applications involving a virtual, voxelized eye phantom, and patient CT datasets, is warranted.

## OC-0359 Microdosimetric evaluation of intermediate-energy brachytherapy sources using Geant4-DNA

G. Famulari<sup>1</sup>, P. Pater<sup>1</sup>, S.A. Enger<sup>1,2</sup>

<sup>1</sup>McGill University, Medical Physics Unit, Montreal, Canada

<sup>2</sup>McGill University Health Centre, Department of Radiation Oncology, Montreal, Canada

### Purpose or Objective

Recent interest in alternative radionuclides for use in high dose rate brachytherapy (Se-75, Yb-169, Gd-153) with average energies lower than Ir-192 has triggered the investigation of the microdosimetric properties of these radionuclides. A combination of Monte Carlo Track Structure (MCTS) simulations and track sampling algorithms was used to predict the clinical relative biological effectiveness (RBE) for fractionated radiotherapy at relevant doses and dose rates. Previous studies have concluded that the dose mean lineal energy in nanometre-sized volumes is approximately proportional to the  $\alpha$ -ratio derived from the linear-quadratic (LQ) relation in fractionated radiotherapy in both low-LET and high-LET radiation.

### Material and Methods

Photon sources were modelled as point sources located in the centre of a spherical water phantom with a radius of 40 cm using the Geant4 toolkit. The kinetic energy of all primary, scattered and fluorescence photons interacting in a scoring volume were tallied at various depths from the point source. Electron tracks were generated by sampling the photon interaction spectrum, and tracking all the interactions following the initial Compton or photoelectric interaction using the event-by-event capabilities of Geant4-DNA. The lineal energy spectra were obtained through random sampling of interaction points and overlaying scoring volumes within the associated volume of the tracks.

### Results

For low-LET radiation, the dose mean lineal energy ratio was approximately equal to the  $\alpha$ -ratio in the LQ relation for a volume of about 30 nm (Fig 1). The weighting factors (often denoted clinical RBE) predicted were 1.05, 1.10, 1.14, 1.19 and 1.18 for Ir-192, Se-75, Yb-169, Gd-153, and I-125, respectively (Fig 2). The radionuclides Se-75, Yb-169, and Gd-153 are 5-14 % more biologically effective than current Ir-192 sources. There is little variation in the radiation quality with depth from the source.

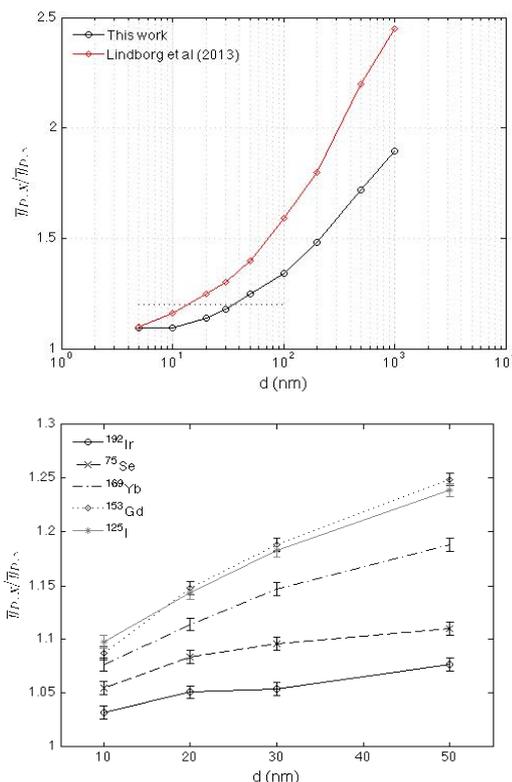

Fig 1: Dose mean lineal energy ratios between Co-60 and 100 kVp X-rays as a function of scoring diameter

Fig 2: Dose mean lineal energy ratios as a function of scoring diameter. The dotted line corresponds to  $\alpha$ -ratio of 1.20.

### Conclusion

Currently, the International Commission on Radiation Protection (ICRP) assigns a radiation weighting factor of unity for all photon emitting sources, equating the RBE of high and low energy photon sources. However, the clinical RBE for lower energy brachytherapy sources are considerably above unity and should be taken into account during the treatment planning process, to ensure that the equivalent dose delivered to the tumour is similar for different sources.

## OC-0360 Dose warping uncertainties for the cumulative rectal wall dose from brachytherapy in cervical cancer

L.E. Van Heerden<sup>1</sup>, N. Van Wieringen<sup>1</sup>, C. Koedooder<sup>1</sup>, C.R.N. Rasch<sup>1</sup>, B.R. Pieters<sup>1</sup>, A. Bel<sup>1</sup>

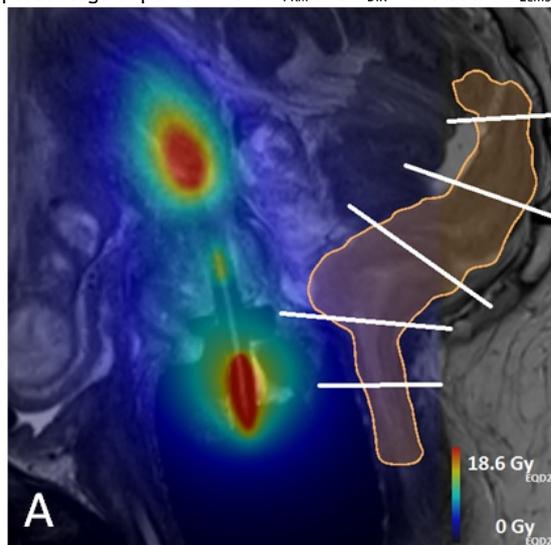

<sup>1</sup>Academic Medical Center, Radiation Oncology, Amsterdam, The Netherlands

### Purpose or Objective

Brachytherapy (BT) is part of radiotherapy for women with locally advanced cervical cancer; nowadays, BT is commonly given in multiple applications to the tumour area. In clinical practice, the 2 cm<sup>3</sup> receiving the highest dose (D<sub>2cm3</sub>) in the rectum is calculated by assuming that the high dose volumes overlap for each treatment. To account for rectal deformation due to differences in filling and/or the presence of air, many authors state it is preferable to sum the 3D dose distributions using dose warping after deformable image registration (DIR). However, little is known about the reliability of DIR for dose warping. The purpose of this study is to quantify the dose warping uncertainty in the rectum using a physically realistic model, which describes rectal deformation.

### Material and Methods

Seven patients were studied, treated with MRI-guided PDR BT (two times 24 x 0.75 Gy, given in two applications BT1 and BT2). DIR was performed using the Feature-Based Deformable Registration (FBDR) tool, connected to a research version of Oncentra®Brachy (Elekta Brachytherapy, Veenendaal, the Netherlands). The delineated rectums were converted to 3D surface meshes, and a mapping was established to propagate elements on the surface of rectum<sub>BT1</sub> to the surface of rectum<sub>BT2</sub>. The transformation vectors were used to deform the BT1 dose distribution. Next, the BT1 and BT2 doses were summed voxel-by-voxel. To investigate the dose warping uncertainty a physically realistic model (PRM) describing rectal deformation was used. In this model the central axes of rectum<sub>BT1</sub> and rectum<sub>BT2</sub> were constructed. The axes were assumed to be fixed in length. For both rectum<sub>BT1</sub> and rectum<sub>BT2</sub>, orthogonal planes were reconstructed at 5 evenly spaced positions on the axis (Fig. A). 100 points were evenly distributed over the intersection curve of each plane with the rectal wall. It is assumed that the most dorsal point of the rectum is fixed and also that the rectal wall only stretches perpendicularly to the central axis. For point pairs on rectum<sub>BT1</sub> and rectum<sub>BT2</sub> that were at the same location according to the PRM, the dose for BT1 and BT2 was added ( $D_{PRM}$ ) and compared as a 'ground truth' to the DIR accumulated dose ( $D_{DIR}$ ) in the BT2 point. For BT, the high dose regions in the OAR are most relevant and points within the 2 cm<sup>3</sup> volume receiving the highest dose should be correctly identified. We therefore evaluated the percentage of points where  $D_{PRM}$  and  $D_{DIR}$  were both  $>D_{2cm^3}$ .

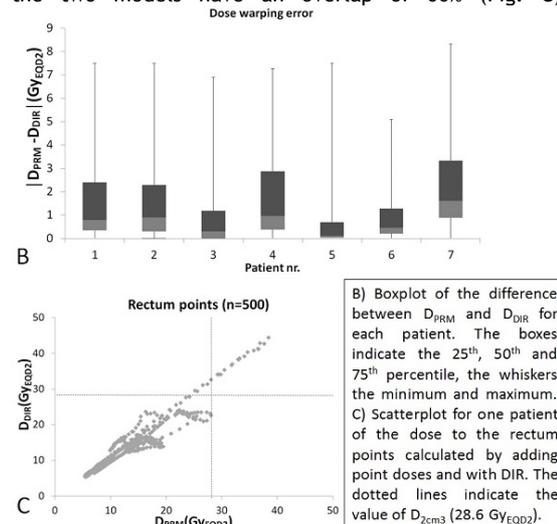

**A** Sagittal MRI with the applicator *in situ* and the dose in colour wash. The rectum is shown together with 5 orthogonal planes as defined by the model. Over each plane 100 points were evenly distributed.

### Results

Over all patients,  $D_{DIR}$  varied between 1.1-44.4Gy<sub>EQD2</sub> and  $D_{PRM}$  varied between 1.1-40.1Gy<sub>EQD2</sub> ( $\alpha/\beta=3$ Gy for late OAR toxicity,  $T_{1/2}=1.5$  hours). For point pairs, the absolute difference between  $D_{DIR}$  and  $D_{PRM}$  was 0-8.3Gy<sub>EQD2</sub> (Fig. B). The 2 cm<sup>3</sup> volumes receiving the highest dose according to

the two models have an overlap of 66% (Fig. C).

### Conclusion

With the rectal model it is feasible to quantify dose warping uncertainties, which could be as high as 8.3 Gy<sub>EQD2</sub>. Most points (>66%) in high dose regions were correctly identified as part of  $D_{2cm^3}$ .

### OC-0361 Commissioning of applicator-guided SBRT with HDR Brachytherapy for Advanced Cervical Cancer

S. Aldelaijan<sup>1</sup>, S. Wadi-Ramahi<sup>1</sup>, A. Nobah<sup>1</sup>, N. Jastaniyah<sup>2</sup>

<sup>1</sup>King Faisal Specialist Hospital and Research Center, Biomedical Physics, Riyadh, Saudi Arabia

<sup>2</sup>King Faisal Specialist Hospital and Research Center, Radiation Oncology, Riyadh, Saudi Arabia

### Purpose or Objective

There is emerging evidence that dose escalation to the "GEC ESTRO defined" high-risk clinical target volume leads to improved clinical outcome in patients with cervical cancer. For those with large residual disease or with unfavorable topography of parametrial spread, achieving such high doses is limited by the dose to organs at risk. Options include a parametrial boost by EBRT which lack precision and lead to prolongation of overall treatment time or the addition of interstitial needles which require a specialized brachytherapy (BT) program. The option of combining brachytherapy with SBRT, using the applicator as a guide, is being explored at our institution. The purpose of this work is to show how this idea can be successfully implemented using an EBT3 Gafchromic film-based dosimetry system. The effect of positional inaccuracies on overall dosimetric outcome is studied as well.

### Material and Methods

A cube phantom was constructed to snugly accommodate an intrauterine tandem (IU), Fig1a. Pieces of EBT3 film were taped on both sides of the IU to capture the dose distribution. The phantom was CT-scanned and the physician contoured a CTV mimicking large residual parametrial disease, Fig1b. The plan was such that the 7Gy isodose adequately covers the near-distance CTV. The BT plan was used as input for the SBRT plan and the 7Gy to 2.0Gy dose gradient were used to create dose shells, each having its own dose objective and constraint. Three VMAT arcs were used to achieve the goal of  $D_{98\%} > 95\%$  to the entire CTV. Later, HDR BT treatment was delivered using microSelectron v2 and the SBRT was delivered using TrueBeam®. Positioning accuracy of the phantom was done using CBCT imaging with the applicator for image registration. Films were scanned with 10000XL EPSON scanner at 127 dpi and dosimetry was done using the green channel and an in-house MATLAB routine. Intentional

shifts of 1, 3 and 5mm in both the IN/OUT direction and 2D shifts in both IN/OUT and SUP/INF directions were introduced.

### Results

Fig1b shows the 95% (of 7Gy) dose distribution of the combined BT and SBRT treatments. Analysis using 2%/2mm gamma criterion resulted in 99% agreement. Isodose line matching and a cross profile between measured and planned doses are shown in Fig1c-d. Fig2 shows the effect of 1D and 2D isocenter shift on  $D_{98\%}$ ,  $D_{90\%}$  and  $D_{2cc}$  metrics of the CTV. A threshold of +10% was used as a gauge to compare dose values after shift with the zero shift baseline. The most changes in dose were for  $D_{98\%}$  and  $D_{90\%}$ , both exceeded the threshold for 3mm shifts and almost reached -20% for the 5mm shifts.

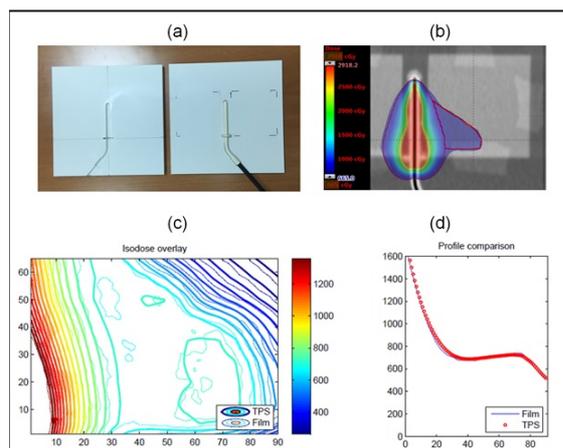

Fig1: (a) The tandem shown inside the custom groove made in a 20x20x20cm<sup>3</sup> FlexiCube phantom, (b) HR CTV with an extended arm to one side showing 95% dose coverage, (c) isodose overlay comparison between planned and measured data, and (d) a cross profile showing the homogenous 7 Gy on the extended arm and comparing planned vs measured data.

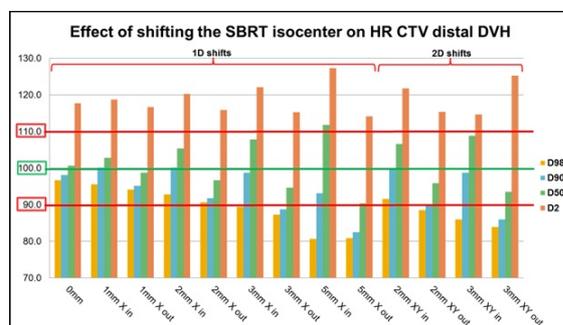

Fig2: Effect of shifting the SBRT isocenter (with respect to the applicator) on the  $D_{98\%}$ ,  $D_{90\%}$ ,  $D_{50\%}$  and  $D_{2cc}$  metrics of the HR CTV DVH. An acceptance criterion for dose variation is set to  $\pm 10\%$  (shown by the red labels) for  $D_{98\%}$ ,  $D_{90\%}$  and  $D_{50\%}$  for this work. Figure clearly shows that shifts exceeding 2 mm jeopardize the goals of the treatment.

### Conclusion

Using the applicator as a guide, SBRT and BT for cervical cancer can be delivered on the same day. The isodos gradient from BT is used to create dose shells needed to deliver doses by SBRT. 2D shifts were shown to affect  $D_{98\%}$  the most and a positioning accuracy of 2mm results in dose variations within +10% from expected.

### OC-0362 Precision IORT - image guided IORT in cluding online CBCT based Monte Carlo treatment pl anning

F. Schneider<sup>1</sup>, L.D. Jimenez<sup>1</sup>, F. Bludau<sup>2</sup>, A. Jahnke<sup>1</sup>, C. Illana<sup>3</sup>, J. Fleckenstein<sup>1</sup>, S. Clausen<sup>1</sup>, U. Obertacke<sup>2</sup>, F. Wenz<sup>1</sup>

<sup>1</sup>University Medical Center Mannheim, Department of Radiation Oncology, Mannheim, Germany

<sup>2</sup>University Medical Center Mannheim, Department for Orthopaedics and Trauma Surgery, Mannheim, Germany

<sup>3</sup>GMV, Innovating Solutions, Madrid, Spain

### Purpose or Objective

The clinical use of intraoperative radiotherapy (IORT) is steadily increasing based on novel applications like breast and brain cancer and spinal column metastases. Traditionally, IORT has been eye and hand guided without treatment planning and inhomogeneity correction. This limits the precision of the application and the precise documentation of the location and the deposited dose in the tissue.

Kypho-IORT is a novel treatment option for patients with spinal column metastases in which a minimally invasive kyphoplasty is combined with a sterilising dose of IORT. Here we present a set-up where we use image guidance by intraoperative cone beam CT (CBCT) for precise online Monte Carlo treatment planning including inhomogeneity correction.

### Material and Methods

During kyphoplasty a working cannula is used to insert a balloon catheter in the vertebra. The same cannula is used to insert a x-ray source with a dedicated Needle Applicator (Carl Zeiss Surgical GmbH, Oberkochen, Germany) to perform the IORT. For treatment planning an intraoperative cone beam CT (CBCT) was performed with the Needle Applicator in place. This CBCT was registered with a preoperative CT (pre-op CT) in Velocity (Varian, California, USA). The spinal cord and the metastasis were contoured on the pre-op CT and the applicator tip was contoured on the CBCT and transferred to the pre-op CT. On both CTs the treatment planning was then performed in Radiance (GMV, Madrid, Spain) using a hybrid Monte Carlo algorithm simulating dose in homogeneous (MCwater) and heterogeneous medium (MChet). Dose distributions on CBCT and pre-op CT were compared with each other (figure 1).

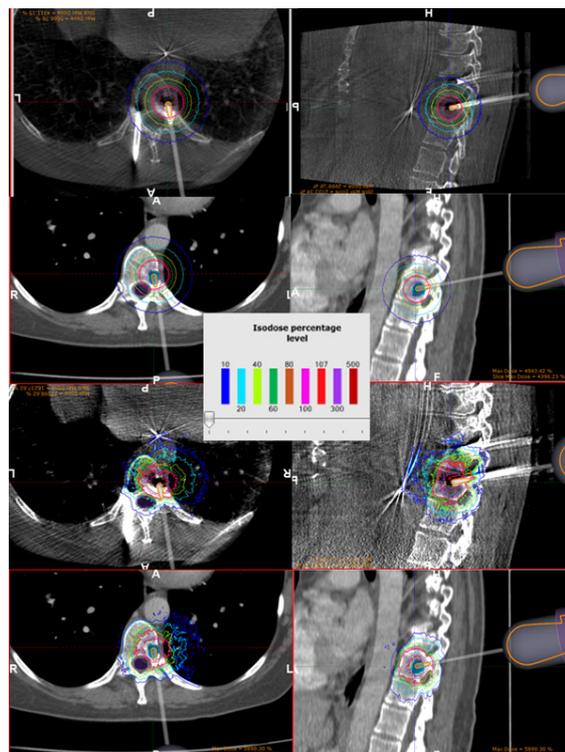

Figure 1: from top to bottom: dose distribution on CBCT (MCwater), pre-op CT (MCwater), CBCT (MChet), pre-op CT (MChet)

### Results

The MCwater calculations showed a spherical dose distribution as expected. The resulting treatment times for the prescription of 8Gy in 13mm distance (in water) from isocenter were within  $\pm 5\%$  of the described treatment time of the INTRABEAM<sup>®</sup> system. Due to the

artefacts of the working cannula on the CBCT the comparison between MChet simulations on CBCT and pre-op CT showed differences up to 50% in dose. The maximum dose in the spinal cord (distance of 11mm from applicator tip) was 11Gy for the MCwater and 7.5Gy for the MChet simulations on pre-op CT.

#### Conclusion

Precision IORT using a combination of intraoperative image guidance and treatment planning improves the accuracy of IORT. However, the current set-up is limited by CT artefacts. Fusing an intraoperative CBCT with a pre-op CT allows the combination of an accurate dose calculation with the knowledge of the correct source/applicator position. This method can also be used for pre-operative treatment planning followed by image guided surgery.

##### OC-0363 Ruthenium-106 brachytherapy for iris and choroidal body melanomas

F.P. Peters<sup>1</sup>, M. Marinkovic<sup>2</sup>, N. Horeweg<sup>1</sup>, M.S. Laman<sup>1</sup>, J.C. Bleeker<sup>2</sup>, M. Ketelaars<sup>1</sup>, G.P.M. Luyten<sup>2</sup>, C.L. Creutzberg<sup>1</sup>

<sup>1</sup>Leiden University Medical Center LUMC, Department of Radiotherapy, Leiden, The Netherlands

<sup>2</sup>Leiden University Medical Center LUMC, Department of Ophthalmology, Leiden, The Netherlands

#### Purpose or Objective

Uveal melanoma is a malignant neoplasm that arises from the neuro-ectodermal melanocytes within the choroid, ciliary body or iris. Ninety percent of uveal melanomas are choroidal melanomas (CM), only six percent originates in the ciliary body and 4% in the iris. Eye-conserving treatment of small to intermediate-sized CM by Ruthenium-106 brachytherapy (Ru106) yields a 95% 5-year local control rate (Marinkovic et al., Eur J Cancer, 2016). Disadvantage of this treatment is that visual acuity decreases to <0.33 in 25% of the patients. Small to intermediate-sized iris melanomas (IM) and choroidal body melanomas (CBM) are also treated by Ru106. As the localisation of the tumour and the organs at risk in IM and CBM are different from those in CM, treatment effectiveness and complications may also differ. This study was conducted to assess outcomes of Ru106 as eye-conserving treatment of IM and CBM in terms of local control, metastasis, survival, eye preservation, treatment toxicity and visual outcomes.

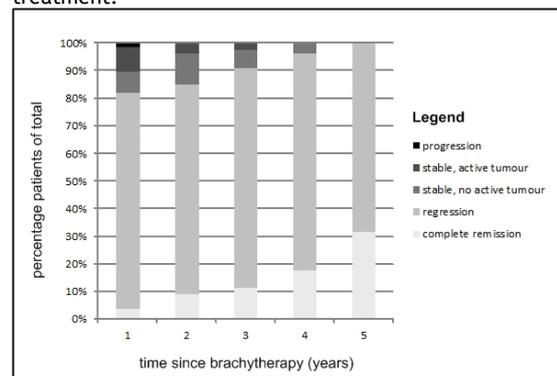

#### Material and Methods

Data was collected on 88 consecutive patients who were treated for IM or CBM from 2006 to 2016. Minimal radiation dose was 120-130Gy; specified at the depth of the tumour base (for IM) or tumour apex (for CBM); provided a maximal corneal dose <500-600Gy, scleral dose <1000Gy and application time <5-6 days. Primary outcome of this study was local control. Secondary outcomes were metastasis, melanoma-related death, eye preservation, treatment complications and post-treatment visual acuity. Durations were calculated using Kaplan-Meier's methodology, risk factors were assessed using a Cox proportional hazards model.

#### Results

Total median follow-up was 36 months (range: 3-115). Of 88 patients, 58 (65.9%) were diagnosed with IM and 30 (34.1%) with CBM. At diagnosis, CBM were larger and more advanced than IM. Figure 1 presents the results of the yearly local site evaluation after treatment. Hence, tumour regression evolved steadily over the years, with >80% already showing regression after one year. Local control rate at the end of follow-up of all tumours was 98.9%. Metastases were diagnosed in 1.1% of the patients;

no deaths due to melanoma occurred during follow-up. Eye preservation rate during follow-up was 97.7%. Treatment-related toxicities were observed in 80.7% of the patients, however most toxicities were mild and transient. Worsening of pre-existing or new cataract was observed in 51.1%; 64.4% of these patients underwent cataract extraction after brachytherapy. Further, dry eyes (29.5%) and glaucoma were (20.5%) commonly observed toxicities. Visual acuity was not affected by Ru106 brachytherapy, with only 2.3% having a visual acuity <0.33 (no useful vision) at follow-up, compared to 13.6% before treatment.

#### Conclusion

Ru106 for IM and CBM yielded excellent local control rate of 98.9% and 97.7% eye preservation. Treatment toxicities were common, but mostly mild and transient. Moreover, Ru106 did not affect visual acuity.

##### OC-0364 Nomogram for predicting maculopathy in patients treated with Ru106 brachytherapy for uveal melanoma

L. Tagliaferri<sup>1</sup>, A. Larichiuta<sup>1</sup>, M. Pagliara<sup>2</sup>, C. Masciocchi<sup>3</sup>, J. Lenkovic<sup>3</sup>, L. Azario<sup>4</sup>, R. Autorino<sup>1</sup>, M.A. Gambacorta<sup>1</sup>, V. Valentini<sup>3</sup>, M.A. Blasi<sup>2</sup>

<sup>1</sup>Fondazione Policlinico Universitario A. Gemelli, Dipartimento di Radioterapia Oncologica - Gemelli ART, Roma, Italy

<sup>2</sup>Fondazione Policlinico Universitario A. Gemelli, Dipartimento di Oftalmologia, Roma, Italy

<sup>3</sup>Università Cattolica del Sacro Cuore, Dipartimento di Radioterapia Oncologica - Gemelli ART, Roma, Italy

<sup>4</sup>Fondazione Policlinico Universitario A. Gemelli, Unità Complessa di Fisica Sanitaria, Roma, Italy

#### Purpose or Objective

Plaque brachytherapy (BT) as a practicable alternative to enucleation for the treatment of medium-sized choroidal melanomas. However, the BT is not free from local toxicity. The aim of this study was to develop a predictive model for maculopathy occurrence after ruthenium-106 plaque brachytherapy in uveal melanoma.

#### Material and Methods

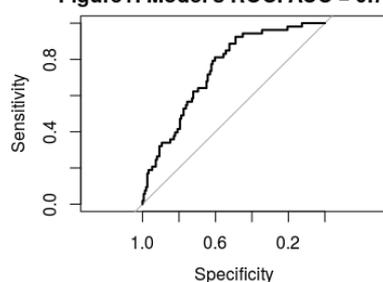

Patients from institutional database with choroidal melanoma treated with ruthenium-106 plaque from December 2006 to December 2014 were selected. Inclusion criteria were: dome-shaped melanoma, distance to the Fovea > 1.5 mm and tumor thickness > 1 mm and < 5mm. In each case, the prescribed dose was 100 Gy at tumor apex. Factors analyzed were sex, age, diabetes, tumor size (volume, area, largest basal diameter and apical height), plaque types, distance to fovea, presence of exudative detachment, presence of drusen, presence of orange pigments, radiation dose to the fovea and sclera. Univariate and multivariate Cox proportional hazards were used to define the impact of baseline patient factors on the occurrence of the maculopathy. A p-value <= 0.05 was considered significant. Kaplan-Meier curves were used to estimate freedom from the occurrence of the maculopathy. The model performance was evaluated with

internal validation using Area Under the ROC Curve (AUC) and calibration with Hosmer-Lemeshow test.

### Results

Two hundred and five patients with a median age of 68 (range: 17-92 years) were considered for this analysis. The median follow-up was 41 months. Of 205 patients, 92% were alive. Maculopathy was found in 53 patients (25.8%) after the treatment. Distance to fovea was the main prognostic factor of the predictive model (hazard ratio [HR] of 0.813 [0.75-0.87]  $p = 3.45e-08$ ). Diabetes (hazard ratio [HR] of 2.31 [1.14-4.66],  $p = 0.019$ ), and tumor volume (hazard ratio [HR] of 19.08 [2.06-175.88],  $p = 0.0093$ ) affected the prediction of maculopathy. The prediction model developed can predict events of maculopathy at 3 years with an AUC of 0.74 (figure 1). The calibration showed no statistical difference between actual and predicted maculopathy ( $p=0.22$ ).

Figure1: Model's ROC. AUC = 0.745

### Conclusion

Our maculopathy prognostication model, along with its nomogram, could be a tool for predicting the occurrence of maculopathy at 3 years after treatment. Furthermore, this analysis revealed that tumor volume, distance to the fovea and diabetes can help to predict maculopathy at 3 years after treatment: a predictive model (coefficients and nomogram) is provided and good performance obtained encourage further investigations along this direction.

### OC-0365 Dose contribution to pelvic nodes of image-guided adaptive brachytherapy in cervical cancer

W. Bacorro<sup>1,2</sup>, I. Dumas<sup>3</sup>, A. Levy<sup>2</sup>, E. Rivin del Campo<sup>2</sup>, C.H. Canova<sup>2</sup>, T. Felefly<sup>2</sup>, A. Huertas<sup>2</sup>, F. Marsolat<sup>3</sup>, P. Maroun<sup>2</sup>, C. Haie-Meder<sup>2</sup>, C. Chargari<sup>2</sup>, R. Mazon<sup>2</sup>

<sup>1</sup>Benavides Cancer Institute- UST Hospital, Radiation Oncology, Manila, Philippines

<sup>2</sup>Institute Gustave Roussy, Radiation Oncology, Villejuif, France

<sup>3</sup>Institute Gustave Roussy, Medical Physics, Villejuif, France

### Purpose or Objective

The use of simultaneous integrated boost (SIB) to pathologic pelvic nodes in the treatment of cervical cancer requires integrating in the IMRT plan the contribution of brachytherapy. This study aims to report the BT-delivered doses to pelvic pathologic nodes and to propose SIB dose-fractionation regimens.

### Material and Methods

Patients with locally advanced cervical cancer comprising pelvic nodal involvement and treated with chemoradiation followed by image-guided adaptive pulsed-dose rate BT were included. The pathologic nodes were delineated to report the brachytherapy contribution but without planning aims.  $D_{100}$ ,  $D_{98}$ ,  $D_{90}$  and  $D_{50}$  were reported and converted to 2-Gy equivalents (EQD2), using the linear quadratic model with an  $\alpha/\beta$  of 10 Gy.

### Results

Ninety-one patients were identified, allowing the evaluation of dose delivery in 226 adenopathies. The majority of the studied nodes were located in the external iliac (48%), common iliac (25%), and internal iliac (16%) regions. The EQD2 contribution was  $3.6 \pm 2.2$  Gy,  $4.1 \pm 1.6$ ,

$4.4 \pm 3.3$ , and  $5.2 \pm 3.9$  Gy for the  $D_{100}$ ,  $D_{98}$ ,  $D_{90}$ , and  $D_{50}$ , respectively. The EQD2  $D_{98}$  values were  $4.4 \pm 1.9$  Gy,  $5.4 \pm 3.1$  Gy,  $4.3 \pm 2.1$  Gy for obturator, internal iliac and external iliac nodes respectively, and  $2.8 \pm 2.5$  Gy for the common iliac. Whereas no significant difference was observed between the brachytherapy contributions of external and internal iliac nodes, the doses delivered in common iliac adenopathies were significantly lower ( $p < 0.001$ ).

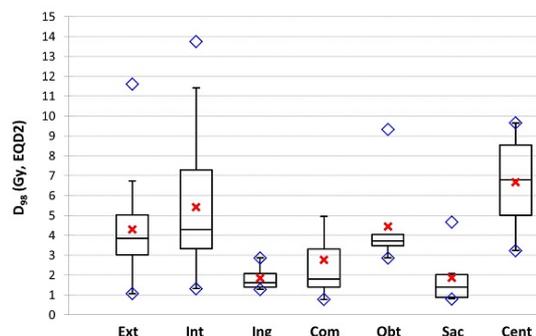

Figure: Descriptive statistics of D98 of pathologic nodes according to regions.

Ext: external iliac, Int: internal iliac, Ing: inguinal, Com: common iliac, Obt: obturator, Sac: presacral, Cent: central (pararactal or parametrial). Red cross: mean value, blue diamond: minimal and maximal values, lower limit of the box: first quartile, upper limit of the box: third quartile, central horizontal bar: median, whiskers: from minimal value to 1.5 x box length. Thus, to deliver a cumulative EQD2  $\geq 60$  Gy to pathologic nodes accounting a pelvic external beam radiation dose of 45 Gy in 25 fractions (44.3 in EQD2) and these estimations, we propose nodal SIB of 2.2 Gy x 25 (55 Gy, 55.9 in EQD2) in the obturator, external and internal iliac nodes, 2.3 Gy x 25 (57.5 Gy, 58.9 in EQD2) in the common iliac nodes, and 2.4 Gy x 25 (60 Gy, 62 Gy in EQD210) in the para-aortic nodes (where the BT contribution can be considered as negligible). **Conclusion**

The contribution of brachytherapy to the treatment of pelvic nodes is significant: around 5 Gy in the obturator, internal iliac, and external iliac areas and 2.5 Gy in the common iliac, allowing the use of simultaneous integrated boost. However, important individual variations have been observed and evaluation of the genuine individual brachytherapy contribution is recommended.

### OC-0366 Cervical cancer with bladder invasion: outcomes and vesicovaginal fistula prognostic factors

R. Sun<sup>1</sup>, R. Mazon<sup>1</sup>, I. Koubaa<sup>2</sup>, I. Dumas<sup>3</sup>, C. Baratin<sup>1</sup>, F. Monnot<sup>1</sup>, P. Maroun<sup>1</sup>, E. Deutsch<sup>1</sup>, P. Morice<sup>4</sup>, C. Haie-Meder<sup>1</sup>, C. Chargari<sup>1</sup>

<sup>1</sup>Gustave Roussy, Radiation oncology, Villejuif, France

<sup>2</sup>Gustave Roussy, Radiology, Villejuif, France

<sup>3</sup>Gustave Roussy, Medical physics, Villejuif, France

<sup>4</sup>Gustave Roussy, Surgery, Villejuif, France

### Purpose or Objective

Although brachytherapy (BT) is a mainstay of the treatment of locally advanced cervical cancer, there are only scarce data on its efficiency in cervical cancer with bladder invasion. The aims were to report the treatment outcomes in this particular situation, as well as vesicovaginal fistula (VVF) incidence and its prognostic factors.

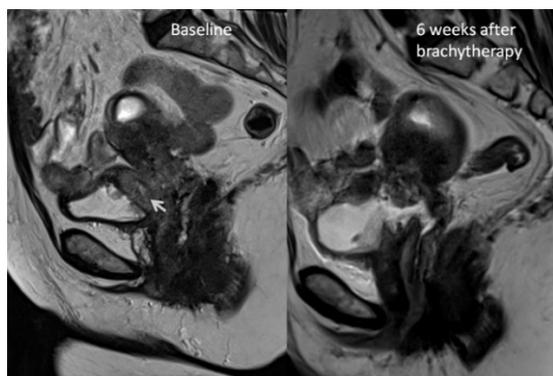

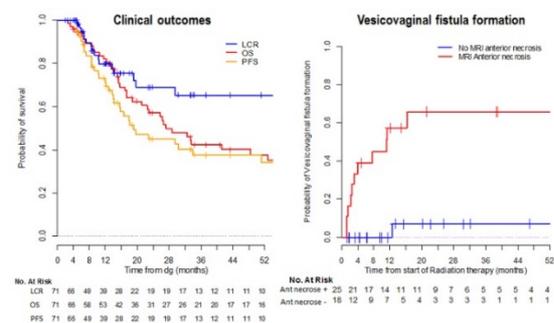

### Material and Methods

Consecutive patients with locally advanced cervical cancer and bladder invasion treated in our institution from 1989 to 2015 were identified. Demographic and tumor features, treatment characteristics, VVF rate, progression-free survival (PFS), local control rate (LCR), and overall survival (OS) were reviewed. Baseline

magnetic resonance imaging (MRI) scans reviews were carried out blind to the clinical data with focus on radiological parameters potentially correlated to the risk of VVF (necrosis, tumor height of bladder involvement, tumor volume). Times were calculated from the date of diagnosis. Survival were estimated using the Kaplan-Meier method and the Cox proportional hazards model.

### Results

Seventy-one patients were identified. Bladder invasion was diagnosed either on imaging in 59% or endoscopically/histologically proven in 41%. All patients received pelvic external beam radiotherapy (EBRT), 45 Gy in 25 fractions  $\pm$  nodal boost to macroscopically involved lymph nodes. Nineteen of the 21 patients with para-aortic nodal metastases received para-aortic EBRT. Concurrent platinum-based chemotherapy (CT) was used in 76%, neoadjuvant CT was used in 14%. After EBRT, 64 patients (90%) received uterovaginal BT (low-dose rate in 48%, pulsed-dose rate in 52%). Eight patients had VVF at diagnosis. Among the 63 patients without VVF at diagnosis, 14 patients (22.2%) developed VVF later on: four before (28.6%) and ten (71.4%) after BT (median time to onset: 3.5 months after the start of EBRT). Twelve of the 22 patients (54.5%) who presented VVF, either at diagnosis or during follow-up, needed surgery (urinary or bowel diversion  $\pm$  pelvicotomy). Estimated OS, PFS and LCR at 2 years were 57.3% (44.9-68.8), 45.0% (32.3-58.5) and 69.1% (54.4-80.7) respectively. Presence of para-aortic nodal metastases was significantly associated with poorer OS on multivariate analysis (HR=4,  $p<0.001$ ). Only the presence of necrosis in the anterior part of the tumor on baseline MRI was strongly associated with the risk of subsequent VVF (57% vs 0% at 1 year, HR=16.7,  $p=0.011$  on a multivariate analysis taking into account the tumor volume). No correlation was found between bladder dose and risk of VVF.

### Conclusion

A curative intent strategy including BT as part of local treatment is feasible in patients with bladder invasion, with a rate of 22% of post-treatment VVF. MRI has a strong predictive value of VVF occurrence. This result has to be confirmed in an independent cohort. Prognosis remains poor in regard to lower-staged lesions, with a high risk of out-of-field failure. Intensification of systemic therapies should be considered.

### OC-0367 Dose-response curve for vaginal stenosis. Final results of a prospective study.

M. Federico<sup>1</sup>, A. Tornero<sup>2</sup>, S. Torres<sup>2</sup>, B. Pinar<sup>1</sup>, M. Rey Baltar<sup>1</sup>, M. Lloret<sup>1</sup>, P. Lara<sup>1</sup>

<sup>1</sup>Hospital Universitario de Gran Canaria Dr. Negrin, Radiation Oncology, Las Palmas de Gran Canaria- Ca, Spain

<sup>2</sup>Hospital Universitario de Gran Canaria Dr. Negrin, Radiación Physics, Las Palmas de Gran Canaria- Ca, Spain

### Purpose or Objective

Vaginal stenosis as consequence of cervical cancer BT treatment severely impact quality of life. No dose constraints have been published so far.

Aim of this study is to identify a threshold level for volume packing and a dose response curve for vaginal stenosis.

### Material and Methods

211 consecutive cervical cancer patients treated between 2008-16 (median FU time 42.4 months) with a median age at BT of 52.6 years (range 23.7- 88.5) were considered. All pts received 3DRCT (45-50 Gy with weekly concomitant CDDP 40 mg/m<sup>2</sup> when feasible) and tandem ovoids HDR BT (or intracavitary-interstitial cylinder application when needed). Patients received simulation CT scan with radiopaque vaginal tube in place in order to delineate vagina from a plane tangential to lower border of pubic bone up to fornix. At BT vaginal packing (VP) was contoured from a plane tangential to lower border of pubic bone up above ovoids surface. Vaginal walls were delineated as a 2 mm expansion of packing subtracted of packing volume. 85 pts. (group A) received CT based BT (5 fractions of 5,5 Gy), 126 patients (group B) received MR based BT (4 fractions of 7 Gy). Group A pts had a treatment slightly optimized to OARs. Group B pts had a treatment optimized to OAR and HRCTV according GEC ESTRO recommendations. All patients entered prospective follow up. Morbidity was scored according CTCAE 4.0 vaginal volume was also measured with appropriate vaginal cylinders (diameters 10 to 45 mm). To assess the relationship between vaginal stenosis, VP and vaginal dose a median VP volume (VPm) among the 5 (group A) or 4 (group B) application each patient received was calculated. Moreover the cumulative EBRT+BT EQD2 dose to vagina was calculated. A Logistic model (LM) was used to analyze data.

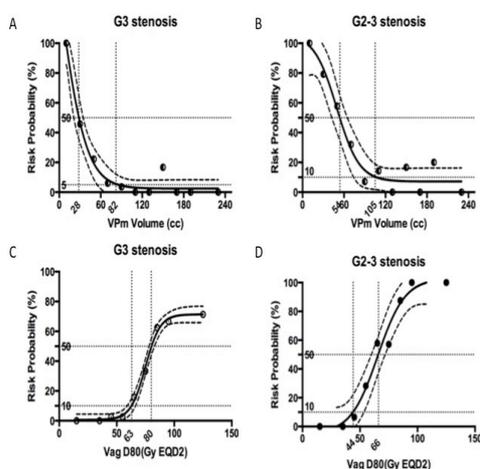

### Results

Results are summarized in Tab1. In 929 applications a double exponential fit was noticed between vaginal dose and VP volume, with a fast growing exponential part (minimal variations in VP volume corresponding to huge variations in vaginal dose), and a slow growing exponential part (variation in VP volume have modest impact on dose). VP volume cut off values dividing the two parts of the curve for all considered vagina DVH parameters were encompassed between 75 and 80 cc.

LM showed good correlation ( $R^2=0.97$  and  $0.96$  respectively) between VPm and G3 or G2-3 vaginal stenosis (Fig1 A\_B). Risk of vaginal stenosis G3 or G2-3 was less than 10% when a VPm volume  $>82$  or  $105$ cc was obtained. A dose response curve was found for G3 or G2-3 stenosis and vaginal EBRT+BT EQD2 D80 ( $R^2$  0.99 and 0.98 respectively) with a risk of G3 or G2-3 stenosis lower of 10% when EQD2 dose parameters was lower than 63 and 44Gy EQD2 respectively (Fig1 C-D).

Vaginal Stenosis CTCAE 4.0	# of patients	Average age at BT	Average vaginal volume at last FU visit (cc)	VPm (cc)	Average D80 EBRT+BT (Gy EQD2)
G0	89	51.5±14.4	75.4±12.8	115.1±52.3	46.3±8.4
G1	45	50.5±12.5	58.4±8.6	80.3±39.2	57.4±12.3
G2	35	55.3±13.6	39.3±9.5	60.4±29	66.6±17
G3	29	62±9.2	16.8±7	44.5±25	82±22.6

Tab.1 patients and treatment characteristics by vaginal stenosis group

### Conclusion

At our knowledge this is the first report finding a correlation between vaginal stenosis, VP volume and vaginal dose on a relatively large serie. Further studies on larger dataset are needed to confirm such data

### OC-0368 Postoperative vaginal brachytherapy: a quality assurance dummy-run procedure in the PORTEC-4 trial

R. Nout<sup>1</sup>, E. Astreinidou<sup>1</sup>, M. Laman<sup>1</sup>, C. Creutzberg<sup>1</sup>  
<sup>1</sup>Leiden University Medical Center LUMC, Department of Radiotherapy, Leiden, The Netherlands

### Purpose or Objective

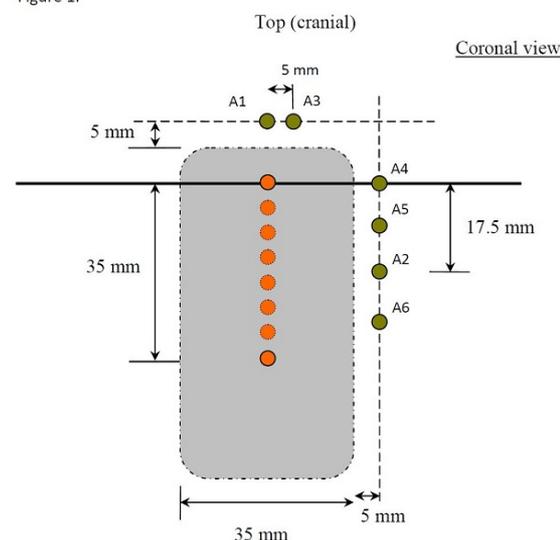

As part of the quality assurance program in the ongoing randomized multicenter PORTEC-4 trial a 'dummy-run' procedure for vaginal brachytherapy was mandatory before centers could participate. The aim was to evaluate whether the CT- or MRI based clinical target volume (CTV) and organ at risk (OAR) delineations and the standard treatment plans were according to the trial protocol, especially since for many centres this involved introduction of CT-based delineation and planning for vaginal brachytherapy.

### Material and Methods

Pelvic CT and MRI scan of a postoperative endometrial cancer patient with a cylinder in situ were made available to participating Dutch centers. Centers were asked to use their own treatment planning and delineation software and follow the study protocol in order to: 1) delineate CTV and OAR's: bladder, rectum, sigmoid and small bowel; 2) reconstruct the single line source path; 3) create a treatment plan prescribing 7 Gy at 5 mm from the surface of the applicator (point A2, fig 1); 4) perform DVH analysis. The CTV consisted of the proximal 4 cm of the

vagina to a depth of 3 mm from the mucosal surface. To account for anisotropy in the longitudinal direction of the source two points (A1 and A3) were defined at 5 mm from the cranial applicator surface and additional points (A4-6) were added (fig 1). The average dose between A1 and A3 should be approximately 100%, with A1 minimal 90% and A3 maximal 110%. Central evaluation of contours and treatment plans took place and in case of deviations from the protocol, feedback was provided and necessary steps in the dummy-run repeated.

Figure 1.

### Results

Fifteen centers participated, 12 centers used CT planning, 2 used MRI planning and 1 both. For 11 plans some adjustments were required, and in 6 cases a second revision was requested. Main reasons for adjustments were: delineation (N=8), dose planning (N=7), reconstruction (N=2). Three different commercially available treatment planning systems and HDR sources were used. Table 1 summarizes dose to points A1-6, CTV and OAR's of the final submissions. Consistency with the protocol improved and interobserver differences significantly decreased with the revisions.

Table 1. Treatment planning results.

	Mean (%)	SD (%)	Range (%)
A1	92.3	1.7	89.3-94.9
A2	100.7	1.4	100-100.5
A3	108.3	1.4	105.8-110.6
A4	84.1	6.0	76.6-99.0
A5	97.4	1.9	94-100.7
A6	99.0	1.3	97.4-102.1
Average A1-A3	100.3	0.9	98.2-101.4
	Mean (Gy)	SD (Gy)	Range (Gy)
CTV D98	7.8	1.0	7.0-9.2
CTV D90	7.0	1.1	5.9-8.6
Bladder d2cc	5.6	0.4	4.9-6.1
Rectum d2cc	5.7	1.0	3.5-6.4
Sigmoid d2cc	3.7	1.7	1.4-6.4
Bowel d2cc	5.0	2.2	1.0-7.3

### Conclusion

Interobserver variation in delineation resulted in the largest dose deviations, most pronounced for bowel on postoperative CT. The use of a second point (A3) at the apex was most useful for controlling the anisotropy of the source and should be recommended for dose reporting in routine clinical practice.

## Poster Viewing : Session 8: Radiobiology

**PV-0369 The potential of hyperpolarized  $^{13}\text{C}$  MRS to monitor the effect of vascular disrupting agents**

<sup>3</sup>Aarhus University Hospital, PET Centre, Aarhus C, Denmark

<sup>4</sup>Aarhus University Hospital, Center of Functionally Integrative Neuroscience, Aarhus C, Denmark

<sup>5</sup>Radboud University Medical Center, Department of Radiation Oncology, Nijmegen, The Netherlands

**Purpose or Objective**

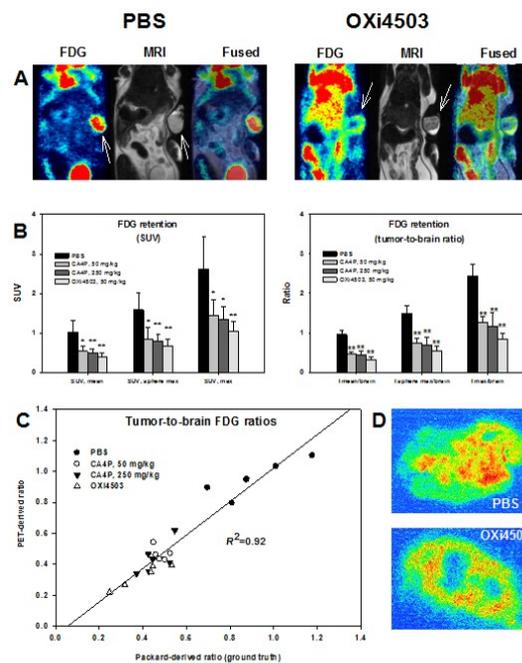

Targeting tumor vasculature with vascular disrupting agents (VDAs) is attractive. Since treatment effects precedes tumor shrinkage, ways of detecting metabolic changes to assess treatment efficacy are warranted. Positron emission tomography (PET) using fluorodeoxyglucose (FDG) is currently a first-choice imaging approach for early assessment of metabolic changes during treatment. However, hyperpolarized  $^{13}\text{C}$  magnetic resonance spectroscopy (MRS) is more refined since it allows dynamic measurements of the metabolism of  $^{13}\text{C}$ -labeled substrates *in vivo*. The aim of this study is to investigate the potential of hyperpolarized  $^{13}\text{C}$  MRS to monitor the vascular changes induced by combretastatin-A4-phosphate and its structural analogue OXi4503.

**Material and Methods**

The VDAs combretastatin-A4-phosphate (CA4P) and OXi4503 were tested in mice bearing subcutaneous C3H mammary carcinomas. Hyperpolarized  $[1-^{13}\text{C}]$ pyruvate was intravenously injected while hyperpolarized  $^{13}\text{C}$  MRS was performed with a 9.4 T MRI scanner and parameters of interest was calculated. Other, similarly treated, mice were PET scanned using a nanoScan Mediso PET/MRI scanner following administration of FDG. Ultimately, metabolic imaging results were compared to direct measures of vascular damage derived from dynamic contrast-agent enhanced magnetic resonance imaging (DCE-MRI) and histological analysis and to the clinical relevant endpoint tumor regrowth delay.

**Results**

Treatment efficacy was confirmed by DCE-MRI, tissue and tumor growth analysis, which revealed profound vascular damage and associated changes in blood-flow-related parameters, cell death and slowed tumor growth. FDG-PET revealed early detectable changes in signal, which may reflect true changes in glucose metabolism, impaired FDG delivery or a mixture of both. Nonetheless, the ratio of  $[1-^{13}\text{C}]$ lactate/ $[1-^{13}\text{C}]$ pyruvate area under the curve (AUC ratio) and the lactate time-to-peak (TTP), calculated from hyperpolarized  $^{13}\text{C}$  MRS, was unaffected by treatment.

**Fig. 1.** FDG-PET as a means to visualize and quantify early metabolic changes during VDA treatment. A: FDG-PET/MRI images showing a PBS treated (control) and an OXi4503 treated tumor-bearing mice. Arrows indicate tumor location. B: bar charts shows summarized data for all treatments using SUV or reference-tissue-based quantification of whole-tumor average or tumor sub-volume glucose metabolism. Mean values  $\pm$  SD are plotted.  $P < 0.05$ ; \*,  $P < 0.001$ ; \*\*. C: scatterplot showing the close relationship between PET-derived and Packard-derived (ground truth) whole-tumor to whole-brain tracer ratios. D: examples of high-resolution invasive analysis of the intratumoral distribution of FDG retention.

**Conclusion**

Even though DCE-MRI and FDG-PET demonstrated significant changes after treatment with VDAs, the hyperpolarized  $^{13}\text{C}$  MRS AUC ratio and the lactate TTP did not change. Further experiments including additional tumor models and validation against established technologies are needed to explore the usefulness of hyperpolarized  $^{13}\text{C}$  MRS for early predicting of VDA efficacy.

**PV-0370 MicroRNA-200c radiosensitizes Human Cancer Cells with Activated EGFR or HER2-associated Signaling**

I.A. Kim<sup>1</sup>, T. Koo<sup>2</sup>, B. Cho<sup>3</sup>, E. Choi<sup>3</sup>, D. Lee<sup>3</sup>, H. Kim<sup>3</sup>, D. Kim<sup>3</sup>, J. Park<sup>3</sup>

<sup>1</sup>Seoul National University School of Medicine, Radiation Oncology, Seoul, Korea Republic of

<sup>2</sup>Seoul National University Graduate School of Medicine, Radiation Oncology, Seoul, Korea Republic of

<sup>3</sup>Seoul National Univ. Bundang Hospital, Medical Science Research Institute, Seongnam-Gyeonggi-Do, Korea Republic of

**Purpose or Objective**

A member of the miRNA-200 family, miRNA-200c (miR-200c), recently was found to have tumor-suppressive properties by inhibiting the epithelial-mesenchymal transition (EMT) process in several cancers. miR-200c also interacts with various cellular signaling molecules and regulates many important signaling pathways. In the present study, we investigated the radiosensitizing effect of miR-200c and the mechanism of radiosensitization in a panel of human cancer cell lines.

### Material and Methods

To predict the potential targets of miR-200c, a microRNA database was used for bioinformatics analysis. Malignant glioma (U251), breast cancer (SKBR3, MDAMB468) and lung carcinoma (A549) cell lines were obtained from the American Type Culture Collection (ATCC, Manassas, VA, USA). Cells were transfected with pre-miR-200c or control pre-miRNA using siPORTNeoFX™ transfection reagent (Ambion, Austin, TX, USA). Anti-miR-200c was mixed with Opti-MEM (Invitrogen, Grand Island, NY, USA), incubated and added directly to cells. RT-PCR was performed using the Taqman miRNA reverse transcription kit and the Fast Real-Time PCR System (Applied Biosystems, Carlsbad, CA, USA). Clonogenic assay, immunoblotting and immunocytochemistry was performed.

### Results

Ectopic overexpression of miR-200c led to down-regulation of p-AKT, p-EGFR, and p-HER2 and increased the radiosensitivity of U251, A549, SKBR3, and MDA-MB-468 cells. In contrast, a miR-200c inhibitor led to up-regulation of p-AKT, p-EGFR, and p-HER2 and decreased radiation-induced cell killing. miR-200c led to persistent  $\gamma$ H2AX foci formation and down-regulated pDNA-PKcs expression. Autophagy and apoptosis were major modes of cell death. Bioinformatics analysis predicted that miR-200c could have association with EGFR, AKT, MAPK, VEGFA, HIF1AN. We also confirmed that miR-200c downregulated expression of VEGF, HIF-1 $\alpha$ , and MMP2. Overexpression of miR-200c inhibited invasion, migration, and vascular tube formation. These were associated with downregulation of E-cadherin and EphA2, and up-regulation of N-cadherin. miR-200c showed no observable cytotoxic effect on normal human fibroblasts and normal human astrocytes.

### Conclusion

Taken together, our data suggest that miR-200c is an attractive target for improving the efficacy of radiotherapy via unique modulation of the complex regulatory network controlling cancer pro-survival signaling and EMT.

### PV-0371 Novel molecular radiobiology for personalised prostate cancer radiotherapy

N. McDermott<sup>1</sup>, A. Meunier<sup>1</sup>, T. Jameson<sup>2</sup>, A. Mansour<sup>2</sup>, C. Haynes<sup>2</sup>, A. Flores<sup>2</sup>, A. O'Callaghan<sup>1</sup>, L. Marignol<sup>1</sup>

<sup>1</sup>Trinity Centre for Health Sciences Discipline of Radiation Therapy, Radiation Therapy, Dublin, Ireland  
<sup>2</sup>Mount Sinai School of Medicine, International Health, New York, USA

### Purpose or Objective

The integration of tumour-specific biological parameters to the decision-making process is anticipated to overcome the recognised limitations of the current risk stratification system for prostate cancer and transform the practice of radiation oncology. Molecular imaging techniques are rapidly advancing our ability to assess the extent and aggressiveness of prostate cancer. Differential analyses of extensive genetic profiles of specimens have progressed the use of genetic signatures from tumour tissue in providing additional prognostic information. Adopting an hypothesis-based approach to the identification of novel radiobiology that can assist the personalisation of prostate radiotherapy, we propose that the signalling pathways that regulate several cancer hallmarks and are responsive to hypoxia, such as Notch and YB-1 regulate the molecular response of cells to radiation.

### Material and Methods

The analysis of a panel of 22Rv1 prostate cancer cells was used to support the identification of novel biomarkers of radioresistance. First, an isogenic model of radioresistance was generated in 22Rv1 prostate cancer cells through exposure to 30 x 2-Gy dose fractions. Second, radioresistance was induced in 22Rv1 cells through exposure to hypoxic conditions (0.5% O<sub>2</sub>, 24hrs). miRNA

profiling of these samples was performed and validated by RT-PCR. Novel signalling interactions were characterised by western blotting, and a series of cell-based assays.

### Results

Exposure to fractionated 2Gy-irradiation to a cumulative total dose of 60Gy selected for 22Rv1 cells increase in clonogenic survival following irradiation (1.3 fold increase in survival after 2Gy and 2.2 fold increase after 10Gy) when compared to both parent 22Rv1 and aged-matched controls. The cross-evaluation strategy of the molecular modifications associated with a combination of radiobiological factors has identified miR-4284 as down regulated amongst radiation resistant models. Further evaluation of this miRNA indicates interaction with RLIM, RASGEF1, YB-1 and Notch-3. YB-1 inhibition with Fisetin significantly reduced clonogenic survival following irradiation, and modified Notch-3 receptor activation. Analysis of RNA extracted from a series of pooled samples from prostate cancer patients identified elevation of notch-3 mRNA levels in higher grade and hypoxic tumours. Validation in cell lines further identifies modification in Notch-3 activation following 5-Gy irradiation.

### Conclusion

This study identifies novel molecular radiobiology that may explain the multiple effects of radiation on the molecular biology of prostate cancer cells. This work has the potential to influence future direction of suitability and treatment of radiotherapy prostate patients.

### PV-0372 Histology-specific quantitative mapping and targeting of glucose and glutamine metabolism in NSCLC

T.W.H. Meijer<sup>1</sup>, P.N. Span<sup>1</sup>, W.J.M. Peeters<sup>1</sup>, R. Biemans<sup>3</sup>, L.F. De Geus-Oei<sup>2</sup>, D. Vriens<sup>2</sup>, L.J. Dubois<sup>3</sup>, J. Bussink<sup>1</sup>

<sup>1</sup>UMC St Radboud Nijmegen, Radiation Oncology, Nijmegen, The Netherlands

<sup>2</sup>Leiden university medical center, Radiology, Leiden, The Netherlands

<sup>3</sup>Maastricht University Medical Centre, Radiation Oncology, Maastricht, The Netherlands

### Purpose or Objective

Increased glycolysis and glutamine use are related to resistance to radiotherapy. Therefore, targeting tumor cell metabolism may improve radiotherapy efficacy in NSCLC. In this prospective cohort study, we describe pharmacokinetic rate constants of <sup>18</sup>F-FDG metabolism ( $K_1$ - $k_3$ ) and fractional blood volume ( $V_b$ ) in regions with different levels of glucose metabolic rate ( $MR_{glc}$ ) and compare these between the major NSCLC histological subtypes (adeno- (AC) and squamous cell carcinomas (SCC)). Furthermore, glycolytic rate and growth delay plus apoptotic index by glucose and/or glutamine inhibition were assessed in six NSCLC cell lines *in vitro*.

### Material and Methods

One-hour dynamic <sup>18</sup>F-FDG-PET/CTs were acquired in 38 NSCLC patients (tumor size at least 30 mm in diameter). Parametric images of Patlak  $MR_{glc}$  values were obtained. Lesions were delineated using the fuzzy locally adapted Bayesian (FLAB) algorithm. Tumors were divided into three equal volumes of increasing  $MR_{glc}$ , in which  $K_1$ - $k_3$  and  $V_b$  were computed.

For *in vitro* experiments, AC (H522, HCC827, H1975) and SCC (H520, H226, SW900) NSCLC cell lines were used. Glycolytic rate of cell lines was assessed by the percentage extracellular acidification rate (% ECAR) under normoxia and physiologic amount of glucose (i.e. 1.5 mM) using Seahorse. Growth delay and apoptosis analyses were performed under normoxia and 1.5 mM glucose using InCuCyte. To examine the effect of metabolic inhibition on growth delay and apoptotic index, the glycolysis inhibitor lonidamine and/or glutaminase inhibitor 968 were used.

## Results

In SCC compared to AC, lesion  $MR_{glc}$  and  $k_3$  were significantly higher and  $V_b$  was significantly lower. AC showed less heterogeneity relative to SCC in terms of mean  $MR_{glc}$ ,  $k_3$  and  $V_b$ . In SCC, a significant higher value for  $k_3$  and lower value for  $V_b$  was found in regions with higher  $MR_{glc}$ .

Percentage ECAR under normoxic conditions was higher in AC than SCC cell lines, corresponding to the presence of  $^{18}F$ -FDG metabolism in areas with high  $V_b$  in AC on dynamic PET. Differences between histological subtypes were less obvious in the inhibitor experiments. All cell lines show decreased growth rate by glycolysis inhibition using lonidamine. The combination of lonidamine with the glutaminase inhibitor 968 was detrimental for cell growth. In all cell lines, except H520, apoptotic index increased using the combination therapy.

## Conclusion

Adeno NSCLC show glycolysis under better perfused/oxygenated conditions (aerobic glycolysis) *in vivo* and *in vitro*, while SCC NSCLC exhibit anaerobic glycolysis (high glycolytic rate under poor vascularization). Apart from glucose, glutamine usage is critical for these tumors. All cell lines show a marked growth delay with increased apoptosis upon metabolic inhibition with both lonidamine and 968. Therefore, inhibiting metabolism might be a general approach to optimize treatment, especially in combination with radiotherapy in NSCLC.

### PV-0373 Epigenetic and metabolic reprogramming as a target for prostate tumor radiosensitization

A. Dubrovskaja<sup>1</sup>, C. Peitzsch<sup>1</sup>, A. Tyutyunykova<sup>1</sup>, M. Cojoc<sup>1</sup>  
<sup>1</sup>OncoRay - Center for Radiation Research in Oncology, Medical Faculty Dresden Carl Gustav Carus- TU Dresden, Dresden, Germany

#### Purpose or Objective

Radiotherapy remains one of the main modalities to treat solid cancers and is one of the mainstays of curative prostate cancer treatment. Nevertheless, the risk of recurrence after radiotherapy still remains substantial in locally advanced disease. Tumor relapse after radiotherapy is attributed to the population of cancer stem cells (CSCs) which survived the treatment. Therefore, analysis of the CSC populations might be an important predictive tool of radiotherapy outcome and individualized treatment selection. However, compelling evidence suggests a high plasticity of CSCs imposed by tumor treatment. This study is aiming to investigate the interconnection of the glutamine metabolism and cancer cell plasticity in the development of tumor radioresistance for the development of new biomarkers to predict radiation treatment outcome.

#### Material and Methods

The employed methodological approaches include gene expression analysis, comparative genomic hybridization array, proteomic analysis, metabolic profiling, *in vitro* radiobiological clonogenic survival assays, assessment of the histone methylation marks and CSC marker expression, analysis of DNA damage repair and oxidative stress response. This study is based on the different models including tumor cell lines and their radioresistant derivatives, prostate cancer xenografts, *ex vivo* treated tissues and analysis of the publicly available TCGA prostate cancer datasets.

#### Results

Our study revealed that irradiation causes long-term upregulation in the expression of stem cell markers and induces tumor cell reprogramming. Furthermore, radioresistant and tumorigenic cell populations undergo a phenotypic switch during the course of radiotherapy. This phenotypic plasticity is associated with genetic, epigenetic and metabolic changes induced by irradiation. Expression of CSC markers and proteins involved in

glutamine metabolism can be used to predict clinical outcome of prostate cancer patients.

#### Conclusion

Our studies suggest that radioresistant properties of prostate cancer cells are dynamic in nature and that combination of irradiation with therapeutic agents which prevent tumor cell reprogramming and metabolic switch may restore the cytotoxic effects of irradiation in radioresistant CSC populations.

### PV-0374 Molecular insights into a disease-relevant DNA damage response pathway

B. Xu<sup>1</sup>

<sup>1</sup>Southern Research Institute, Molecular Radiation Biology Laboratory, Birmingham, USA

#### Purpose or Objective

The optimal DNA damage response (DDR) is critical to prevent genetic instability. The DDR is also critical to promote cellular survival in response to DNA damage as targeting optimal DDR pathways leads to sensitization to radiotherapy. The Speckle type Poz Protein (SPOP), an E3 ubiquitin ligase adaptor, has recently been identified as the gene that has the most common somatic point mutations in prostate cancer. SPOP mutations are associated with genomic alterations, indicating a role for SPOP in the maintenance of genome stability. We, and others, have recently demonstrated a critical role of SPOP in the DDR, suggesting SPOP mutants may represent a subgroup of patients that have hyper sensitivity to DNA damaging therapies. However, how SPOP mutations might impact its function and their roles in the progress of prostate tumorigenesis remain to be extensively studied. The objective of this research is to elucidate the functional significance of SPOP in the DNA damage response pathways and to identify a subgroup of prostate cancer patients that have distinctive radiotherapeutic responses.

#### Material and Methods

Using computational modeling, we assessed the importance of the Serine 119 residue in the SBC-MATH domain. We characterized prostate cancer cells expressing the S119N dominant negative mutation using Western blot analysis, immunofluorescence microscopy, flow cytometry, and radiosensitivity by colony formation analysis. We also used *in situ* proximity ligation assay to demonstrate the interaction of SPOP with ATM. By mass spectrometry we identified a list of proteins that displayed alterations in association with SPOP in response to DNA damage.

#### Results

We found that Serine 119 residing in the SBC-MATH binding interface is in close contact with non-polar residue of the SPOP-binding consensus motif. We found that prostate cancer cells expressing mutation of S119 displayed impaired DNA damage responses. Using *in situ* proximity ligation assay, we demonstrate that Serine 119 is essential for SPOP interaction with ATM. We show that ATM phosphorylates SPOP on Serine 119 in response to DNA damage. Characterization of the functional significance of ATM-mediated SPOP phosphorylation indicates a wide range of downstream targets regulating cell cycle progression and DNA repair. By mass spectrometry we have identified a list of proteins that displayed alterations in association with SPOP in response to DNA damage. We found that alterations of SPOP interaction with these proteins are required for activation of the pathways involved in cell cycle checkpoints and Non-Homologous End Joining (NHEJ).

### Conclusion

We reveal a critical pathway linking ATM and SPOP in regulation of prostate cancer initiation and therapeutic responses to radiation. This also provides the first evidence for a pathophysiological relevant mutation linked to ATM phosphorylation in the DDR.

Award Lecture: Jack Fowler University of Wisconsin Award

### OC-0375 Dosimetric quantification of the „true“ ano-inguinal lymphatic drainage of anal cancer patients

H. Dapper<sup>1</sup>, G. Habl<sup>1</sup>, M. Mayinger<sup>1</sup>, M. Oechsner<sup>1</sup>, S.E. Combs<sup>1</sup>, D. Habermehl<sup>1</sup>

<sup>1</sup>Klinikum rechts der Isar der Technischen Universität München, Department of Radiation Oncology, München, Germany

#### Purpose or Objective

The ano-inguinal lymphatic drainage (AILD) to the inguinal lymph nodes is located in the subcutaneous adipose tissue on the medial thigh. Even though those node-vessels are very thin and hardly to detect with lymphangiography, this fact is described and shown in standard anatomy atlases. New fluorescence-imaging methods like the indocyanine-green-method corroborate this fact. Anal cancer (AC) patients undergo a combined chemoradiation (CRT) protocol and the clinical target volume (CTV) encompasses the inguinal lymph drainage because of its affection in about 30% of all patients. Current contouring atlases suggest delineation of the primary tumor region, the mesorectum, inguinal and iliacal lymph nodes but do not advise the inclusion of the true AILD. Aim of this work was the retrospective analysis of the incidental dose to the AILD in an anal cancer patient cohort who underwent definitive CRT with VMAT-IMRT and using structure sets according to current guidelines.

#### Material and Methods

VMAT-IMRT plans of 10 anal cancer patients who had been treated with CRT during 2014 and 2016 were analyzed. On these plans we created a new volume, the expected ano-inguinal lymph drain (AILD). Based on anatomic descriptions, we connected the soft tissue between the anus and the inguinal vessels with the following demarcations: The caudal demarcation was defined 2 cm below the tuberculum minus. The cranial end of AILD was at the level of the symphysis (anal) or where no more soft tissue connection between anus and inguinal could be identified (inguinal). Ventral demarcation was the femoral skin, dorsal was the transition of the gluteal muscles to the subcutaneous adipose tissue. The lateral demarcation was the adductor muscles (anal) and the medial femur bone or at least 0.5 cm around femoral vessels (inguinal). We examined dose parameters (minimum, maximum, median, V10, V20, V30, V40, V45, V50) that were delivered to the AILD target volume and the AILD outside of the previous PTV (AILD-PTV) as represented in the dose-volume histogram.

#### Results

All of the 10 patients received at least 39.6 Gy to the inguinal lymph nodes, 45 Gy to the iliacal lymph nodes and 50.4 Gy to the primary tumor side. The median volume of AILD and AILD-PTV was 1066 cm<sup>3</sup> and 689 cm<sup>3</sup>, respectively. Mean Dmin, Dmax and Dmean were 5.5 Gy, 58.1 Gy and 38.4 Gy for AILD and 5.5 Gy, 55.2 Gy and 31.1 Gy for AILD-PTV, respectively. Mean V30, V40, V45, V50 for AILD was 71%, 55%, 45% and 31%, respectively. For AILD-PTV it was 57%, 29%, 18% and 5%, respectively.

#### Conclusion

At least 71% of the volume of the expected AILD received at least an expected required treatment dose of 30 Gy incidentally. Especially the caudal parts of the created volumes, with a clear distance to the previous PTVs,

received an inadequate therapeutic dose. Concerning the low number of locoregional relapses in AC patients after definitive CRT one has to balance increased skin side effects by including the AILD into the standard CTV against a rigid oncological-anatomical interpretation of the local lymphatic drainage.

### OC-0376 Trajectory Optimization in Radiotherapy Using Sectioning (TORUS)

C. Locke<sup>1</sup>, K. Bush<sup>1</sup>

<sup>1</sup>Stanford Cancer Center, Radiation Oncology, Stanford, USA

#### Purpose or Objective

One of the most challenging problems in trajectory optimization for radiotherapy is properly handling the synchronization of the medical accelerator's dynamic delivery. The initial coarse sampling of control points implemented in a Progressive Resolution Optimization type approach (VMAT) routinely results in MLC aperture forming contention issues as the sampling resolution increases. IMRT based solutions such as 4Pi avoid MLC synchronization issues through use of a static gantry, but inevitably suffer from longer treatment times. This work presents an approach to optimize continuous, beam-on radiation trajectories thorough exploration of the anatomical topology present in the patient and formation of a novel dual metric graph optimization problem.

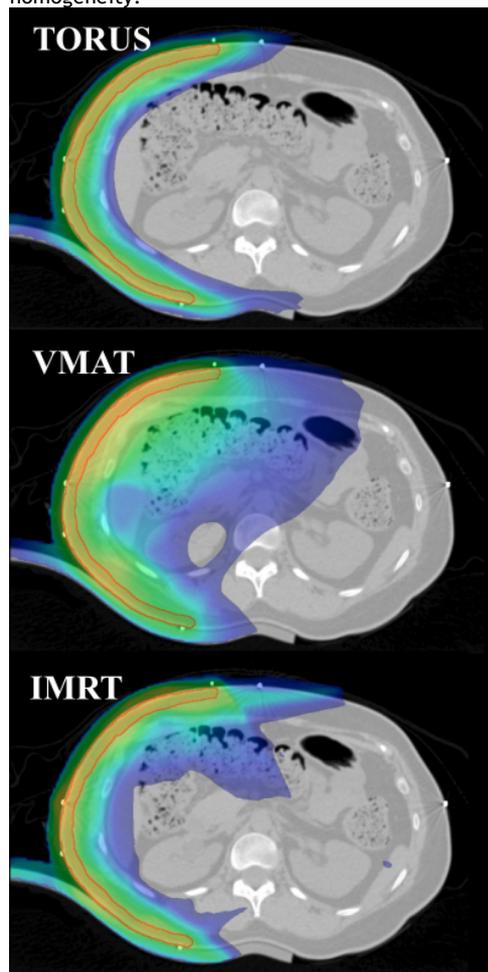

#### Material and Methods

This work presents a novel perspective on trajectory optimization in radiotherapy using the concept of sectioning (TORUS). TORUS avoids degradation of 3D dose optimization quality by mapping the connectedness of target regions from the BEV perspective throughout the space of deliverable coordinates. This connectedness information is then incorporated into a graph optimization problem to define ideal trajectories. The unique usage of two distance functions in this graph optimization permits the TORUS algorithm to generate efficient dynamic trajectories for delivery while maximizing the angular flux through all PTV voxels. 3D dose optimization is performed for trajectories using the Varian's Photon Optimizer (version 13.6.23).

#### Results

The TORUS algorithm is applied to three example treatments: chest-wall, scalp, and the TG-119 C-shape phantom. When restricted to only coplanar trajectories for the chest-wall (dose distributions shown in Figure 1) and scalp cases, the TORUS trajectories are found to outperform both 7 field IMRT and 2 arc VMAT plans in delivery time, organ at risk sparing, conformality, and homogeneity. When the coplanar restriction is removed for the TG-119 phantom and the static non-coplanar trajectories are optimized, TORUS trajectories have superior sparing of the central core avoidance with shorter delivery times, with similar conformality and

homogeneity.

#### Conclusion

The TORUS algorithm is able to automatically generate trajectories having improved plan quality and delivery time over standard IMRT and VMAT treatments. TORUS offers an exciting and promising avenue forward toward increasing our dynamic capabilities in radiation delivery.

#### OC-0377 Limited interfractional variability of respiration-induced tumor motion in esophageal cancer RT

P. Jin<sup>1</sup>, M.C.C.M. Hulshof<sup>1</sup>, N. Van Wieringen<sup>1</sup>, A. Bel<sup>1</sup>, T. Alderliesten<sup>1</sup>

<sup>1</sup>Academic Medical Center, Radiation Oncology, Amsterdam, The Netherlands

#### Purpose or Objective

Respiration-induced tumor motion is one of the major sources of intrafractional uncertainties in esophageal cancer RT. However, the variability thereof during the treatment course is unclear. In this study, we investigated the interfractional variability of respiration-induced esophageal tumor motion using fiducial markers and 4D-CBCT.

#### Material and Methods

We included 24 patients with in total 65 markers implanted in/around the primary esophageal tumor. Per patient, a 3D planning CT (pCT) and 7-28 (median: 8) 3D-CBCTs were acquired. Using the fluoroscopy projection images of the 3D-CBCTs, 10-breathing-phase 4D-CBCTs were retrospectively reconstructed. First, for each 4D-CBCT, the 10 phases were rigidly registered to the pCT based on the vertebra. Next, each marker in each phase was registered to its corresponding marker in the pCT to

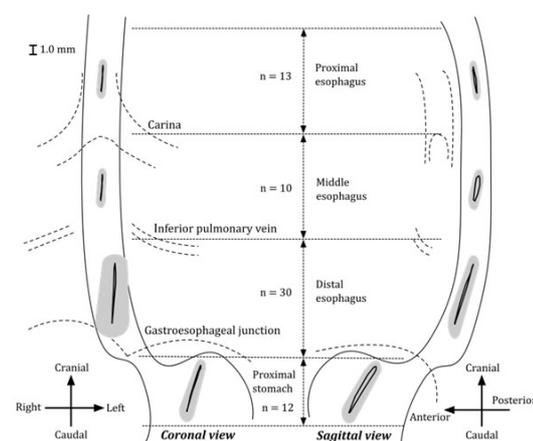

calculate the peak-to-peak amplitude of the respiration-induced marker motion and the marker motion trajectory. The mean and standard deviation (SD) of the peak-to-peak amplitudes over the treatment course were compared between the left-right (LR), cranial-caudal (CC), and anterior-posterior (AP) directions; and between the proximal, middle, distal esophagus, and proximal stomach. Further, the SDs of the peak-to-peak amplitudes and marker positions at the inhalation and exhalation were calculated to assess the interfractional variability of amplitude and trajectory shape. The correlation between the mean peak-to-peak amplitude and these SDs was also assessed.

#### Results

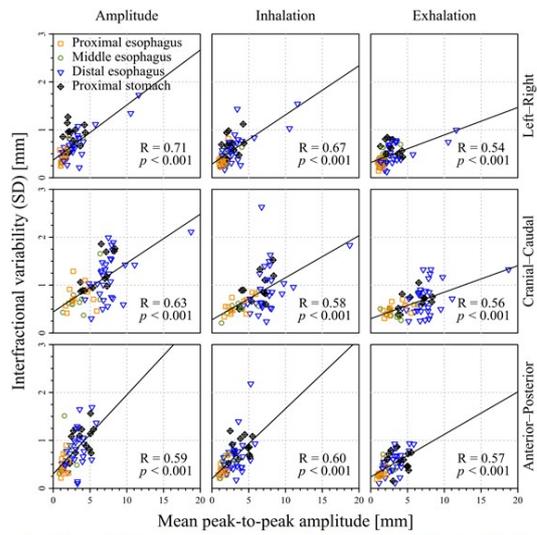

Overall, the mean and SD of the peak-to-peak amplitudes were significantly larger in the CC than in the LR/AP directions (median of mean[SD] in LR/CC/AP (mm): 2.0[0.6]/6.4[0.9]/2.4[0.7];  $p < 0.05$ , Friedman with Wilcoxon signed-rank test). It was also found to be significantly larger for the distal esophagus (2.6[0.6]/7.3[1.2]/3.1[0.7]) and proximal stomach (2.2[0.9]/6.8[1.1]/4.2[1.1]) than for the proximal (1.4[0.4]/2.7[0.7]/1.3[0.4]) and middle (1.6[0.5]/3.2[0.6]/1.6[0.5]) esophagus in all three directions (Fig. 1;  $p < 0.05$ , Kruskal-Wallis with Dunn's test). Moreover, the SDs of peak-to-peak amplitudes and marker positions at the inhalation and exhalation were  $\leq 2.1$ mm (median:  $\leq 0.9$ mm) in all three directions, suggesting a small interfractional variability of the motion amplitude and a stable trajectory shape (Fig. 2). Further, a weak correlation (coefficient R: 0.54-0.71,  $p < 0.001$ ) was found between the mean peak-to-peak amplitude and the interfractional variability of amplitude and trajectory shape (Fig. 2), implying that in addition to the peak-to-peak amplitude, other factors such as stomach fillings could also influence the interfractional variability of amplitude and trajectory shape.

#### Conclusion

The amplitude and variability of the respiration-induced esophageal tumor motion were found to be dependent on direction and region. The limited interfractional variability suggests that using a single planning 4D-CT may be sufficient to take into account the respiration-induced esophageal tumor motion.

**Fig. 1** Illustration of the average trajectory (black lines) and the standard deviation (SD) of the mean positions (grey area) of the markers for all patients throughout the breathing cycle in the four regions of the esophagus. The trajectories are projected on the coronal (left) and sagittal (right) views of the schematic esophagus drawing. *Note:* The 1.0 mm scale is only for the trajectories and SDs of mean marker positions and the trajectories are not scaled to the esophagus drawing. The number of markers in each region is indicated by n.

**Fig. 2** Mean peak-to-peak amplitude versus interfractional variability measured by the standard deviation (SD) of (left column) the peak-to-peak amplitude of respiration-induced motion, (middle column) the marker positions at the end of inhalation, and (right column) the marker positions at the end of exhalation, in the left-right, cranial-caudal, and anterior-posterior directions. The correlation coefficient,  $R$ , and the linear regression line are also given with the significance level.

Teaching Lecture: State of the art multimodality treatment of rectal cancer

SP-0378 State of the art multimodality treatment of rectal cancer

C. Rödel<sup>1</sup>

<sup>1</sup>Klinikum der Johann Wolfgang Goethe Univ Frankfurt univ hospital, Academic Department of Radiation Oncology, Frankfurt, Germany

The monolithic approach to apply the same schedule of preoperative 5-fluorouracil (5-FU)- or capecitabine-based chemoradiotherapy (CRT), or short-course preoperative radiotherapy, to all patients with clinically staged TNM stage II/III rectal cancer need to be questioned. Five randomized trials have been completed to determine if the addition of oxaliplatin to preoperative 5-FU/capecitabine-based CRT offers an advantage compared with single-agent CRT. In contrast to the German CAO/ARO/AIO-04 trial, results from the ACCORD 12, STAR-01, PETACC-6 and NSAPB R-04 trials failed to demonstrate a significant improvement of early or late efficacy endpoints with the addition of oxaliplatin. Most of the phase II trials incorporating cetuximab into CRT reported disappointingly low rates of pCR; the combination of CRT with VEGF inhibition showed encouraging pCR rates but at the cost of increased surgical complications. Novel clinical trials currently address (1) the role of induction and consolidation chemotherapy before or after CRT, (2) minimal or omitted surgery following complete response to CRT, or (3) the omission of radiotherapy for selected patients with response to neoadjuvant chemotherapy. The notion of different multimodal treatment concepts according to tumor stage, location, mesorectal fascia margin status, molecular profiles, tumor response, and patients' preferences becomes increasingly popular and will render the multimodal treatment approach of rectal cancer more risk-adapted.

Teaching Lecture: SBRT for spine and non-spine bone metastases: what role in routine practice?

SP-0379 SBRT for spine and non-spine bone metastases: what role in routine practice?

M. Dahele<sup>1</sup>

<sup>1</sup>VU University Medical Center, Amsterdam, The Netherlands

Not all bone metastases, tumours and patients are equal - the underlying theme of this session is a practical, more personalized approach to the treatment of patients with bone metastases.

Topics will include:

What is SBRT for bone metastases?

Do current clinical guidelines for the treatment of bone metastases mention SBRT?

Why consider SBRT for bone metastases?

What data is there for spine and non-spine bone SBRT?

What are the options if there is no "high-level" data to support using SBRT?

Is SBRT the only way to deliver high doses to bone metastases?

What are some of the reasons for being cautious with SBRT and high-dose radiotherapy for bone metastases?

What are some of the clinical challenges of bone SBRT?

What resources are needed to provide SBRT for bone metastases?

Teaching Lecture: Challenges in proton radiotherapy

SP-0380 How to reduce range uncertainties

A. Knopf<sup>1</sup>

<sup>1</sup>Knopf Antje, Groningen, The Netherlands

Sources of range uncertainties [1]

- Imaging (CT imaging and calibration / CT conversion)
- patient setup
- intra-fractional changes
- beam delivery (measurement uncertainty during commissioning)
- dose calculation (biology, mean excitation energy, range degradation)

Monitor range uncertainties

- PET [2]
- Prompt gamma [3]

Correct for range uncertainties

- Range probe + adaptation
- Range probe can be done in different ways
- Shoot through [4]
- CBCT [5]
- Implanted detectors [6]

Reduce range uncertainties

- Dual energy CT [7]
- Proton radiography [8]
- MC dose calculations [1]

References:

**SP-0381 Clinical challenges we currently face****E. Troost<sup>1</sup>**<sup>1</sup>TU Dresden- Med. Faculty Carl Gustav Carus, Radiotherapy and Radiation Oncology, Dresden, Germany

Proton beam therapy poses numerous challenges to modern radiotherapy. Aspects that will be discussed during the lecture include: strategies for patient selection, challenges irradiating moving targets, obstacles arising from imaging modalities available at the gantry or in the treatment room and outcome assessment.

**Teaching Lecture: Targeting histones and epigenetic mechanisms in radiation biology and oncology****SP-0382 Targeting histones and epigenetic mechanisms in radiation biology and oncology****A.H. Ree<sup>1</sup>**<sup>1</sup>Akershus University Hospital, Department of Oncology, Lørenskog, Norway

In modern radiation oncology, new insights into molecular radiobiology provide an opportunity for the rational integration of molecularly targeted therapeutics in clinical radiotherapy in an effort to optimize radiation effects. Recognizing the 4Rs of classic radiobiology - reoxygenation, redistribution within the cell cycle, recovery from DNA damage, and repopulation - each contributing either to improved or impaired tumor control in fractionated radiotherapy, an appealing strategy for enhancing radiation efficacy may be to target fundamental biological mechanisms governing all of the processes. In that context, epigenetic modifications have become a topic of renewed interest. DNA is normally tightly wrapped in histone octamers to form nucleosomes, dynamic structures that can be remodeled by a range of molecular processes including DNA methylation and methylation or acetylation of histones. Furthermore, because epigenetic alterations can be reversed by certain classes of drugs, they are interesting candidates as targets for radiation sensitizers. For example, conveyed by alterations in DNA methylation or histone acetylation patterns, inhibitors of DNA methyltransferases or histone deacetylases (HDAC) may cause perturbations in the regulation of genes implicated in tumor hypoxia, cell cycle progression, DNA damage repair, and cell death.

From our research program on HDAC inhibitors combined with radiotherapy for colorectal cancer, we have observed:

1. Enhanced radiation-induced suppression of tumor cell clonogenicity *in vitro*.
2. Prolonged radiation-induced tumor growth delay of normoxic and hypoxic *in vivo* models.
3. Histone hyperacetylation of patients' tumors.
4. Clinical treatment responses.
5. Overlapping but acceptable toxicities from the two treatment modalities.
6. Biological markers of treatment toxicity in patients' surrogate tissue.
7. Normal tissue apoptosis and autophagy in experimental models.

We initially reported on tumor cell radiosensitization and associated cell cycle effects in human colorectal carcinoma cell lines exposed to HDAC inhibitors. In human colorectal carcinoma xenograft models, we observed significant tumor growth delay following fractionated radiation combined with daily injections of the mice with the HDAC inhibitor vorinostat, compared to the radiation treatment alone. Furthermore, there was a similar tumor volume effect in irradiated hypoxic xenografts in mice injected with vorinostat and xenografts irradiated under

normoxic conditions, demonstrating that the HDAC inhibitor had counteracted the radioresistant hypoxic phenotype.

Next, we conducted the Pelvic Radiation and Vorinostat (PRAVO) phase 1 study. This trial for symptom palliation in advanced gastrointestinal cancer was undertaken in sequential patient cohorts exposed to escalating doses of vorinostat combined with standard-fractionated palliative radiotherapy to pelvic target volumes, and was the first to report on the therapeutic use of an HDAC inhibitor in clinical radiotherapy. It was designed to demonstrate that vorinostat reached the radiotherapy target (detection of tumor histone hyperacetylation) and the applicability of non-invasive tumor response assessment (using functional imaging). Following gene expression array analysis of study patients' peripheral blood mononuclear cells (PBMC), we identified markers of vorinostat activity related to cell cycle progression and reflecting the appropriate timing of drug administration in the fractionated radiotherapy protocol. Because common side effects of vorinostat single-agent therapy include intestinal toxicities, the primary objective of the PRAVO study was to determine tolerability to vorinostat in combination with pelvic radiation. Of note, in PBMC from the patient cohort that specifically experienced dose-limiting intestinal toxicities from vorinostat, genes implicated in cell death were significantly enriched. Using preclinical models at relevant drug concentrations, apoptotic and autophagic features in cultured normal intestinal epithelial cells and significant weight loss in mice following administration of the compound were observed as functional endpoints. These findings underscored that apoptosis and autophagy may play a central role in treatment toxicity from HDAC inhibitors and should be taken into consideration in the clinical context.

In conclusion, epigenetic mechanisms may be exploited in radiation oncology. As illustrated by our research program involving targeting of histone acetylation, the combined clinical and translational approach for studying tumor radiosensitization, systemic normal tissue responses, and organ-confined radiation adverse effects may be part of a template for future preclinical and early-phase clinical studies assessing radiation combined with molecularly targeted therapeutics in general and epigenetic modifiers in particular.

**Teaching Lecture: State of the art and future improvements in in-room cone beam CT image quality****SP-0383 State of the art and future improvements for in-room cone-beam CT image quality****D. Moseley<sup>1</sup>**<sup>1</sup>Princess Margaret Cancer Centre University Health Network, Radiation Medicine Program, Toronto, Canada

Cone-beam CT systems are standard features on most medical linear accelerators. These systems are routinely used to deliver image-guided radiation therapy. The "cone-beam" geometry presents several challenges for computed tomography reconstruction. These challenges are both due to the physics of the situation and engineering limitations. These limitations include x-ray scatter as well as object truncation due to a limited FOV. In addition, a key component in the cone-beam CT system is the amorphous silicon flat-panel detectors which acquire the 2D projection images. These devices have slower readout, increased image noise and increased image lag as compared to slice-based helical CT detectors. This talk will introduce some of the challenges to image quality for in-room cone-beam CT. How do these limitations affect their use in patient setup correction,

intra-fraction monitoring, dose accumulation / reconstruction and perhaps dose adaptation? Current research which aims to overcome these limitations will be highlighted.

### Teaching Lecture: Radiomics for physicists - understanding feature extraction, modelling, performance validation and applications of radiomics

---

#### SP-0384 Radiomics for physicists - understanding feature extraction, modelling, performance validation and applications of radiomics

S. Walsh<sup>1</sup>

<sup>1</sup>MAASTRO Clinic, Maastricht, The Netherlands

The field of radiomics, the high-throughput mining of quantitative image features from (standard-of-care) medical imaging for knowledge extraction and application within clinical decision support systems to improve diagnostic, prognostic, and predictive accuracy, offers significant and substantial advances for the medical community. Radiomics utilizes advanced image analysis/machine-learning techniques coupled with the explosion of medical imaging data to develop and validate potent quantitative imaging biomarkers (QIB) for precision medicine. This lecture describes the practice of radiomics, its hazards, challenges/opportunities, and its potential to support clinical decision making (currently predominantly in oncology, however, all imaged patients may benefit from QIBs). Lastly, the discipline of radiomics is developing swiftly; though it is absent standardized evaluation of both the scientific veracity and the clinical importance of published radiomics investigations. There is an obvious and evident need for rigorous evaluation criteria and reporting strategies to guarantee that radiomics fulfills its promise. To this end for both retrospective and prospective studies, the radiomics quality score (RQS: [www.radiomics.org](http://www.radiomics.org)) and an online digital phantom (DOI: 10.17195/candat.2016.08.1) are offered to provide guidance and help meet this need in the field of radiomics.

#### Workflow of a Radiomics analysis

### Teaching Lecture: Focus on lung cancer: What a radiotherapy department should offer their patients

---

#### SP-0385 Focus on lung cancer: What a radiotherapy department should offer their patients

M. Guckenberger<sup>1</sup>

<sup>1</sup>University Hospital Zürich, Department of Radiation Oncology, Zurich, Switzerland

After years of stagnation, the treatment of lung cancer has recently advanced tremendously. This rapid progress is associated with new challenges and requirements on the optimal radio-oncological care of lung cancer. Most importantly, radiotherapy for lung cancer needs to be integrated into a multi-disciplinary and multi-professional team involving medical oncology, pulmonology, thoracic surgery, radiation oncology, pathology, radiology, nuclear medicine, psycho-oncology and palliative care. National and international guidelines need to form the basis for development of institutional specific guidelines and each

team member should be aware of the each other's qualifications and limitations. Institutional experience has been demonstrated to affect outcome in radiotherapy for early and local advanced stage NSCLC forming the rationale for more centralized lung cancer care. Treatment decision making should be performed in multi-disciplinary tumor boards. Concomitant radio-chemotherapy is recommended in all appropriately selected patients with locally advanced NSCLC but only little progress has been made in this field: whereas new a large number of new drugs have made their way into treatment of stage IV NSCLC (EGFR inhibitors, ALK inhibitors, immunotherapy) none has been approved as combination partner with radiotherapy, yet. Imaging for staging and target volume definition should be stage and location adapted including CT with or w/o IV contrast, FDG-PET CT and consider information from endoscopic staging. A motion compensation strategy is required for all patients with respiration correlated 4D-CT imaging forming the basis; there are no clinically significant differences in the specific motion compensation strategy. Treatment planning using static or dynamic rotational intensity modulated techniques have largely replaced 3D conformal techniques especially in complex shaped early stage and locally advanced stage of disease. Risk adapted fractionation is standard in stereotactic body radiotherapy for early stage NSCLC and total doses need to be >100Gy BED. Based on the RTOG 0617 trial, conventionally fractionated doses of 60 - 66Gy remain a standard of care and further dose escalation should only be performed in centers with sufficient expertise. Image-guided treatment delivery is highly recommended in curative treatment for lung cancer. Adaptive re-planning is frequently necessary in case of larger anatomical changes. Adaptive re-planning for a shrinking tumor is technically challenging and may reduce doses to organs at risk especially in patients with very large tumor volumes, where a curative dose is otherwise hard to achieve. Follow-up and evaluation of the institutional specific results are important components of all quality assurance systems.

---

### Teaching Lecture: How to write a research proposal for a grant?

---

#### SP-0386 How to write a research proposal for a grant?

P. Lambin<sup>1</sup>

<sup>1</sup>MAASTRO Clinic, Maastricht, The Netherlands

**Introduction:** Financial resources from Universities are cut down and scientists are more often expected to fund their own research. There are different phases in the process of writing grants, summarized hereunder:

Step 0: Identify what your expertise is in which you will have convincing papers and/or preliminary data. Screen the possible grants for scientific research regularly. (6-12 months before the deadline for submission)

Step 1: When you have identified grants that are suitable for your work, try to get as much information as possible about the grant itself. Identify the (best) partners that you will need for your research project, especially in the case of proposals for the European Commission.

Step 2: Write a skeleton of the research proposal with brief concepts, hypothesis objective and keywords for each of the main parts of the proposal. This should be completed at least 3 months before the deadline for submission. Before doing too much work, discuss it with experts and colleagues of your departments. It is easy at this point to make big changes in the structure of the proposal, but very difficult after much of the writing has been done. A research proposal consists of several parts: *Background (Problem definition)*: insist on the "why" you want to do this.

*Main hypothesis (at end of problem definition)*  
*Objective* - has to be very clear and must refer to the study population  
*Research question* VERY IMPORTANT! - it must be crystal clear and simple, end with a question mark. From a good research question you can derive the methods.  
*Specific aims (not too much sub questions, they make the proposal less clear!)*

*Preliminary data*- The preliminary data should support your hypothesis

*Workplan*- Develop a separate work plan for each aim. Don't spend too much space on detailed methodology. The question to think about when developing the workplan is - "What experiments do I need to do to accomplish the specific aim?". The experiments should always try to answer questions and not be just about data collection. This is the idea behind 'hypothesis driven research'. The hypothesis is tested by conducting smart experiments. The work plan should use modern and elegant techniques, but must also be feasible. Try to convince the reviewer that you can do it. Convince the reviewer you will have access to the data.

*Statistic*: work out the sample size and the validation  
*Budget* - it must be realistic. Often you need real offers from HR and external parties.

Step 3: Plan a second discussion with experts in the area  
 Step 4: fill the gaps, do a series of proofreading on the electronic and the paper version and submit it.

---

#### Symposium: Rectal cancer - prediction and individualisation

---

##### SP-0387 Sequence of radiotherapy, chemotherapy, and surgery: current concepts and trials

R. Glynne-Jones<sup>1</sup>

<sup>1</sup>Mount Vernon Hospital, Northwood Middlesex, United Kingdom

Adenocarcinoma of the rectum is a heterogeneous disease. Surgery and radiotherapy (RT) both serve as a primary modality to achieve local control, and each as a single modality can be curative, but surgery with total mesorectal excision (TME) is the mainstay of treatment and a multimodality approach has usually been considered more effective in locally advanced rectal cancer (LARC). Historically the high loco-regional recurrence rate after radical surgery alone, which was a challenge to salvage and resulted in symptoms, which are difficult to palliate, has dominated decision-making. Metastatic disease is now the commonest mode of recurrence and cause of death, and hence currently the focus of treatment is the reduction of metastatic disease. For patients who are either medically unfit or refuse the operation, radiotherapy alone or chemoradiotherapy is frequently recommended as an alternative option, but rarely leads to cure unless early stage. Around 15% of patients with LARC achieve a complete response after CRT with 20-30% having a minimal response. However, in the event of a complete clinical response many now advocate a non-operative 'watch-and-wait' strategy. From the oncological point of view there are several potentially appropriate options including surgery alone, neoadjuvant chemotherapy, short course preoperative radiotherapy (SCPRT) with a long or short interval to surgery, chemoradiotherapy (CRT) and combinations of the above. Preoperative radiotherapy reduces local recurrence, but does not impact on overall survival. This reduction in local recurrence comes at a price. The increasing focus on the quality of life leads us to recognize that, in return for gains in local control for a few, many patients suffer long-term adverse consequences of surgery and RT. Symptoms such as chronic pain, faecal incontinence, and sexual difficulties are reported in both sexes. The 'low anterior resection syndrome' (LARS) or LARS is frequently reported by

patients and enhanced by the addition of SCPRT/CRT. The gains in function achieved by a long rectal remnant are lost if radiotherapy is added. For this reason trials have been developed, which omit radiotherapy if a good response to chemotherapy is observed. Appropriate selection is the key to the best results. Individualization requires an effective MDT, which takes account of current guidelines, but selects the optimal treatment according to good quality MRI, surgery and pathology. The decisions should reflect the staging and clinical features and molecular biology of the tumour, and also the wishes and preferences of the patient. The MDT should audit its results regularly to move with developments in technology and re-evaluate its decision-making. From all of the above, it is clear that the ability to predict tumor response before and after each of these possible strategies would be useful to tailor the use and intensity of neoadjuvant treatment

##### SP-0388 Organ preservation by optimised radiotherapy: ready for prime time?

G. Beets<sup>1</sup>

<sup>1</sup>Netherlands Cancer Institute Antoni van Leeuwenhoek Hospital, The Netherlands Cancer Institute, Amsterdam, The Netherlands

The basis of the current treatment of rectal cancer is a radical total mesorectal excision (TME), and while this provides superior oncological control, it is associated with morbidity and functional problems. Broadly there are three types of organ preservation approaches:

1. transanal local excision of a very early tumors, in which the mesorectum is left untreated because the risk of lymph node metastases is very low or non-existent
2. transanal local excision of early tumors with added (neo)adjuvant radiotherapy to eradicate potential small mesorectal lymph node metastases
3. upfront ChRT for mostly larger tumors, with omission of TME surgery only when reassessment shows a clinical complete response

All organ preservation approaches inherently accept a higher incidence of residual disease in the bowel wall or lymph nodes and rely on active surveillance to detect and treat residual disease when still amenable to salvage TME. The real oncological risk of organ preservation is that some of the regrowths could not be easily amenable to salvage surgery and that some could be the source of metastases. Although the available series suggest that with adequate selection and follow up this risk is very small, the exact risk is not yet well established.

##### Assessment of response

The most commonly used restaging modalities to assess a complete response in the bowel wall and the lymph nodes are rectal examination, flexible sigmoidoscopy and MRI, including diffusion weighted imaging (DWI). The difficulty for T2w MRI, as with all imaging methods, is to distinguish fibrotic thickening from viable tumor cells. Adding DWI improves the accuracy but there is still a tendency to overestimate the presence of residual tumor. For the lymph nodes T2w MRI is currently the best imaging method, with a reasonable accuracy, better than in primary staging. The luminal component of the tumor is very well assessed with endoscopy and digital rectal examination (DRE). A typical complete response presents as a white scar in the rectal mucosa, with or without telangiectasia and no palpable lesions. However, the endoscopic findings are sometimes less clear with small residual flat ulcers, some residual redness of the mucosa, and with subtle soft lesions on DRE. Half of these "near complete responses" actual complete responders in the healing phase of the bowel wall. Biopsies have a limited value due to sampling errors. A local excision of the remaining scar could provide histological proof, however with disadvantage of a higher complication rate than in non-irradiated patients, with sometimes a painful slow

healing ulcer. Another alternative is to extend the observation interval for an additional 1-2 months. **Follow up - detection and treatment of regrowth** Regrowths are inherently a part of the organ preservation approach, and follow-up should be aimed at early detection of local regrowth. The vast majority of local regrowths after W&W are located intraluminal and occur within 12-18 months. The backbone of local follow up is frequent examination by DRE and endoscopy during the first two years, supplemented by MRI to detect the less frequently occurring regrowths deeper in the bowel wall or lymph nodes. Our current schedule has a 3-4 monthly flexible sigmoidoscopy and MRI in the first year and 6 monthly thereafter until year 5.

A TME is the best oncological option when a patient presents with a regrowth. Alternatives can be considered in various situations, such as a local excision of an isolated luminal regrowth in a patient with a high operative risk or patient preference to avoid major surgery and/or a definitive colostomy. Organ preservation series show that with adequate follow and early detection local regrowths occur in 15-25% and are mostly amenable to salvage treatment with good outcome.

#### Conclusion

Organ preservation constitutes a paradigm change with different treatment concepts: willingness to adapt the surgical plan according to the response, prolonging the observation time in good responders, the role of TME as salvage surgery, and expanding the role of patients in treatment choices. Although the risk seems low, there is no high-level evidence that organ preservation is as safe as standard TME surgery. This should be balanced against the possible benefits: avoidance of operative morbidity and mortality of a TME procedure, and an improved quality of life through. Because of a high interest of patients, the surgical community should cautiously move ahead and offer the option of organ preservation to patients in a controlled setting and combine this with providing further evidence. This can be achieved by setting up a prospective organ preservation protocol with standardized assessment and follow up in centers that add their data to a large multicenter database. At least initially it seems wise to concentrate organ preservation in a limited number of centers in order to gain sufficient expertise more quickly.

#### SP-0389 Imaging and molecular profiles to predict response to chemoradiotherapy: where do we stand?

K. Haustermans<sup>1</sup>

<sup>1</sup>UZ KUL, Department of Radiation Oncology, Leuven, Belgium

The tumor response to preoperative chemoradiotherapy (CRT) is heterogeneous. About 20% of the patients achieve a pathological complete response (pCR). Patients with a pCR have a favorable long term outcome with excellent local control and disease-free survival. Adopting a watch and wait strategy in these patients is appealing since rectal cancer surgery entails complications, morbidity and even mortality. Strategies should be explored to precisely select patients who are candidates for a less invasive strategy. Conventional imaging lacks accuracy for restaging after CRT and is therefore not useful to select candidates for organ preservation. In recent years, there has been growing interest in molecular markers and functional imaging to improve clinical response assessment. Since immunity and inflammation play a critical role in tumorigenesis, inflammatory parameters might give useful information on the patient's tumor response. Another promising strategy for the prediction of the response to CRT is the use of functional imaging. Diffusion-weighted imaging (DWI) and 18F-fluorodeoxy glucose positron emission tomography (FDG PET-CT) have emerged as promising tools in the prediction of tumor response before, during and after CRT. Besides the common parameters determined on these images such as

the Apparent Diffusion Coefficient (ADC) and the Standardized Uptake Value (SUV), tumor phenotypes can also be characterized by extracting a large number of quantitative image features (radiomics). A uniform prospective registration of patients with rectal cancer managed with a non-surgical approach will result in a detailed understanding of patient selection and will enable us to assess long-term outcome.

---

#### Symposium: Radiotherapy of brain tumours

---

#### SP-0390 Radiotherapy for low grade glioma in adults in 2017. What's crazy!

S. Villà Freixa<sup>1</sup>

<sup>1</sup>Catalan Institute of Oncology. Universitat Autònoma de Barcelona, Radiation Oncology, Badalona. Catalonia, Spain

Diffuse low grade glioma (LGG) is a heterogeneous group of tumors in terms of survival. Maximal surgical resection is the initial optimal treatment but no clear evidences have been published. Adjuvant treatment using radiotherapy (RT) and chemotherapy has been used in high risk patients and a significant improvement of survival has been shown. RT plays a key role in the RTOG series but timing, volumes and dose are still undefined. After the final results of EORTC 22033 and RTOG 98-02 trials it has been suggested that chemotherapy is active for LGG. Indeed, chemotherapy did not imply a decline in MME score in the American trial. Nowadays however the main argument for delaying RT in patients with LGG is to avoid neurocognitive and quality of life deteriorations. Nevertheless, no significant differences in quality of life were reported between RT and temozolomide groups in the EORTC 20033 trial when analysis of the questionnaires were done, with acceptable level of compliance. Notably, median progression free survival for patients in the RT group was superior to chemotherapy group (not significant). In the new era of molecular biology for gliomas with its prognostic potential role, it is important to underlay that the major strength of EORTC 22033 trial was that molecular data (*IDH 1/2*, *1p/19q* co-deletion) were available in more than 80% of patients (45% of patients in the RTOG 98-02 trial). RT seemed to be as effective as temozolomide in patients with *IDH1* or *IDH2* mutations and *1p/19q* co-deletion. For Radiation Oncology community, it is pending to solve several questions: 1- Defining volumes (GTV, CTV, PTV), and protecting hippocampus using co-registrations with CT, different sequences of MRI and PET scan. 2- Using new modifications of IMRT (as VMAT) or protontherapy as standard. 3- Determining dose fractionation and total dose, taking into account that the standard EORTC dose of 50.4 Gy has not been compared with lower total dose. In conclusion, it seems that in high risk LGG patients the combination of RT with chemotherapy improves survival and progression free survival and that RT is comparable to temozolomide. However, Radiation Oncology community has to step forward in defining techniques and total dose and fractionation.

#### SP-0391 What is the role of combined chemoradiotherapy for grade III glioma in adults?

A. Chalmers<sup>1</sup>

<sup>1</sup>Inst. of Cancer Sciences-Univ. Glasgow The Beatson West of Scotland Cancer Center, Department of Clinical Oncology, Glasgow, United Kingdom

Classification, prognosis and treatment of grade III glioma is now determined predominantly by molecular biomarkers, with *1p19q* chromosomal co-deletion conferring a clear prognostic benefit and also being associated with better response to chemotherapy. The

importance of this molecular biomarker is reflected in the updated WHO classification of central nervous system tumours that was published in 2016.

Long term data from two large, randomised trials have shown that patients with 1p19q co-deleted anaplastic oligodendrogliomas derive significant survival benefit from the addition of chemotherapy to radiotherapy. More recent data from the NOA-04 study indicate that primary chemotherapy is not superior to primary radiotherapy in any molecular subgroup of anaplastic glioma and hence do not support the concept of 'delayed radiotherapy' in these patients.

Despite the documented association of chemosensitivity with 1p19q co-deletion, a recent planned interim analysis of the CATNON study revealed that patients with anaplastic astrocytomas with intact 1p19q chromosomal regions also derive significant benefit from the addition of adjuvant temozolomide to radiotherapy. It is not yet known whether the use of temozolomide concomitant with radiotherapy confers additional benefit; these hotly anticipated data are not expected to be available for at least two years.

Hence, all patients with grade III gliomas appear to benefit from both chemotherapy and radiotherapy, with maximum survival benefit being achieved by 'early' rather than 'delayed' treatment. A number of questions remain, including the optimum scheduling of these treatments and the optimum radiotherapy regime for the different molecular subtypes. The question of radiation dose and volume is particularly important for this group of patients in whom long term survival can be anticipated and the risks and potential impact of neurotoxicity are significant. Strategies to reduce the long term neurocognitive impact of radiotherapy in these patients should be developed and incorporated into future clinical trials.

#### SP-0392 'Paediatric' brain tumours in adults

C. Seidel<sup>1</sup>

<sup>1</sup>*Universitätsklinikum Leipzig, Klinik für Radioonkologie und Strahlentherapie, Leipzig, Germany*

Paediatric brain tumours are rare in adults. Prospective trials are often lacking and treatment recommendations are essentially based on the experiences in children - although tumors in adults are different in many aspects. Efficacy and applicability of "paediatric" approaches in adult patients is therefore a matter of debate. Medulloblastoma (MB): MB is the most common brain tumor in children. It is relatively rare in adults, with an estimated incidence of 0.6 per million. MB in adults differ from the paediatric population in terms of location of tumor, histologic and molecular subtype and course of disease. In children MB frequently arise in the midline at the floor of the 4<sup>th</sup> ventricle and vermis, whereas in adults the hemispheres are primarily involved. In children the majority of histological subtypes consist of the classical variant. In adults the desmoplastic variant is more frequently found. In adults late relapses are frequent. Like in children, surgery followed by radiotherapy is the standard of care. The addition of adjuvant chemotherapy confers a survival benefit according to a large retrospective analysis of American National database in more than 400 adult patients. After adjustment for relevant demographic and clinical factors, this study found that the addition of adjuvant chemotherapy to craniospinal irradiation was associated with superior overall survival for adult MB. In the recently closed German NOA-7 trial the addition of maintenance chemotherapy with 8 cycles cisplatin, vincristine and CCNU was investigated in a prospective, multicentric setting. Toxicity and survival profile of this study will be important for future treatment protocols. Novel stratifications of treatments in childhood MB are increasingly based on molecular genetic profiles. There have been clues over the past decade that adult MB is

biologically separate from childhood medulloblastoma. It has been shown that adult MB comprises 3 molecular variants rather than 4 and that the majority of tumors are SHH with smaller percentages comprising Wingless (WNT) and group 4. Moreover, several genomic studies have suggested that adult SHH MB is distinct from the pediatric entity, being enriched for PTCH1 and SMO mutations and coupled with a near absence of TP53 mutations. It can be expected that these information will in future gain an increasing importance for selecting adequately tailored treatment concepts for adult MB. Ependymoma (EP): Adult intracranial ependymoma are rare accounting for 2% to 5% of all intracranial malignancies. Decisive management principles were established across the age groups, especially the attempt for radical resection. Postoperative local radiotherapy is the standard of care in children regardless of histological subtype. The role of adjuvant radiotherapy in the adult, however, is unclear and subject to controversies. The role of additional chemotherapy is unclear in children and adults. In children genetically distinct subgroups have been identified by genomic alteration in classic grade II and III ependymomas. They are supratentorial ependymomas with C11orf95-RELA fusion or YAP1 fusion, infratentorial ependymomas with high (type B) or low (type A) copy alteration number, and spinal cord ependymomas. Myxopapillary ependymomas and subependymomas have different biology and a better prognosis than ependymomas with typical WHO grade II or III histology. However, data for adults is scarce. Translation of molecular findings into clinical practice and adapted treatments is essential both for children and adults with the aim to improve tumour control and survival. Embryonal tumours (former stPNET): According to the new WHO classification of 2016 the former stPNET are now classified as embryonal tumours with distinct sub-classifications according to conventional histological description and the availability of molecular genetic profiles. Until today treatment concepts are still based on the traditional histological description both in children and adults. Embryonal tumours at supratentorial location are rare. Treatment concepts for these tumours both for children and adults are controversial. Surgery and craniospinal irradiation are still the corner stones in treatment management for both children and adults. The addition of chemotherapy is subject to prospective trials in children. With the introduction of the new classification and molecular genetic profiles adapted treatment concepts will evolve in future both for children and adults. Key points: Current concepts for paediatric CNS tumours in adults are based on experiences generated in paediatric neuro oncology. It is an open question whether these concepts prove to be as efficient and feasible. Late effects are known in children, but information is scarce for adults. There is a need for specifically tailored concepts in adults.

---

#### Symposium: MR guided radiotherapy: the new standard of care in 10 years time

---

#### SP-0393 Clinical opportunities with MR guided external beam RT

S. Mook<sup>1</sup>

<sup>1</sup>*UMC Utrecht, Department of Radiation Oncology, Utrecht, The Netherlands*

Nowadays, image guided radiotherapy is considered standard of care and is an integrated part of radiation treatment. Currently, cone beam computer tomography is the modality of choice for image guidance, however, limited soft tissue contrast and the absence of real time intrafraction imaging cause restrictions to its application. The superior soft tissue visualization of MRI was the incentive for the development of the MR linac system,

which combines a 1.5 Tesla MRI with a high-end linear accelerator. The MR linac will provide real-time high-quality MRI guidance, not only before, but also during treatment.

With the introduction of the MR linac, radiotherapy will enter a new era of high precision treatment with a wide range of opportunities. MRI guidance will improve tumor targeting accuracy, allow for smaller PTV margins and thus result in a reduction of normal tissue exposure. Consequently, highly accurate tumor targeting with small PTV margins will enable hypofractionation and dose escalation up to ablative dose levels, potentially omitting the necessity of surgery to control the macroscopic tumor. In addition, daily and even intrafraction plan adaptation and dose painting based on anatomical changes, tumor regression and functional MR imaging will further refine dose escalation and might provide an organ-sparing treatment strategy for a growing number of indications. The excellent soft tissue contrast in combination with advanced online motion-compensation of the MR linac will also broaden the potential indications for radiotherapy. Besides its numerous opportunities, the MR linac also brings challenges. Its clinical implementation requires thorough revision of workflows and clinical protocols, training of personnel, adaptation of QA procedures, etc. In addition, a standard assessment methodology for the evaluation of innovations in radiotherapy such as the MR linac is required.

In conclusion, the MR linac has the potential to provide a high-precision, high-dose, adaptive, non-invasive therapy, with improved local control, less toxicity and the possibility of omitting surgery in an extended field of radiotherapy indications.

#### **SP-0394 MR guided brachytherapy - successes and potential future developments**

P. Hoskin<sup>1</sup>

<sup>1</sup>Mount Vernon Hospital, Northwood Middlesex, United Kingdom

Brachytherapy has led the way in the development of MR guided radiotherapy. The technical requirements in brachytherapy differ from external beam planning in that the source being placed within the CTV means that the problems of tissue inhomogeneity and beam entry and exit profiles do not need consideration. The main challenge in brachytherapy is to design applicators which can be readily visualised on MR so that accurate definition of applicator geometry within the CTV is achieved. In the two most common indications for brachytherapy, gynaecological cancers and prostate cancer MR guided techniques are well established and considered standard practice. The development of MR guided gynaecological brachytherapy demonstrates well the advantages of the superior anatomical information obtained from MR and the ability to accurately delineate tumours defining the CTV. The evolution can be traced from conventional point A based dosimetry using orthogonal x-rays to 3-D image guided brachytherapy using MR which has been estimated to account for a 13% increase in survival with modern treatment techniques. Similarly in prostate cancer, whilst ultrasound-based implantation is the standard for definition of the CTV registration with MR provides additional information. As the practice of focal therapy and dose painting using functional MR information evolves then MR based planning is seen to have significant advantages which will again translate into patient benefit. For the future refinement of MR compatible applicator design, access to MR guided implant techniques and MR based planning algorithms will further enhance the role of MR in brachytherapy.

#### **SP-0395 Challenges associated with MR guided radiotherapy**

D. Jaffray<sup>1</sup>

<sup>1</sup>Princess Margaret Cancer Centre University Health Network, Toronto, Canada

The sensitivity and definition of magnetic resonance (MR) imaging makes it a compelling technology to guide the delivery of highly conformal radiotherapy (RT).

Technological advances have now made this concept a reality in a variety of forms ranging from its use in the design of the treatment plan to enabling on-line planning and/or real-time verification of plan delivery. While the paradigm of MR-guided radiotherapy already is operating in various forms, including dedicated machines that combine MR imaging and delivery, there are numerous challenges that prevent the full exploitation of this technology to maximize the therapeutic ratio for today's cancer patient. These challenges can be broadly grouped as biological, physics / computational, operations / procedural, and cost / value. While the implementation of MR-guided RT is advancing, clinical, research, and industry teams are exploring the radiobiological effects, addressing computation of dose and deformation, developing adaptive workflows, and seeking evidence of the value of these new processes will bring to the patient and health system as a whole. In this presentation, the full scope of these challenges will be presented to provide the audience with an understanding of their interplay and to allow them to identify areas of priority.

#### **SP-0396 Can we perform RCTs evaluating MR guided radiotherapy?**

V. Valentini<sup>1</sup>

<sup>1</sup>Università Cattolica del Sacro Cuore - Policlinico A. Gemelli, Gemelli ART, Rome, Italy

Image guided radiotherapy (IGRT) has offered in the last years great opportunities to reduce treatment related uncertainties and errors and to develop new dose escalation protocols with local control improvement and toxicity reduction. The recent technological introduction of MRI in RT treatment rooms, offer new IGRT paradigms, which will allow an adaptive therapy, approach through the analysis of organ motion 3D and 4D features and volume changes. To define the metric to evaluate the assumed benefit is of utmost importance in order to achieve the best clinical outcomes in the daily management of radiotherapy (RT) treatments delivery. The issue to apply the RCT methodology to measure the assumed clinical benefit of this new technology is challenging the appropriateness of this approach, as any time that an innovative technology has to be evaluated, and the cost and time needed to get a reliable evaluation. On the other side the cost effectiveness benefit of this new technology needed to have a proper metric to allow a full understanding of its role. The possibility to manage RCT, in term of aim, feasibility and expected outcome, and to use a similarity large data base approach will be addressed.

#### **Symposium with Proffered Papers: Novel approaches in head and neck tumour control**

#### **SP-0397 State of the art in head and neck tumour radiobiology**

B. O'Sullivan<sup>1</sup>

<sup>1</sup>Princess Margaret Cancer Centre University Health Network, Toronto, Canada

Much contemporary knowledge and application of radiobiology to cancer treatment derives from experience and management of head and neck cancers (HNCs). In part, this relates to the more accessible nature of these

lesion compared to other cancers for observation and tissue access, and because radiotherapy (RT) has provided a dominant approach as a primary treatment for these lesions. Current principles are governed by strong observational studies that described outcomes determined by overall treatment time in addition to RT dose and fractionation, and the hazard associated with accelerated proliferation. Subsequently clinical trials and their combination in individual patient meta-analyses confirmed these principles (e.g. MARCH, 2006). At the same time the same investigators have shown an added benefit to addition of concurrent chemotherapy (CTx) compared to standard fractionated RT alone (MACH-NC 2000, 2009). In essence, the combination of RT with CTx needs to be considered in unison, since outcomes today are frequently inextricably linked to the application of both approaches. Following these studies significant evolution in a variety of areas has taken place. These include the emergence of HPV-related disease on the one hand and a developing significant sub-population of elderly patients who may be unable to tolerate intensive treatments used for younger patients and whose biology may differ. In addition, new treatment approaches have emerged as well, including potential combination of systemic agents with altered RT fractionation (where increased efficacy appears to be present), use of induction CTx, the use of biotherapies, the introduction of trans-oral surgical approaches (including robotic approaches that may also require additional application of adjuvant RT) and the nascent introduction of immunotherapy. For these reasons, while the focus of this talk is on radiobiology, and predominantly in HPV-negative tumors, it remains necessary to address principles of combination with other agents and approaches. For example, exploration of biomarkers in the microenvironment of surgical wounds may influence outcome of post-surgical adjuvant RT +/- CTx. Understanding RT-CTx interaction requires an understanding of the principles of spatial cooperation, synergy, and independent cell kill, including ways to exploit biological phenomena, such as apoptosis, hypoxia, or directly enhancing the direct cell kill through influence on DNA repair or on double strand breakage. A sustained search for biomarkers of response to agents that may influence RT outcomes is ongoing as exemplified by ERCC1 in the case of Cisplatin and for hypoxia, the description of hypoxia gene signatures is undergoing validation in the context of prognostic and predictive impact and the pre-therapeutic value of identifying those who may benefit from hypoxic modification of RT. An additional adverse biological modifier of RT outcome is represented by smoking exposure which confers adverse survival outcome overall within a complicated matrix of activity including adverse influence on the host through additional comorbidity, causation of the cancer that may be adversely effected as a function of the intensity of tobacco exposure, or may influence the response to RT in current smokers who continue to smoke during RT. Finally, beyond smoking, other tumor-host microenvironment interaction exists. The most significant interest in this area today is the emergence of programmed death-ligand 1 (PD-L1)/programmed death-1 (PD-1) interaction in inhibiting anticancer T-cell immunity with the possibility of generating durable responses and extended overall survival using targeted therapy. Much interest has been generated for a range of possible HNC scenarios in the context of RT. Approaches under consideration include modification of RT volumes, RT and CTx interaction with immune check point inhibitors and application of these combinations in different risk subsets, and the continued search for ways to exploit the rare instance of RT induced immune-mediated systemic response, a phenomenon termed the 'abscopal effect'. For the latter, local RT may induce regression of metastatic cancer at distant sites which have not been irradiated through induction of adaptive immune responses. This effect governs such

clinical trial questions as reduction of the intensity of treatment to regions that traditionally have been managed with conventional elective doses of RT or for the management of oligometastases. Also, elderly patients require novel approaches and there is considerable evidence that aging affects the immune system and anti-tumor response in the elderly, particularly through T cell function. Combining standard RT with immune modulation is an attractive strategy in the elderly due to their poorer anti-tumor T cell function and the favorable toxicity profile of emerging immunotherapy approaches. Trials addressing these approaches are currently in design.

#### SP-0398 Novel developments in the radiobiology of HPV-positive head and neck tumours

S. Nuyts<sup>1</sup>

<sup>1</sup>University Hospital Gasthuisberg, Leuven, Belgium

Head and neck squamous cell carcinoma (HNSCC) is a highly heterogeneous disease that is often the result of tobacco and/or alcohol abuse or infection with high-risk Human papillomaviruses (HPV). Worldwide, an increase in HPV related oropharyngeal carcinoma's is seen. Despite the fact that the HPV positive HNSCC form a distinct clinical entity with better treatment outcome, all HNSCC are currently treated uniformly with the same treatment modality. However, it is expected that the results of ongoing randomized studies will reshape radio-chemotherapy schedules for this tumour group. At present, biologic basis of these different outcomes and their therapeutic influence are an area of intense investigation.

The radiobiological differences between HPV+ and HPV-head and neck tumours and resulting treatment possibilities will be discussed from the perspective of the 5 Rs.

Over the last couple of years several hypotheses have been put forward correlating radiotherapy response to micro-environmental (immune system and hypoxia) and tumour intrinsic factors. It has been hypothesized that the immune system plays a more important role in clearance of HPV related HNSCC compared to HPV- HNSCC due to the expression of viral proteins. On the other hand the presence of high-titer serum antibodies to these viral proteins indicates the presence of immune tolerance and opportunities for immunotherapeutic approaches. One of the most studied environmental factors in relation to radiotherapy response is hypoxia, which is known to result in radiation resistance. Some studies suggest a possible influence of hypoxia in radiation sensitization in HPV+ HNSCC, whilst others suggest a more ambiguous role for tumour hypoxia. Moreover, factors influencing the intrinsic radiotherapy response such as the role of cancer stem cells, differences in DNA repair capacity and influence of HPV on cell cycle and cell death pathways will be discussed. In this presentation, we will thus summarize the molecular basis for different radiotherapy response based on HPV status, novel treatment opportunities and possible biomarkers for HPV positive HNSCC.

#### OC-0399 Transcriptome analyses of the radiation response in HNSCC cells with different radiation sensitivity

J. Heß<sup>1,2</sup>, A. Michna<sup>1</sup>, U. Schötz<sup>2,3</sup>, M. Selmsberger<sup>1</sup>, H. Zitzelsberger<sup>1,2</sup>, K. Unger<sup>1,2</sup>, K. Lauber<sup>2,3</sup>

<sup>1</sup>Helmholtz Zentrum Muenchen - German Research Center for Environmental Health, Research Unit Radiation Cytogenetics, Muenchen, Germany

<sup>2</sup>Helmholtz Zentrum Muenchen - German Research Center for Environmental Health, Clinical Cooperation Group "Personalized Radiotherapy in Head and Neck Cancer", Neuherberg, Germany

<sup>3</sup>Ludwig-Maximilians-University, Department of

*Radiotherapy and Radiation Oncology, Muenchen, Germany*

#### **Purpose or Objective**

Radio(chemo)therapy is a crucial treatment modality for head and neck squamous cell carcinoma (HNSCC) and radioresistance is a major reason for therapy failure and is related to tumour recurrence and poor prognosis. However, the underlying molecular mechanisms are largely unknown. In order to gain knowledge on this fundamental and clinically relevant feature, we established an in vitro model of CAL-33 HNSCC cell line subclones with different radiosensitivity. The main aim of the study was to identify signalling pathways and key regulators of radioresistance by static and dynamic global mRNA expression analyses followed by gene association network (GAN) reconstruction and pathway enrichment analyses.

#### **Material and Methods**

Subclones with altered radiosensitivity were generated by fractionated irradiation of the parental CAL-33 cells and colony formation assays were performed to confirm the differences in radiosensitivity. Selected subclones were characterized at the genome and transcriptome levels by SKY, array CGH, and mRNA-microarray analyses. Temporally differentially expressed genes upon irradiation were identified using natural cubic spline regression modelling on time-course transcriptome data. Moreover, early and late responding genes were determined. GANs were reconstructed using a partial correlation-based approach. Pathway enrichment analyses were conducted employing the Reactome pathway database. Microarray gene expression data were technically validated by qRT-PCR.

#### **Results**

The characterization of two subclones with enhanced radiation resistance (RP) and enhanced radiosensitivity (SP) revealed distinct genomic and transcriptomic changes compared to the parental cells. Interestingly, the expression of the endogenous retrovirus ERV3-1 in response to irradiation has been observed in all of the CAL-33 cells, suggesting a role in the radiation response of HNSCC cells. Differentially expressed genes after irradiation shared by both subclones pointed to important pathways of the early and late radiation response, including senescence, apoptosis, DNA repair, Wnt, PI3K/AKT, and Rho GTPase signalling. The analysis of the most important nodes of the GANs revealed pathways specific to the radiation response in different phenotypes of radiosensitivity. Exemplarily, for the RP subclone the senescence-associated secretory phenotype (SASP) together with GPCR ligand binding were considered as crucial.

#### **Conclusion**

Our study presents comprehensive gene expression data of CAL-33 subclones with different radiation sensitivity. Based on these data GANs have identified known to be linked to the radiation response phenotypes. The resulting GANs and pathways associated with the resistant phenotype are of special interest and include SASP together with GPCR ligand binding. The identified pathways may represent key players of radioresistance, which could serve as potential targets for molecularly designed, therapeutic intervention.

#### **OC-0400 Prognostic impact of tumor infiltrating lymphocytes and PD-L1 expression in head and neck cancers**

D. Ou<sup>1,2</sup>, J. Adam<sup>3</sup>, I. Garberis<sup>3</sup>, P. Blanchard<sup>1</sup>, F. Nguyen<sup>1</sup>, A. Levy<sup>1</sup>, O. Casiraghi<sup>3</sup>, P. Gorphe<sup>4</sup>, I. Breuskin<sup>4</sup>, F. Janot<sup>4</sup>, S. Temam<sup>4</sup>, J. Scoazec<sup>3</sup>, E. Deutsch<sup>1</sup>, Y. Tao<sup>1</sup>  
<sup>1</sup>*Institut Gustave Roussy, Department of Radiation Oncology, Villejuif, France*

<sup>2</sup>*Fudan University Shanghai Cancer Center, Department*

<sup>3</sup>*Institut Gustave Roussy, Department of Pathology, Villejuif, France*

<sup>4</sup>*Institut Gustave Roussy, Department of Head and Neck Oncology, Villejuif, France*

#### **Purpose or Objective**

The aim of the present study was to investigate the prognostic value of CD8+, FoxP3+ tumor infiltrating lymphocytes (TILs) and PD-L1 expression in patients with head and neck squamous cell carcinoma (HNSCC) treated with definitive radiotherapy combined with cisplatin or cetuximab.

#### **Material and Methods**

Immunohistochemistry for CD8, FoxP3 was performed on formalin or formalin-acetic acid-alcohol fixed, paraffin-embedded, pretreatment tissue samples of 77 patients from a previously reported HNSCC cohort. PD-L1 results were evaluable in 38 patients only. The Kaplan-Meier method, univariate and multivariate analyses (MVA), were used to analyze the correlations of these biomarkers expression with patient/ tumor characteristics and treatment outcomes.

#### **Results**

CD8+ and FoxP3+ TIL densities differed significantly by HPV/p16 status, primary tumor location, T stage, and N stage. High CD8+ TIL level was identified in MVA as an independent prognostic factor for improved PFS (HR=0.3, 95%CI 0.1-0.7, p = 0.01) and there was a non-significant trend for better OS (HR=0.4, 95%CI 0.2-1.1, p = 0.07). High FoxP3+ TILs and PD-L1+ correlated with a favorable OS in the UVA, but not in the MVA. In p16+ subpopulation, high CD8+TILs patients had improved 5-year OS compared with low CD8+TILs patients (100% vs. 88.9%, p=0.049), and PD-L1+ patients had improved 3-year OS compared with PD-L1- ones (100% vs. 50.0%, p=0.01). In low CD8+ TILs tumors, 5-year LRC of patients treated with CRT was improved vs. those with BRT (92.3% vs. 51.0%, p=0.01), while in high CD8+ TILs, no significant difference with CRT vs. BRT.

#### **Conclusion**

Immune factors in the tumor microenvironment correlated with HNSCC clinicopathological features and survival outcomes. CD8+ TILs were independently correlated with an improved clinical outcome in HNSCC patients and may potentially be correlated with different treatment outcome by cisplatin or cetuximab. Further work is warranted to validate these findings in a larger independent cohort and investigate the potentially associated causal mechanisms.

#### **Symposium: Experimental therapies**

---

#### **SP-0401 Grid therapy: past, present, and future**

A. Siegbahn<sup>1</sup>

<sup>1</sup>*Stockholm University, Department of Physics, Stockholm, Sweden*

Irradiation of tumours with grids of x-ray beams was proposed already about a decade after W.C. Röntgen's original discovery of x rays. Grid therapy was thereafter used in the clinic during the first half of the past century, mainly to reduce the incidence of radiation-induced skin reactions. The beam elements (forming the grid) were approximately 1 cm wide and were separated with a similar distance to form a chessboard-shaped irradiation pattern at the patient surface. The dose distribution in the target volume was alternating between very high peak- and low valley-doses. Later, it was realized that the toxicity was also reduced for other organs located beneath the skin, if leaving tissue volumes, in-between the radiation beam elements, unirradiated. In recent years, a large cohort of head-and-neck, thoracic and abdominal

cancer patients have been treated with the grid technique using high-energy linac-generated photon beams. Grid therapy has normally been considered only when other treatment options have failed. For that reason, only sporadic cases with advanced disease and large bulky tumours have been treated with grid therapy. Large in-beam peak doses, e.g. 15 Gy, have been given to the target volume in a single treatment fraction. Although certain sub-volumes of the target (in-between the beams) are given low doses, significant reductions of the size of large tumours have been demonstrated. Grid therapy has been found to produce limited toxicity in the surrounding sensitive tissues. The high normal-tissue tolerance to beam grids is closely related to the so-called dose-volume effect which has been characterized for single beams. Experiments with beam sizes in the millimetre to centimetre range with both proton- and photon-beams have demonstrated that the tolerance doses for various biological endpoints, e.g. different skin reactions and nervous-system white-matter necrosis, are rising with reduced beam sizes. Research carried out within the American space exploration program in the 1950s showed that the tolerance doses increased dramatically for micrometre-wide beams. Certain endpoints, e.g. moist desquamation, are never observed for sufficiently small beam widths, even for extremely high doses. The migration of cells from unirradiated to irradiated volumes and an improved vascular repair if only a short segment of a vessel is irradiated have been stated as reasons for the improved tissue repair observed. Experiments and preclinical radiotherapy trials with photon- and ion-beam grids, containing beam elements of widths in the micrometre to millimetre range, have recently been carried out. These experiments have demonstrated the high degree of normal-tissue tolerance to irradiation with grids of narrow beams up to doses (hundreds of Grays) which are much higher than those used clinically. In ongoing radiobiological research, there are still some open questions regarding the tumour response to spatially modulated beams. A differential effect on the tumour vasculature has been reported. The so-called bystander effect has also attracted many researchers' interests. However, the direct effects of radiation, due to radiation that directly hits the cell nuclei and cause DNA double-strand breaks, are generally believed to be much more important for the cell survival. Whether the bystander effect significantly changes the outcome of grid therapy has not been proven because both beneficial and destructive bystander responses have been reported. The x-ray beams produced by the early machines were of low energy and highly divergent. Therefore, the beam elements in the grid began to overlap already close to the patient surface. The large divergence made it difficult to produce a tissue-sparing effect at larger depths and also made it nearly impossible to produce a uniform dose in the target by cross-firing irradiation grids with opposing beams. Nowadays, more parallel x-ray beams of high energy and fluence rate are available. Thus, there is a real possibility to exploit the normal-tissue sparing effect of radiation grids for the treatment of more deep-seated organs. Development in beam technology has provided new possibilities to cross-fire radiation grids with the aim of producing a uniform dose in the target volume. Furthermore, beams containing charged particles, e.g. electrons, protons and carbon ions, have recently been suggested for use in grid therapy. The limited range, and the sometimes increased radiobiological effectiveness of charged-particle beams, may be found advantageous. Some results from the most recent research on grid therapy will be shown in this presentation.

#### **SP-0402 Strategies for radiosensitization with gold nanoparticles**

**S. Krishnan<sup>1</sup>**

<sup>1</sup>*UT MD Anderson Cancer Center Radiation Physics, Houston- TX, USA*

Radiation therapy is a long-established component of modern therapy for localized cancers. However, its ultimate utility is limited by the inherent resistance of some cancer cells to ionizing radiation. To circumvent this problem, radiation dose escalation, targeting resistance pathways or resistant cells with novel agents, or image-guided tumor-targeted therapy are currently being investigated. Emerging evidence from an explosion of knowledge and research regarding oncologic uses of gold nanoparticles suggests that unique solutions to each of these problems of radiation resistance can be formulated via the use of gold nanoparticles. Gold nanoparticles can be used to augment the efficacy of radiation therapy via physical dose enhancement based on an increase in photoelectric absorption due to the high atomic number (Z) of gold that accumulates preferentially within the tumor due to passive extravasation of nanoparticles through "leaky" tumor vasculature. This radiation dose enhancement can be heightened via biological targeting. Enhancement of radiation therapy efficacy can also be achieved via extrinsic actuation of tumor-homing nanoparticles to generate mild temperature hyperthermia which enhances vascular perfusion and reduces hypoxia initially and causes vascular disruption subsequently to improve radioresponse. The extrinsic energy source is light for colloidal gold nanoparticles with a large absorption cross section that absorb and scatter light strongly at a characteristic wavelength (their plasmon resonance) and have a high thermal conductivity to couple this heat to the surrounding tissue.

The interface between nanotechnology and radiation oncology warrants continued investigation by interdisciplinary teams of physicists, chemists, biologists, clinicians, and engineers in industry and academia. This talk will review the current understanding of the use of gold nanoparticles as radiosensitizers, and outline a path to potential clinical translation of these concepts of radiation sensitization.

#### **SP-0403 Potentials of Cerenkov imaging in radiotherapy**

**A. Spinelli<sup>1</sup>**

<sup>1</sup>*Fondazione Centro San Raffaele, Medical Physics, Milano, Italy*

In this talk we will provide an overview of Cerenkov radiation (CR) production mechanism, we will then show examples of Cerenkov luminescence imaging (CLI) of small animals and humans. The potential uses of CLI for quality assurance (QA) and real time in vivo dosimetry during external-beam radiation therapy (RT) will be also presented.

The mechanism of CR production is quite unique with respect to other and more common charged particles and matter interaction mechanisms. In this case when a charged particle travels through a dielectric medium, it becomes locally polarized, with the atoms comprising the medium behaving such as elementary dipoles. If the speed of the particle is less than the speed of light in the medium, symmetry of the polarization results in a negligible field at larger distances. However, if the particle's speed exceeds that light in this medium, the polarization field becomes asymmetric along the particle track producing a resultant dipole field at larger distances from the track [1].

For a beta particle travelling in water the energy threshold for Cerenkov emission is equal to 261 keV. This energy threshold is relatively low and thus CLI can be applied to image most of the beta plus and minus emitters commonly

used in nuclear medicine, and as will be described in this talk, also to provide a novel method to monitor external-beam RT.

CLI is becoming a well-established method for preclinical in vivo small animal optical imaging and has been also applied to humans for example to image a patient treated with <sup>131</sup>I [2]. A very recent approach is the use of CLI for the analysis of ex vivo fresh tumor specimens removed during neurosurgery [3].

From the radiotherapy side there has been considerable interest in the possible use of CLI to monitor external-beam radiation therapy. The main dosimetric parameters that could be measured are the percent depth dose (PDD) and the lateral dose profile of the radiation beam. It has been hypothesized that these parameters can be directly measured by imaging the CR induced in a water phantom as a surrogate of the dose.

In the literature it has been shown that due to the anisotropy of the CR emission some differences arise between the CR-derived and the true dose profiles, these differences in the PDD and lateral dose profile can be taken into account by using correction factors derived from Monte Carlo simulations [4].

A more practical approach to reduce the effect of Cerenkov emission anisotropy is adding a CR-excitable fluorophore to the water in the phantom, the addition of a fluorophore allows more accurate estimation of the PPD [5].

The use of CLI for real-time portal imaging during CyberKnife radiation therapy was also investigated by irradiating a water tank phantom. Imaging at 30 frames per second was acquired showing that CLI is a feasible tool to image dynamic and static objects [6].

An interesting development is the use of CR to visualize in real time the dose delivery during radiation therapy [7], more precisely it has been shown that it is possible to visualize the surface dose during the treatment. In conclusion, the use of CLI in the RT field could lead to a novel approaches to perform QA and real time in vivo dosimetry

#### Symposium: Adaptive radiotherapy (both anatomical and 'functional' changes)

##### SP-0404 Development and Clinical Implementation of Image Registration and Dose Accumulation

K. Brock<sup>1</sup>

<sup>1</sup>MD Anderson Cancer Center, Imaging Physics, Houston, USA

Image registration is challenging in simple cases of deformable tissues. In the presence of anatomical and functional changes, these challenges can substantially increase. This presentation will evaluate the translation of standard deformable image registration techniques to challenging cases of anatomical and function response. Limitations of the techniques in the adaptive scenario will be discussed and validation techniques will be described. Although all registration techniques have uncertainties, once understood and quantified, the clinical application of these registration techniques can often improve the treatment in the adaptive radiotherapy treatment paradigm. One of the primary uses of deformable image registration for adaptive radiotherapy is dose accumulation, including the accumulation of dose assessed on each treatment fraction as well as the propagation of the initially planned dose onto the adaptive or replanning image. This process generates a wealth of data that can overwhelm a clinical process. Strategies will be discussed for distilling this data down into meaningful data that can be clinically evaluated. This presentation will also illustrate dose accumulation workflows that are clinically feasible as well as the use of deformable registration for dose propagation between an initial and adaptive planning image.

Objectives for this presentation include:

1. Describing techniques and limitations of image registration in the presence of anatomical and functional changes
2. Addressing the question: how accurate is accurate enough for clinical use
3. Illustrating a workflow for dose accumulation that is clinically feasible
4. Strategies for reporting dose accumulation results

##### SP-0405 Adaptive strategies to account for anatomical changes

J.J. Sonke<sup>1</sup>

<sup>1</sup>Netherlands Cancer Institute, Radiotherapy department, Amsterdam, The Netherlands

Geometric uncertainties limit the precision and accuracy of radiotherapy. In room imaging techniques are now readily available to reimage the patient prior to and during treatment. Typically, these images are used to reposition the patient and thus minimize target misalignment. Anatomical changes, however, frequently occur during treatment but cannot be accurately corrected for using a couch shift. Adaptive radiotherapy, on the other hand, utilizes an imaging based feedback loop to adjust the treatment plan and thus has to potential to account for such anatomical changes. In this presentation, the magnitude and frequency of anatomical changes will be exemplified and various adaptive protocols will be described. Finally, current challenges and future perspective of adaptive strategies to account for anatomical changes will be discussed.

##### SP-0406 Adaptive strategies to account for functional changes

I. Toma-Dasu<sup>1</sup>

<sup>1</sup>Karolinska Institutet, Medical Radiation Physics, Stockholm, Sweden

The progress and technological development of functional and molecular techniques for imaging tumours has offered the possibility of redefining the target in radiation therapy and devising the treatment in an innovative manner accounting for relevant biological information on metabolic, biochemical and physiological factors known to

be related to poor treatment response. Thus, dose painting approaches have been proposed based on the hypothesis that local recurrence is related to resistant foci not eradicated by the currently prescribed doses, which might however be controlled by delivering non-homogeneous dose distributions targeting specific tumour phenotypes related to local control or risk of relapse after (chemo)radiotherapy. Clinical implementation of dose painting, however, is not a trivial task and the success cannot be guaranteed as there are several potential challenges and limitations related to the imaging techniques, the underlying radiobiological aspects and the current techniques for delivering the heterogeneous dose distributions. This talk will present a paradigm shift from focusing on the radiobiological dose prescription, such as in dose painting approaches, to biologically adapted radiation therapy, based on tumour responsiveness assessed with functional imaging. Thus, the general idea is to use functional information from advanced imaging modalities for the assessment of the tumour response early on during the course of the treatment followed by the adaptation of the treatment for the patients for which poor response is predicted. A previous study showing that the early response to treatment of NSCLC patients can be evaluated by stratifying the patients in good and poor responders based on calculations of the effective radiosensitivity derived from two FDG-PET scans taken before the treatment and during the second week of radiotherapy will be presented. Complementing studies on the feasibility of effective radiosensitivity calculations for H&N cancer patients as well as the identification of the optimal window during the treatment for assessing the effective radiosensitivity will also be presented. For the patient classified as poor responders, the distribution of the effective radiosensitivity displayed as a map of response overlapping onto the GTV could be used for guiding adaptive planning approaches. Thus, the method to be presented in this talk would allow the delineation of the sub-volumes expressing lack of response, hence the sub-volumes that should receive a dose boost as adaptive treatment based on functional imaging. Several strategies for treatment adaptation, including photon and proton irradiation, will be considered. This is an extremely novel approach to response assessment and treatment adaptation that opens the way for true treatment individualisation in radiation therapy.

---

**Symposium: Focus on lung cancer: What a radiotherapy department should offer their patients**

---

**SP-0407 PET/CT artefacts for RT planning**

A. Santos<sup>1</sup>

<sup>1</sup>Hospital Cuf Descobertas- S.A., Nuclear Medicine Department, Lisboa, Portugal

Nuclear Medicine, along with PET/CT technology has been playing an important role in the detection, staging and follow-up of lung cancer. The therapeutic approach to lung cancer can vary, depending on the staging of the tumour, being Radiotherapy one of the most important of the available treatments. The association of PET/CT to radiotherapy planning has a synergic effect that will benefit the patient. Nuclear Medicine Technologists (NMT) that perform PET/CT must be aware of the numerous artefacts and pitfalls that can influence the acquired images and the results of the diagnostic procedure. The equipment must have its quality standards assured, radiopharmacy aspects must be covered, the patient should be correctly prepared and also perform all stages of the procedure accordingly. Anyhow, artefacts and pitfalls can randomly occur and this is why it is so important to have theoretical knowledge and practical skills in order to correctly identify the artefacts and correct it

when required. In addition, the active participation of the Radiotherapy technologists (RTT) in the multidisciplinary team surely increases the quality of the results. NMT benefit from the valuable inputs from RTT, since these professionals are specialists in radiotherapy patient positioning, and will be the common factor between PET/CT acquisition and radiotherapy treatment. Also, RTT commonly have a prior relation with the patient and this might play an important role in the patient welfare. The humanization of patient care, along with the state of the art of the technology, are the focus of the multidisciplinary team that surrounds the patient.

**SP-0408 ART in lung cancer: when and for whom?**

P. Berkovic<sup>1</sup>

<sup>1</sup>C.H.U. - Sart Tilman, Radiotherapy department, Liège, Belgium

Lung cancer is the most common cause of cancer death worldwide [1]. Non-small cell lung cancer (NSCLC) accounts for 80 - 85% of all lung cancers of which about 30% are locally advanced (LA) at diagnosis [2]. Although concurrent chemoradiotherapy (cCRT) improves survival compared to sequential one (sCRT) [3], there remains room for improvement in the treatment of LA-NSCLC. Within the radiotherapy component, several possible treatment strategies were investigated, such as altered fractionation and/or dose escalation. However, dose escalation is severely hampered by normal tissue toxicity [4] and can lead to deleterious results when used without taking patient-, tumor- and treatment characteristics into account. This hurdle can be overcome by patient-individualized treatment approaches such as individualized dose-escalation using fixed dose constraints or adapting the treatment-fields to the shrinking tumor. However, adaptive radiotherapy (ART) is time consuming and it is not clear which patient is eligible or what the optimal time point for ART should be. Technical advances, such as intensity-modulated radiotherapy (IMRT) and tumor motion strategies, may further improve the therapeutic ratio. To reach full potential, these strategies imply the use of image-guided radiotherapy (IGRT), e.g. by using a cone-beam computed tomography (CBCT). The latter also allows monitoring tumor volume or -position changes over the treatment course. In this lecture we will address both anatomical- and especially tumor volume changes during chemoradiation and analyse potential predictive factors of volume and dosimetric parameter changes, as well as the potential gain to organs at risk (OARs) while maintaining target volume coverage. Furthermore, the optimal implementation strategy regarding selection of patients (who) and timing of imaging/replanning (when) will be discussed with an overview of the results, from a physician's perspective.

**SP-0409 Improvements in physics, DIBH in lung**

M. Josipovic<sup>1</sup>

<sup>1</sup>The Finsen Center - Rigshospitalet, Copenhagen, Denmark

Radiotherapy in deep inspiration breath hold (DIBH) has been successfully applied in breast cancer patients and recently also for mediastinal lymphoma, exploring the benefit of inflated lungs and changed position of the heart. Patients with lung cancer may benefit dosimetrically of these anatomical changes as well. In addition, DIBH mitigates lung tumour motion. However, DIBH has not yet gained wide implementation in this patient group.

In this talk, some of the most widely applied techniques for DIBH will be presented, together with addressing the DIBH compliance of lung cancer patients. Intra- and interfractional reproducibility of tumour position and the differential motion of the lymph nodes relative to the peripheral tumour has to be evaluated for DIBH radiotherapy as well, since these uncertainties have impact on planning target volume (PTV) margins in photon radiotherapy and robustness of the proton therapy. In radiotherapy of patients with locally advanced lung cancer, the relatively high doses delivered to the healthy tissue, result in treatment related toxicity. DIBH offers a potential to reduce irradiation of the heart structures, the lungs and the oesophagus, potentially improving toxicity risks.

When treating in DIBH, image guidance has to be performed in DIBH as well. The optimal modalities will be discussed, with their impact on treatment uncertainties. Radiotherapy for early stage lung cancer is delivered with stereotactic body radiotherapy (SBRT, or SABR). In this patient group motion mitigation is a bigger challenge than toxicity risks. Very small mobile tumours may not be visualised on cone beam C T (CBCT), used for radiotherapy image guidance and hence SBRT cannot be delivered safely. With improved image quality in DIBH, small tumours can be visualised on daily CBCTs and safe and fast treatment can be delivered within 3-4 DIBHs of 20 seconds duration with flattening filter free beam.

#### Symposium: Education and research grants

---

##### SP-0410 ERC grants - how to succeed

M. Vooijs<sup>1</sup>

<sup>1</sup>MAASTRO GROW School for Oncology, Radiation Oncology, Maastricht, The Netherlands

The mission of the European Research Council (ERC) is to encourage the highest quality research in Europe through competitive funding and to support investigator-driven frontier research across all fields, on the basis of scientific excellence. ERC grants fund basic science and technology of intrinsically risky projects, progressing in new and the most exiting research areas and characterised by the absence of disciplinary boundaries. In this interactive lecture I will discuss my experiences with obtaining ERC grants. If you are attending and interested in writing an ERC grant I encourage you to send me your questions / experiences by email in advance: marc.vooijs@maastrichtuniversity.nl

##### SP-0411 ESTRO educational grants and mobility grants

M.C. Vozenin<sup>1</sup>

<sup>1</sup>Centre Hospitalier Universitaire Vaudois, Department of Radiation Oncology, Lausanne Vaud, Switzerland

ESTRO educational grants and mobility grants will be presented in detail along with specific advices and presentation of the required format that will enable you to submit a successful application.

##### SP-0412 ESTRO educational grant - if you don't try, you won't win

M. Spalek<sup>1</sup>

<sup>1</sup>The Maria Sklodowska-Curie Memorial Cancer Center, Radiotherapy, Warsaw, Poland

Young and confused. A first year radiation oncology resident - a totally new field of knowledge, new people, demanding tasks and high expectations. I was trying to find a good source of knowledge, contacts and possibilities for an ambitious physician. Then I discovered ESTRO and the section of ESTRO School courses. The offer looked excellent, but the fee and costs of travel with accommodation were unbearable without financial support. 'GRANTS & FELLOWSHIP' tab was promising. And finally - educational grant for young radiation oncology professionals. I thought that I will try - why not? I did not expect that I will be chosen (a newbie without a strong scientific background) and... I was wrong. I awarded the grant. Evidence-based Radiation Oncology in Varna, Bulgaria - that was my choice.

During my presentation I will tell a story of my application, try to find possible reasons of the success, tell some practical information about realization, present useful tips and sum up the whole adventure with ESTRO educational grant.

##### SP-0413 ESTRO mobility grant - establishing intravital brain imaging in preclinical models

J. Birch<sup>1</sup>, L. Gilmore<sup>1</sup>, A. Chalmers<sup>1</sup>

<sup>1</sup>Institute of Cancer Sciences, Translational Radiation Biology, Glasgow, United Kingdom

Glioblastoma (GBM) is an aggressive form of primary adult brain tumour that typically has a very poor clinical outcome and a very high rate of disease recurrence. The high recurrence rates are thought to be due in part to the invasive nature of glioblastoma cells, which allows them to infiltrate the healthy brain tissue surrounding the tumour mass and thereby preventing complete surgical resection and limiting the radiation dose that can be safely delivered to the target volume.

Our lab is studying the mechanisms by which glioblastoma (GBM) cells are able to invade normal brain tissue and testing the efficacy of putative anti-invasive agents on these processes. However, modelling GBM invasion using *in vitro* approaches is both challenging and limited: it is impossible to recapitulate the complex 3-dimensional structure of the brain in an *in vitro* setting. In order to address this issue we wanted to use an *in vivo* approach, combined with intravital imaging of the brain, to complement and strengthen *in vitro* observations. This approach involves the establishment of patient-derived xenograft tumours in the brains of immuno-compromised mice via intracranial injection of fluorescently labelled primary human glioblastoma cell lines. An intracranial window is then created which allows real time imaging of glioblastoma tumour cells *in situ* using multiphoton microscopy.

In order to establish this complex technique in our lab, we arranged to visit an expert in this field, Dr. Frank Winkler, whose lab routinely use brain intravital imaging of GBM. The primary objective of the visit was for the acquisition and optimization of the necessary skills to establish high quality intravital imaging of the brain at our own institute. We were also interested in establishing valuable communication links with a laboratory that is active and expert in this field that might have the potential to lead to collaborations in the future.

During our visit we observed in detail the surgical techniques that are required to inject glioblastoma tumour cells into the brain and create the intracranial windows necessary to allow intravital imaging. The setting up of this technique is a challenging and involved procedure and this opportunity to witness it first hand was extremely valuable. We were able to gauge the timescale

required for establishment in our own lab as well as equipment and reagents that we will have to source to make it possible. Our hosts in Heidelberg also generously arranged to send an experienced lab member to Glasgow to help improve our surgical technique.

From this initial visit we established a second collaboration with the lab of Prof. Jim Norman at the Beatson Institute of Cancer Research which was instrumental to allowing introduction of the technique to our home institutes.

The ability to talk to our hosts and ask questions in a face to face setting has proved vital in helping us to get a good grasp of all the techniques required. This also allowed us to explore potential for collaborations in the future and for sharing useful reagents such as tumour cell lines between our groups to facilitate our research.

#### SP-0414 Experience with the ESTRO mobility grant; proton irradiation of a 3D dosimeter

E.M. Høye<sup>1</sup>, P.S. Skyt<sup>1</sup>, P. Balling<sup>2</sup>, J. Swakon<sup>3</sup>, J.B.B. Petersen<sup>1</sup>, M. Rydygier<sup>2</sup>, G. Mierzwińska<sup>3</sup>, L.P. Muren<sup>1</sup>

<sup>1</sup>Aarhus University Hospital, Department of Medical Physics, Aarhus, Denmark

<sup>2</sup>Aarhus University, Department of Physics and Astronomy, Aarhus, Denmark

<sup>3</sup>Polish Academy of Sciences, Institute of Nuclear Physics, Krakow, Poland

In my visit to the Cyclotron Center Bronowice in Kraków I investigated the performance of a new 3D dosimeter for proton therapy. The aim of the visit was to study the known quenching effects in the Bragg peak of proton beams in our dosimeter. Denmark is currently building its first proton therapy center, and so a collaboration agreement was made with the Polish center in order to perform irradiations of the dosimeter. Dosimeter samples were prepared with different chemical compositions, and brought to Kraków. A 1D optical laser scanner was sent to Kraków, in order to allow read out of the proton depth dose curve in the dosimeters few hours after irradiation. Based on preliminary results from our measurements, decisions were made as to which chemical compositions to investigate further. New dosimeters were produced for us in Aarhus, and sent to Kraków to be irradiated in the second week.

The experience was logistically challenging, and many people were contributing to the success of the project. The study gave us detailed information as to how the dosimeter can be further optimised for proton therapy. In my presentation I will expand on the challenges we met and on how they were dealt with. I am grateful to ESTRO for allowing me this opportunity, together with all the people in Aarhus and Kraków who helped with the experiments.

#### Poster Viewing : Session 9: Dosimetry

#### PV-0415 Verification of pre-treatment DVH measurements for individual plan QA

J. Stroom<sup>1</sup>, J. Boita<sup>1</sup>, M. Rodrigues<sup>2</sup>, C. Greco<sup>1</sup>

<sup>1</sup>Fundação Champalimaud, Radiotherapy, Lisboa, Portugal

<sup>2</sup>Mercurius Health, Radiotherapy, Lisbon, Portugal

#### Purpose or Objective

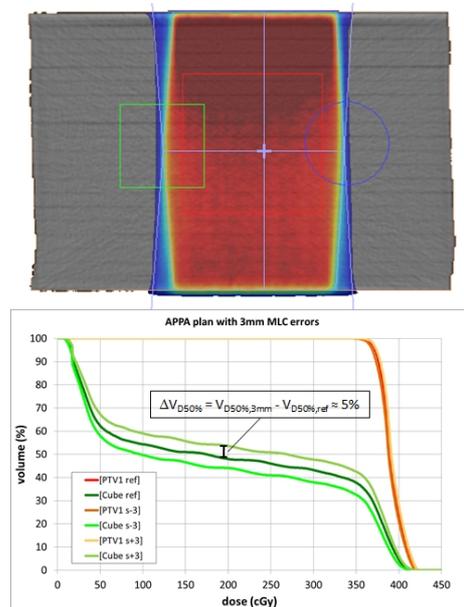

Radiotherapy plan QA by measurements is almost mandatory for IMRT and VMAT. Generally, comparison of planned and measured dose is performed using the clinically not so relevant gamma analysis. Recently software has become available to estimate DVHs based on QA measurements. We have validated two such systems.

#### Material and Methods

Our new system, *3DVH* (v3.3, SunNuclear), converts dose deviations measured with the cylindrical *ArcCheck*

phantom to expected dose deviations in the patient, hence enabling calculation of DVHs for targets and OARs. Our existing system, *PDAPP* (NKI-AVL, Amsterdam), uses back-projection of measured EPID dose images to produce 3D doses in patients or phantoms. These doses and dicom structure files are subsequently read by in-house software (*pDVH*) to calculate DVHs. We performed the following tests:

1. *3DVH*: With the new system, we first measured 30 different clinical plans (VMAT/IMRT) with various energies (6MV - 10FFF) on different linacs (Varian/Elekta) and evaluated the measured 3D dose distributions using 3D gamma (3%,3mm). We then compared with the clinical 2D *ArcCheck* analyses of the same measurements.
2. *3DVH*: We subsequently introduced MU errors or systematic MLC errors (all leaves opened or closed) in a subgroup of 6 Elekta plans before measurement and studied the behaviour of *3DVH*.
3. *3DVH+pDVH*: To compare *3DVH* with *pDVH*, we made 3 conformal plans (AP, AP-PA, 4-field box) and one 4-field IMRT plan on a slab-phantom with PTV and cubic and cylindrical OARs (Fig). The plans with and without errors were measured with the slab-phantom for *PDAPP*, and with *ArcCheck* for *3DVH*. Mean PTV and OAR doses were compared.
4. *3DVH+pDVH*: For the phantom IMRT plan, we predict the effect of an X mm MLC error on the mean PTV dose to be  $X/\langle\text{DMCL}\rangle$ , with  $\langle\text{DMCL}\rangle$  the average leaf pair distance in the plan. For the cube DVHs of the conformal plans leaf motions should shift the penumbra of the AP/PA beams into or out of the 60mm cube and the resulting DVH up and down by  $X/60$ , so  $X=3\text{mm}$  would yield  $\Delta V_{D50\%} \approx 5\%$  (Fig).

Top: the MONACO AP-PA plan on the 20x30x30cm<sup>3</sup> slab phantom. Indicated are the PTV in red, the cube in green, and the cylinder in blue. Below: the corresponding DVHs as measured with *PDAPP+pDVH* for the reference plan (no errors) and the +/- 3mm MLC error plans. Indicated is how the change in  $V_{D50\%}$  is measured from the data.

#### Results

1. Average 3D gamma passing rates of the 30 clinical cases were  $97.7 \pm 3.5\%$  (1SD), comparable to the 2D rates of  $97.0 \pm 2.1\%$ . There was no correlation between 2D and 3D results.

- For the patient error tests, PTV DVHs with MU errors correspond well to expectations. For OARs and MLC errors, trends are as expected but quantitative validation is more difficult (Table).
- Slab phantom results show that generally both systems accurately measure MU errors. Differences between 3DVH and *pDVH* are larger for MLC errors, especially for the conformal plans and OARs (Table).
- Comparing with the predictions, it appears that 3DVH tends to underestimate the effect of MLC errors, whereas *pDVH* performs more accurately (Table).

4	4.1	3.5	4.0	3.9	3.9	3.7	4.1	3.8	4.0			
6			6.0	6.0	6.0	5.8	6.4					

Differences (%) between measured mean ROI doses with and without errors. Last columns show differences for  $V_{\text{D50\%}}$ . Values between brackets indicate the number of plans over which the average is taken. If comparison with a prediction is possible, colors indicate the differences (green < 0.5%, yellow > 0.5%, orange > 1%, red > 2%).

### Conclusion

We developed a procedure to verify DVH measurements for individual patient QA. 3DVH has similar gamma results as 2D ArcCheck for clinical cases. Phantom studies however indicate that 3DVH can underestimate the dosimetric effect of MLC errors, where EPID based *pDVH* performs better.

### PV-0416 Novel methods for normal tissue dose in epidemiological studies of second cancer in radiotherapy

C. Lee<sup>1</sup>, J.W. Jung<sup>2</sup>, C. Lee<sup>3</sup>, M.M. Mille<sup>1</sup>, E. Mosher<sup>1</sup>, C. Pelletier<sup>2</sup>, G. Kuzmin<sup>1</sup>

<sup>1</sup>National Cancer Institute, Division of Cancer Epidemiology and Genetics, Bethesda, USA

<sup>2</sup>East Carolina University, Department of Physics, Greenville, USA

<sup>3</sup>University of Michigan, Department of Radiation Oncology, Ann Arbor, USA

### Purpose or Objective

Dose estimation of normal tissues located outside treatment beam fields is one of the crucial components in retrospective epidemiological studies of late effects in radiotherapy patients but there are three challenges. First, dosimetry methods for out-of-field normal tissues are not well established compared to in-field. Second, radiological images of patient anatomy are not commonly available. Third, even if patient images are available, contouring several normal organs of interest would take substantial effort for large-scale patient cohorts. We have developed computational solutions: to calculate normal tissue doses for out-of-field region, which was validated

by experiment; to construct a realistic surrogate anatomy by using computational human phantoms; and to automatically contour major organs of interest on patient images.

### Material and Methods

We employed XVMC computer code for Monte Carlo radiation transport with enhanced computation speed. We adjusted the virtual source models built in XVMC to match out-of-field dose profile measured in a water phantom. For the cases where patient images are not available, we converted a library of existing computational human phantoms with the range of age and body size in voxel format into Digital Imaging and Communications in Medicine (DICOM)-images by translating material composition and density to Hounsfield Unit. We then converted the organ structures in the voxel phantoms into DICOM-structures and tested the resulting DICOM phantoms with multiple treatment planning systems. Finally, for the cases where patient images may be available for a large number of patients, we developed methods to automatically contour the heart and its substructures, as a start, by using an atlas library derived from 60 adult male and female patients.

### Results

First, the lateral dose profiles computed from XVMC and the water phantom matched well within 15% (<10 cm from field edge) and 40% (> 10 cm and <30 cm from the field edge)(Figure 1). Second, a set of DICOM-images and structures was generated from the pediatric and adult reference and non-reference phantom series (Figure 2). We validated the DICOM phantoms by comparing density and volume of selected organs between the original phantom and Eclipse showing a good agreement less than 5% and 0.1% for density and volume, respectively. Finally, we confirmed that the auto-contoured heart and manually-contoured heart for 30 adult male patients show the Dice coefficients up to 91% for the total heart and up to 84% for the left ventricle.

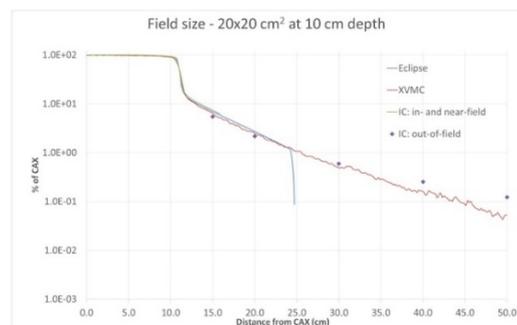

Figure 1. Comparison of lateral dose profile for 20x20 cm<sup>2</sup> beam at the depth of 10 cm within a water phantom among XVMC simulation, ion chamber measurements under Varian Clinac EX, and Eclipse treatment planning system.

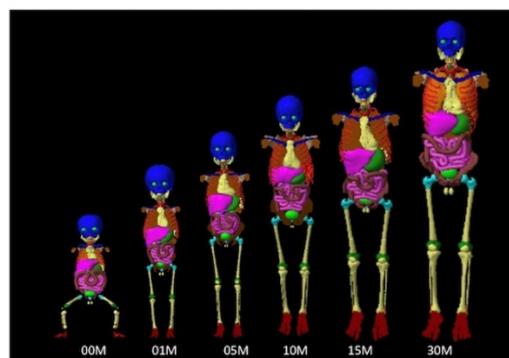

Figure 2. 3D rendering of the DICOM-structures for the reference phantom series from the newborn, 1-, 5-, 10-, 15-year-old and adult male computational phantoms (rendered in Eclipse treatment planning system).

### Conclusion

The computational methods established in this study will be useful for the reconstruction of normal tissue dose to

support epidemiological studies of second cancer in cancer survivors treated by radiotherapy, where radiological images of patients may or may not be available.

#### PV-0417 Validation of an analytical peripheral photon dose model for FFF modality

M.T. Garcia-Hernandez<sup>1</sup>, B. Sanchez-Nieto<sup>2</sup>, J. Roselló Ferrando<sup>1</sup>, L. Irazola<sup>3</sup>, J.A. Terrón<sup>3</sup>, F. Sanchez-Doblado<sup>3,4</sup>  
<sup>1</sup>Hospital General Universitario de Valencia. ERESA, Servicio de Radiofísica., Valencia, Spain  
<sup>2</sup>Instituto Fisica Pontificia Universidad Católica de Chile, Departamento Fisica Médica, Santiago de Chile, Chile  
<sup>3</sup>Universidad de Sevilla, Departamento de Fisiología Médica y Biofísica, Sevilla, Spain  
<sup>4</sup>Hospital Universitario Virgen Macarena, Servicio de Radiofísica, Sevilla, Spain

#### Purpose or Objective

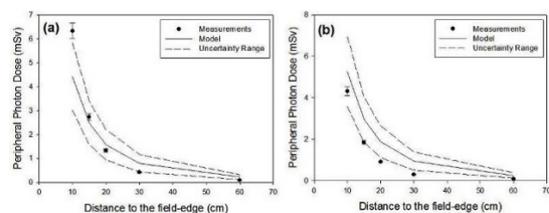

The study of Secondary Malignant Neoplasms, as a consequence of the peripheral doses received by photon radiotherapy patients, is becoming a topic of growing interest due to the higher healing rates and life expectancy accomplished nowadays. Two models have been developed to estimate peripheral doses due to photon and neutron dose deposition (1,2). The aim of this work is the validation of a generic peripheral photon dose model (1) for the flattening filter free (FFF) modality, which was not originally considered.

#### Material and Methods

Measurements were carried out in a Varian Truebeam linac for FF and FFF beams (with 6 and 10 MV) for two different field sizes (3x3 and 10x10 cm<sup>2</sup>) with both, single (gantry 0°) and multiple incidences (0°, 45°, 90°, 135°, 180°, 225°, 270°, 315°). A CC13 (Iba Dosimetry) ionization chamber was placed at a range of out-of-field distances (10 to 60 cm from the field-edge) in a water-equivalent phantom and irradiated with 1000 MU. The obtained results for FF and FFF were compared to estimations with the original model (1).

#### Results

Experimental measurements, together with model predictions for all combinations described were collected. By way of example, results the 10x10 cm<sup>2</sup> field using 6 and 10 MV FFF multiple incidences have been depicted in Fig 1a and 1b, respectively. The uncertainty range (UR) of the model (95% confidence interval) (1) as well as the 5% uncertainty estimated for the experimental measurements, are shown.

#### Conclusion

The original photon model tends to overestimate peripheral doses, especially for the high energy. This is due to the fact that FFF beams, in comparison with FF beams, are associated to lesser scatter in the linac head. This effect is enhanced at higher energies. Thus, despite that the original model could be used for peripheral photon dose assessment in FFF modality (experimental data are almost included within the UR of the model), further investigation should be conducted to better model the effect of the absence of the flattening filter.

#### PV-0418 Characterisation of the prototype plastic scintillation detector (PSD) in a strong magnetic field

M. Asghar<sup>1,2,3</sup>, W. Zhifei<sup>1</sup>, Y. Suh<sup>1</sup>, D. O'Brien<sup>1</sup>, S. Beddar<sup>1</sup>, S.A. Buzdar<sup>3</sup>, G.S. Ibbott<sup>1</sup>

<sup>1</sup>The University of Texas MD Anderson Cancer Center, Department of Radiation Physics, Houston, USA  
<sup>2</sup>Bahawalpur Institute of Nuclear Medicine and Oncology BINO, Department of Medical Physics, BAHAWALPUR, Pakistan  
<sup>3</sup>The Islamia University of Bahawalpur, Medical Physics Research Group- Department of Physics, BAHAWALPUR, Pakistan

#### Purpose or Objective

Novel treatment units are becoming available that combine a magnetic resonance (MR) imager with a megavoltage radiation beam. The magnetic field of the MR imaging affects the trajectories of secondary electrons and influences the performance of several types of radiation detectors, including ion chambers and diodes. A dosimeter that is not influenced by the magnetic field would be valuable for commissioning and quality assurance (QA) of an MR-guided treatment unit. The purpose of this work was to characterise the performance of a PSD in the magnetic field of an MR-LINAC system.

#### Material and Methods

The MR-LINAC system consists of a 1.5 T Achieva MRI system (Philips, Netherlands) and a 7 MV linear accelerator (Elekta, UK). The feasibility of using the prototype PSD (Standard Imaging, USA) in MR-LINAC radiation therapy system was evaluated by investigating possible effects of the strong magnetic field on the performance characteristics of the PSD. The effects of orientation, axial rotation symmetry, and optical connectivity of the PSD and that of the photo-diode position were measured in the presence and absence of the magnetic field.

#### Results

The mean percent differences in the PSD signals for different orientation of the PSD and for various axial rotations of the PSD in the transverse magnetic field between magnet ramped up and down were 1.33% ( $\pm 0.92\%$ ) and 1.37% ( $\pm 1.01\%$ ), respectively. The effects of optical connectivity and photo-diode position were insignificant on the signal.

#### Conclusion

We conclude that the PSD can be used for dosimetry of the MR-LINAC radiation therapy system as the effect of a strong magnet field was insignificant on the characteristics of the PSD investigated. It would be a good detector for commissioning and QA of an MR-guided system.

#### PV-0419 The impact that geometric variability in ionization chamber construction has on k<sub>Q0</sub>

J. Puxeu Vagué<sup>1,2,3</sup>, M. Duch Guillen<sup>4</sup>, M.C. Lizuain Arroyo<sup>3</sup>, W.H. Nailon<sup>2</sup>

<sup>1</sup>Hospital Universitari Sant Joan de Reus, Servei de Protecció Radiològica i Física Mèdica, Reus, Spain  
<sup>2</sup>Edinburgh Cancer Centre, Department of Oncology Physics, Edinburgh, United Kingdom  
<sup>3</sup>Institut Català D'Oncologia, Servei de Física Mèdica i Protecció Radiològica, L'hospitalet de Llobregat, Spain  
<sup>4</sup>Universitat Politècnica de Catalunya, Institut de Tècniques Energètiques, Barcelona, Spain

#### Purpose or Objective

To investigate the influence that geometric uncertainties in the manufacturing process of three different ionization chambers has on the beam quality correction factor  $k_{Q0}$ . Ionization chambers (IC) have been used as reference detectors in clinical practice for decades. In 2000 a new

code of practice (TRS-398) was introduced based on the calibration of the ionization chambers in terms of absorbed dose to water instead of the previous code based on air kerma determination (TRS-277).

Not all standard laboratories have beams with the same user beam qualities. One common approach is for the Standard Dosimetry Laboratory (SDL) to perform a calibration of the user's ionization chamber in the beam quality of the Co-60 source. They may also provide calibration factors for the chamber at other beam qualities whereby correction factors for a particular beam quality are determined by interpolation. When no experimental  $k_{Q_0}$  values are provided, the user can calculate them by using a set of expressions derived from Bragg-Gray theory or obtain  $k_{Q_0}$  values by Monte Carlo (MC) simulation. Analytical and MC  $k_{Q_0}$  values are derived from the nominal geometry of each chamber model since there is no way of knowing the exact dimensions of each user chamber. In contrast, calibration in terms of absorbed dose to water in a SDL, at different beam qualities, is the only method where the response of each individual IC is taken into account.

#### Material and Methods

Three waterproof IC models were selected, PTW-30013 (0.6 cm<sup>3</sup>), PTW-31010 (0.125 cm<sup>3</sup>) and PTW-31016 (0.016 cm<sup>3</sup>). A fourth non-waterproof IC from Nuclear Enterprise (NE2571) was used to validate the MC process and the different Particle Space Files (PSF) used in the MC simulations. Three different geometries were defined for each of the PTW IC using information about the geometric tolerances provided by the manufacturer, which were labelled nominal, maximum and minimum. The maximum geometry was defined as the maximum cavity walls and the minimum dimensions for the central electrode together with the minimum geometry with the minimum cavity walls and the maximum central electrode.  $k_{Q_0}$  values were determined, for the ten geometries defined, at three energies (TPR<sub>20,10</sub>) 6 MV (0.674), 15 MV (0.757) and 18 MV (0.778) using MC simulation performed with the PENELOPE code system, using PenEasy as the main program.

#### Results

Differences in the active collecting volume for the three PTW ionization chambers affects the  $N_{D,w,Q_0}$  coefficients to the same proportion, and their influence on the  $k_{Q_0}$  is less than 0.5% ±0.2% (sigma=1) (Table 1) Table 1.  $k_{Q_0}$  factors determined by simulation for the different geometries defined on each ionization chamber at the different energies. Uncertainties on all values are smaller than 0.2% (sigma =1).

Model	Geometry	Nominal energy and TPR <sub>20,10</sub>		
		6 MV	15 MV	18 MV
PTW_30013	Nominal	0.674	0.757	0.778
	maximum	0.991	0.981	0.973
	minimum	0.990	0.977	0.970
PTW_31010	Nominal	0.992	0.978	0.972
	maximum	0.990	0.970	0.970
	minimum	0.987	0.967	0.970
PTW_31016	Nominal	0.989	0.971	0.972
	maximum	0.987	0.970	0.963
	minimum	0.985	0.969	0.961
NE-2571	Nominal	0.983	0.966	0.959
	Nominal	0.993	0.977	0.974

#### Conclusion

The results provide an estimate of the influence that geometrical uncertainties in the manufacturing process have on  $k_{Q_0}$ , identifying the differences on wall thickness as the main source of influence.

#### PV-0420 Learn before you measure: Method of single-isolated errors analysis for ArcCheck.

<sup>2</sup>University of Warsaw, Faculty of Physics, Department of Biomedical Physics

<sup>3</sup>Warsaw University of Technology, Faculty of Physics, Warsaw, Poland

#### Purpose or Objective

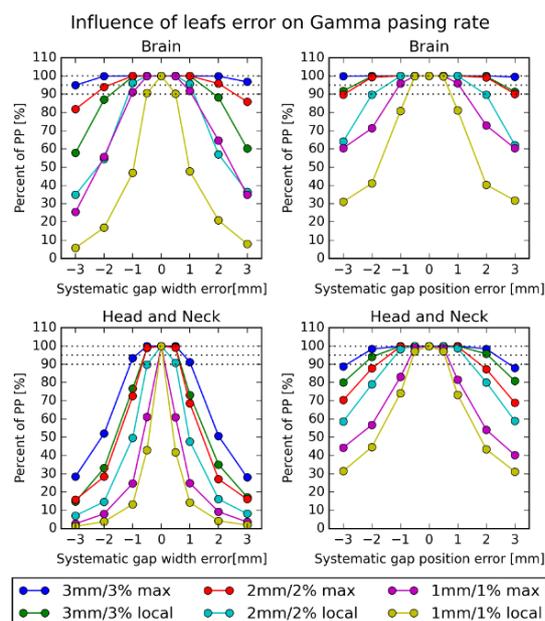

IMRT and VMAT are nowadays techniques used in therapy for many cancer sites. The independent, pre-treatment verification in this type of irradiation is recommended and in some countries - even required. There are different ways of pre-treatment verification and there are many phantoms and softwares design for this. One of them are ArcCheck and SNCPatient (designed by SunNuclear). During gamma evaluation [Depuydt, 2002] it is hard to detect different sources of errors (both phantom and machine). That is the reason to test a method of analysing isolated errors and their influence on gamma results. The method described below can show the dominant sources of errors helping physicists in interpreting gamma evaluation results.

#### Material and Methods

We divided sources of errors into two groups: phantom based (e.g. dose rate (DR) dependence, inclinometer tolerance) and machine based (e.g. gantry angle and leaf positions errors). For all types of errors we prepared an ideal dose distribution (calculated in Eclipse TPS and imported into SNCPatient Software) and a measurement file with an error (MWE). The diodes readouts were calculated from TPS dose distribution. Errors were introduced or into TPS itself (inclinometer tolerance, leaf and gantry positions error) or outside the TPS in Python script (DR dependence of each diode). The resolution of readouts in the MWE were identical to those of real measurement.

#### Results

The influence of ArcCheck DR dependence on VMAT plans results is shown in Table. In about 14% of patients with the mean DR below 100MU/min gamma did not reach 95% passing rate. It means that in case of low DR reason of plan failure can be caused by ArcCheck DR dependence not by wrong realisation. The examples of leaf influence errors are shown in Figure. It can be seen that gap width error is more important for highly modulated plans (H&N versus brain plans). Even some 1mm errors can be detected with global gamma 3mm/3% method which is a good result. In the same time it would be more complicated to detect 2mm systematic shift in leaves which can be connected with phantom position error or misalignment of radiation field defined by MLC. Inclinometer tolerance is the same as gantry positioning tolerance. ArcCheck rotation error and gantry position error can sum up. Rotation error of 0.5deg cannot be seen in gamma 2mm/2%. In the same case dose difference of more than 3% can be seen in high gradient region resulting in lower DTA passing rate. Rotation error does not seem to be symmetrical which can be connected with diodes placement. Tilt error of 0.5deg cannot be seen in gamma 2mm/2% and is symmetrical.

Mean Dose Rate	Gamma GLOBAL		
	3mm / 3%	2mm / 2%	1mm / 1%
[0:100]	100,0 ± 0,0	98,9 ± 2,9	84 ± 25
(100:200]	100,0 ± 0,0	100,0 ± 0,0	91 ± 10
(200:300]	100,0 ± 0,0	99,95 ± 0,27	87 ± 11
(300:600]	100,0 ± 0,0	100,0 ± 0,0	95,5 ± 8,1
[600]	100,0 ± 0,0	100,0 ± 0,0	100,0 ± 0,0
Gamma LOCAL			
	3mm / 3%	3mm / 3%	3mm / 3%
[0:100]	99,986 ± 0,038	99,986 ± 0,038	99,986 ± 0,038
(100:200]	100,0 ± 0,0	100,0 ± 0,0	100,0 ± 0,0
(200:300]	100,0 ± 0,0	100,0 ± 0,0	100,0 ± 0,0
(300:600]	100,0 ± 0,0	100,0 ± 0,0	100,0 ± 0,0
[600]	100,0 ± 0,0	100,0 ± 0,0	100,0 ± 0,0

### Conclusion

The proposed method of analysis of isolated errors gives the magnitude of errors. In general, the most important are leaf gap width errors. Exception and further analysis is required for VMAT patients with low DR. ArcCheck positioning errors should not affect the gamma results while being in specification tolerance.

### PV-0421 In-magnet measurement setup for proof-of-concept and commissioning of MR integrated proton therapy

A. Lühr<sup>1,2,3</sup>, S. Gantz<sup>1,3</sup>, S. Schellhammer<sup>1,3</sup>, O. Zarini<sup>4</sup>, K. Zeil<sup>4</sup>, U. Schramm<sup>4</sup>, A. Hoffmann<sup>1,3,5</sup>

<sup>2</sup>German Cancer Consortium DKTK, Partner Site Dresden, Dresden, Germany

<sup>3</sup>OncoRay - National Center for Radiation Research in Oncology, Medical Radiation Physics, Dresden, Germany

<sup>4</sup>Helmholtz-Zentrum Dresden - Rossendorf, Institute of Radiation Physics, Dresden, Germany

<sup>5</sup>Faculty of Medicine and University Hospital Carl Gustav Carus at the Technische Universität Dresden, Department of Radiation Oncology, Dresden, Germany

### Purpose or Objective

There is growing interest to explore the concept of magnetic resonance integrated proton therapy (MRiPT). However, no experimental proof-of-principle has been established so far. The aim of this work was to develop an in-magnet measurement setup that facilitates to investigate the dosimetric feasibility of MRiPT and to develop a commissioning procedure for future MRiPT devices.

### Material and Methods

A C-shaped 0.95 T permanent neodymium (NdFeB) dipole magnet was used. The magnetic main and fringe fields were characterized using 3D automated Hall probe measurements. A method and procedure were established to perform periodic quality assurance (QA) measurements of the magnetic field's constancy. A 3D vector field representation for the magnetic flux density distribution was calculated by finite-element modeling (FEM) using COMSOL-Multiphysics®. For irradiation experiments, proton beams of 80-225 MeV were collimated using brass apertures having circular voids of either 5 or 10 mm diameter. The beams entered a PMMA slab phantom being placed inside the magnet's horizontal air gap, perpendicularly to the main field component. Proton beam trajectories and depth-dose curves in the presence of the magnetic field were measured with Gafchromic EBT3 film, being placed between the two slabs of the phantom. Reference trajectories were measured without magnetic field. In transmission experiments without phantom, beam deflections were measured with a 2D scintillation detector (Lynx, IBA Dosimetry) positioned perpendicular to the beam at 24 cm distally from the magnet.

### Results

Magnetometry results (Fig. 1) validated the 3D magnetic flux density distribution as calculated by FEM. The simulation tended to underestimate the measured magnetic field strength in the plateau area by about 2% (mean difference 20 mT). In repeated QA measurements, field strength changes remained below a threshold of 3 mT. For all proton energies, the lateral beam deflection due to the magnetic field increased with depth in the phantom. Lateral displacement of the Bragg peak position increased with initial energy, from 1.1 (±0.4) mm to 10.7 (±0.8) mm, for 80 and 180 MeV (Fig. 2), respectively. In transmission measurements, only lateral deflections were measurable, ranging from 56 (±0.5) to 30 (±0.5) mm for beam energies between 80 and 225 MeV, which was in excellent agreement with theoretical predictions.

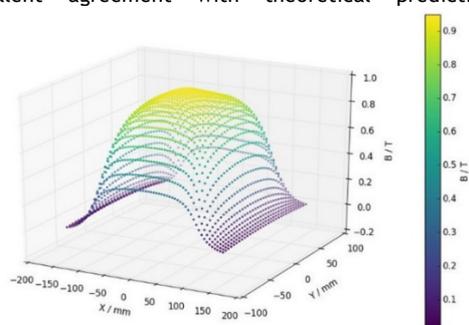

Figure 1: Measured data set of the main B-field component along the central plane of the magnet.

Figure 2: EBT3 film scan of a 180 MeV proton pencil beam trajectory in a PMMA phantom deflected by the transverse magnetic field.

### Conclusion

An in-magnet measurement setup for first MRiPT proof-of-principle experiments has been realized. Measurements of the magnetic field and proton beam trajectory in tissue-equivalent material proved to be feasible and facilitate the development of commissioning and QA procedures for MRiPT. Ongoing experiments focus on the impact of realistic treatment fields as well as the effect of inhomogeneous media on the dose distribution. The data

obtained are instrumental for building and validating beam models for MRIPT, as reported in a separate abstract.

#### PV-0422 Direct determination of $k_Q$ in a clinical carbon ion beam using water calorimetry

J.M. Osinga-Blättermann<sup>1,2</sup>, U. Ankerhold<sup>1</sup>, S. Brons<sup>3</sup>, S. Greilich<sup>2</sup>, O. Jäkel<sup>2,3</sup>, A. Krauss<sup>1</sup>

<sup>1</sup>Phys. Techn. Bundesanstalt PTB, Department of Dosimetry for Radiation Therapy and Diagnostic Radiology, Braunschweig, Germany

<sup>2</sup>German Cancer Research Center DKFZ, Division of Medical Physics in Radiation Oncology, Heidelberg, Germany

<sup>3</sup>Heidelberg Ion-Beam Therapy Center, HIT, Heidelberg, Germany

#### Purpose or Objective

Until now, the dosimetry of carbon ions with ionization chambers has not reached the same level of accuracy as that of high-energy photons: the associated standard uncertainties differ by about a factor of three [TRS-398, IAEA, 2000]. This is mainly caused by the limited knowledge of the so-called  $k_Q$  factor, which corrects for the different response of the ionization chamber to the actual user beam quality  $Q$  (here:  $^{12}\text{C}$ ) compared to the reference beam quality  $Q_0$  (here:  $^{60}\text{Co}$ ). The aim of this work is to experimentally determine the  $k_Q$  factor in order to exploit the possibility of significantly improving the accuracy of ionization chamber-based dosimetry of clinical carbon ion beams.

#### Material and Methods

Water calorimetry by means of the transportable water calorimeter of the National Metrology Institute of Germany (PTB - Physikalisch-Technische Bundesanstalt) is implemented in the entrance channel of a scanned 6 cm x 6 cm radiation field of 429 MeV/u carbon ions at the Heidelberg Ion-Beam Therapy Center (HIT). This enables the direct calibration of ionization chambers and thus the experimental determination of  $k_Q$ . In order to achieve an overall low measurement uncertainty, the irradiation parameters and the resulting radiation field have been characterized in detail as they strongly influence several calorimetric and ionometric correction factors. In total, three separate series of measurements were performed to determine the values for  $k_Q$  for the two Farmer-type ionization chambers FC65-G (IBA) and TM30013 (PTW).

#### Results

By means of water calorimetry, a standard measurement uncertainty of 0.8% could be achieved for the experimental  $k_Q$  values corresponding to about a threefold reduction of the uncertainty compared to calculated values. For both ionization chambers, a comparison of the experimental  $k_Q$  factors with corresponding literature values (TRS-398, German DIN 6801-1) will be presented and discussed.

#### Conclusion

This study showed for the first time that the experimental determination of the  $k_Q$  factor for carbon ion beams by means of water calorimetry is achievable with unprecedented accuracy. This result enables the significant reduction of the overall uncertainty related to ionization-based dosimetry of clinical carbon ion beams.

#### PV-0423 AAPM TG-158 recommendations for neutron dosimetry for photon, electron, and light-ion therapy.

R. Howell<sup>1</sup>, B. Bednarez<sup>2</sup>, S. Kry<sup>1</sup>

<sup>1</sup>UT MD Anderson Cancer Center Radiation Physics, Radiation Physics, Houston- TX, USA

<sup>2</sup>University of Wisconsin, Medical Physics, Madison, USA

#### Purpose or Objective

The American Association of Physicists in Medicine Task Group (TG) 158, measurement and calculation of doses

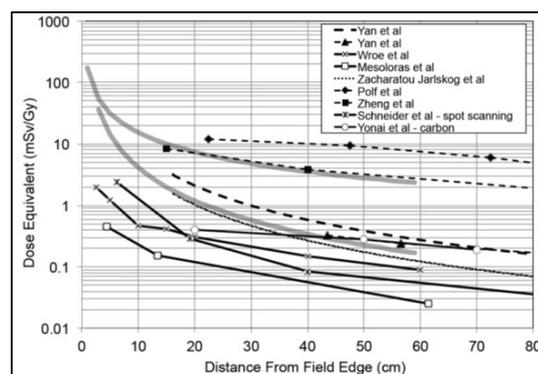

outside the treatment volume from external-beam radiation therapy (EBRT), was created to provide guidance for physicists in assessing and managing non-target doses. Neutron detection in particular, presents many unique challenges and is infrequently performed by medical physicists. Neutron data in the literature span many orders of magnitude and are difficult to interpret and compare. The primary objectives of this presentation are convey the neutron relevant information from TG-158 for photon, electron, and light-ion EBRT: (1) to provide an overview of neutron data reported in the literature (2) to summarize various detectors that can be used to measure secondary neutrons and specifically address limitations in different measurement environments and (3) summarize recommendations from AAPM TG-158 for neutron dosimetry for clinical care and research applications.

#### Material and Methods

The TG-158 was completed in 2016 and is expected to be published in 2017. The committee reviewed approximately 320 publications in the literature, a large fraction of which focused on secondary neutrons and neutron measurement techniques for photon, electron, and light-ion EBRT.

#### Results

This presentation will provide an overview of neutron data reported in the literature, which span many orders of magnitude. Figure 1 is an example of neutron data from proton and carbon therapy. Similar examples will be discussed for photon and electron beam EBRT. This presentation will also summarize various detectors that can be used to measure secondary neutrons. Neutron detectors are highly energy dependent and thus, knowledge of the energy spectrum being measured is essential. The secondary neutrons from electron, photon, and light-ion therapy have a wide energy range, i.e., from thermal up to about 10 MeV for photon/electron therapy and thermal up to 250 MeV for light ion therapy. Moreover, many neutron detectors cannot be used in or near the primary field because of issues such as pulse-pile-up and interactions of particles within the detector, among others. Thus, each neutron detector will be presented in the context of its energy sensitivity and its suitability for measurements in-or near the primary field. Finally, this presentation will summarize the recommendations of TG-158 for neutron dosimetry for clinical care and research applications.

**Figure 1:** Summary of published data from several studies of neutron dose equivalent from proton and carbon therapy. The upper and lower bounds of neutron dose equivalent from photon IMRT data are also included for reference (solid grey lines).

#### Conclusion

This presentation will highlight the unique challenges of measuring neutrons and will provide guidance on how to select the most appropriate for these measurements for photon, electron, and light-ion therapy.

<sup>10</sup>Klinikum Passau, Radiation Oncology, Passau, Germany

<sup>11</sup>Strahlentherapie Bautzen, Radiation Oncology, Bautzen, Germany

**Purpose or Objective**

SBRT is not mapped on the treatment algorithms for primary liver tumors. We evaluated safety and efficacy of SBRT for primary liver cancer in a patterns-of-care and patterns-of-outcome analysis.

**Material and Methods**

The working group "Stereotactic Radiotherapy" of the German Society for Radiation Oncology performed a retrospective multicenter analysis of SBRT for hepatocellular and cholangiocellular carcinoma (HCC and CCC). Eleven centers with experience in pulmonary SBRT participated. SBRT for this indication was introduced in 1999 and data were entered into a centralized database. The analysis comprised 206 lesions in 174 patients after retrieval of patient, tumor and treatment data from the aforementioned multi-center database. HCC and CCC were analyzed separately and pooled. Available factors were analysed for local control (LC), overall survival (OS) and toxicity.

**Results**

The range of lesions per center was 1-100 with a median of 13 patients per center. In 174 patients 206 lesions were treated, 134 (65%) HCC and 72 CCC lesions. Karnofsky Performance Status was 80-100 in 88% and 60-70 in 12%. Child-Turcotte-Pugh stage in HCC was A, B and C in 62%, 29% and 6%. Largest tumor diameter was median 5 cm (SD 3.9) with 144 patients having a single target lesion, 26 with 2, 3 with 3 and 1 with 4 lesions. PTV volume was median 127 cc (5 - 3553). Median BED<sub>10</sub> prescribed to the PTV margin was 72 Gy (range 36 - 180 Gy): SBRT was delivered in a median of 5 fractions (3-17) to a median PTV prescription dose of 45 Gy (30 - 68 Gy). Median follow-up of patients alive was 12 months. Local control was 89%, 87% and 83% at 12, 18 and 24 months with no significant difference between HCC and CCC. Two-year LC was 81% vs. 91% (p = .075) for doses < 72Gy BED vs ≥ 72 Gy BED, respectively. Median OS was 16.7 months, 17.5 months and 14.6 months for HCC vs CCC (p=n.s.). Gastroduodenitis was grade 2 or 3 in 2% and 1%, respectively. Data on other toxicity was only available in 41% and was ≥ grade 2 in 4%: this was esophageal variceal bleeding grade 2 in 3 patients and deteriorated liver function in 3 patients.

**Conclusion**

This is to our knowledge the largest series on SBRT in primary liver cancer reported. Local control is good in this cohort for both HCC and CCC with a moderate median BED, and median overall survival is well in the range of other series of SBRT in these entities. Prospective trials should be conducted to further validate the role of SBRT in primary liver tumors.

**OC-0425 Clinical experience with stereotactic MR-guided adaptive radiation therapy for pancreatic tumors**

A. Bruynzeel<sup>1</sup>, F. Lagerwaard<sup>1</sup>, O. Bohoudi<sup>1</sup>, S. Tetar<sup>1</sup>, N. Haasbeek<sup>1</sup>, S.S. Oei<sup>1</sup>, B. Slotman<sup>1</sup>, M. Meijerink<sup>2</sup>, S. Senan<sup>1</sup>, M. Palacios<sup>1</sup>

<sup>1</sup>VU University Medical Center, Radiation Oncology, Amsterdam, The Netherlands

<sup>2</sup>VU University Medical Center, Radiology, Amsterdam, The Netherlands

**Purpose or Objective**

The duodenum is the primary dose-limiting organ when performing SBRT for locally advanced pancreatic cancer (LAPC). With technical and imaging advancements, the incidence of grade ≥3 small bowel toxicity (bleeding, perforation, strictures) has decreased to <10%, but potential toxicity continues to be a cause of concern. Stereotactic MR-guided adaptive radiation therapy (SMART) is a promising innovation, enabling besides daily plan adaptation, optimal and real-time normal tissue sparing while delivering high biological doses. The SMART approach was clinically implemented at our center in May 2016, using the MRIdian system (ViewRay). We report on SMART delivery in the first nine pts.

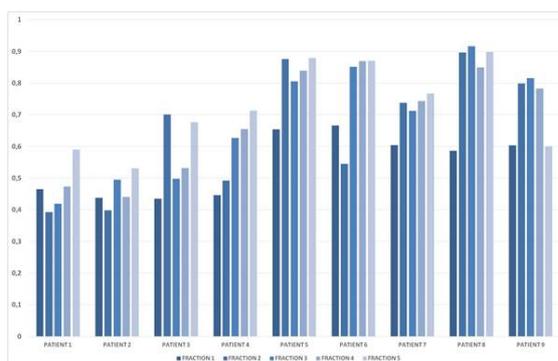

**Material and Methods**

SMART for LAPC is delivered in 5 fractions of 8 Gy (BED<sub>10Gy</sub> 72 Gy), in two weeks on non-consecutive days, with prophylactic prescription of dexamethasone and ondansetron. Target (GTV) and organs-at-risk (OAR) contouring is performed on a MR-scan acquired at the MRIdian 0.35T during a 17 sec shallow inspiration breath-hold (BH). The GTV-PTV margin is 3mm, and the final PTV (PTV<sub>opt</sub>) is created after subtraction of OAR within the initial PTV. A BH MR is repeated prior to each treatment fraction, and setup performed by GTV alignment. After contour deformation and adjusting OAR within 3 cm of the PTV<sub>opt</sub>, the original plan is re-optimized using the same number and direction of IMRT beams, to create a "plan of the day". Patient specific QA includes an independent dose calculation step, followed by treatment delivered in BH periods under continuous MR-guidance. Respiratory-gating is performed using the GTV within the PTV<sub>opt</sub>, implying a 3mm safety boundary. BH is facilitated using an in-house developed video-feedback system, consisting of a mirror in the MR-bore and a monitor mounted at the head end of the MRIdian. Pts can observe in real-time the projected GTV within the PTV<sub>opt</sub> on a sagittal tracking image derived from the MRIdian console (Fig 1).

## Results

SMART was delivered in 45 fractions in nine pts (4F, 5M; ages 55-87 yrs) with LAPC. Two pts had biliary stents. All pts were able to complete the BH delivery. Median duration of the SMART delivery was 54 min (range 42-73). With the video-feedback method, median gated treatment efficiency (ratio between actual beam-on time and delivery time) was 0.66 for all fractions, ranging from 0.40-0.92 (Fig 2). Pt follow-up is still limited, but early results show no grade  $\geq 3$  acute toxicity. Prospectively-scored patient reported outcomes revealed maximum Grade 2 fatigue and nausea in, respectively, 6 pts and 1 pt.

## Conclusion

SMART is novel treatment approach for LAPC that requires no placement of fiducials, and is well tolerated, even by elderly pts and those with stents. Initial experience revealed that delivery within a one hour time-frame per fraction is feasible. Updated clinical follow-up data will be presented.

<sup>12</sup>Fondazione Giovanni Paolo II, Unit of Radiotherapy- Unit of General Oncology, Campobasso, Italy

<sup>13</sup>Fondazione Giovanni Paolo II, Unit of Medical Physics, Campobasso, Italy

## Purpose or Objective

To evaluate the impact of radiation dose on overall survival (OS) in patients treated with adjuvant chemoradiation (CRT) for pancreatic adenocarcinoma (PAC).

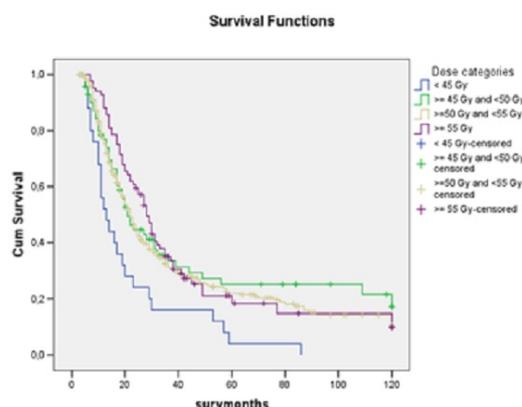

## Material and Methods

A multicenter retrospective analysis on 514 patients with PAC (T1-3; N0-1; M0) treated with surgical resection with macroscopically negative margins (R0-1) followed by adjuvant CRT was performed. Exclusion criteria included metastatic or unresectable disease at surgery, intraoperative radiotherapy (IORT), macroscopic residual disease (R2), postoperative death (within 60 days after surgery) and histological diagnosis different from ductal carcinoma. We analyzed patients stratifying them into 4 groups based on radiotherapy doses (group 1: < 45 Gy, group 2:  $\geq 45$  and < 50 Gy, group 3:  $\geq 50$  and < 55 Gy, group 4:  $\geq 55$  Gy). Adjuvant chemotherapy was prescribed to 141 patients. Survival functions were plotted using the Kaplan-Meier method and compared through the log-rank test. Clinical and pathological parameters associated with significant differences in OS at the univariate analysis were entered into a multivariable Cox model using a forward stepwise [Wald] strategy (p removal  $\geq 0.10$ ; p addition < 0.05) based on likelihood ratio test, in order to obtain a final model including only the subset of variables significant in predicting OS. All tests were two-sided and a p value < 0.05 was considered statistically significant.

## Results

Median follow-up was 20 months (3-120). At univariate analysis a worse OS was recorded in patients with higher Ca19.9 levels (> 90 U/ml; p < 0.001), higher tumor grade (G3-4, p = 0.004), R1 resection (p = 0.004), higher pT stage (pT3-4, p = 0.002) and positive nodes (p < 0.001). Furthermore, patients receiving increasing doses of chemoradiation showed a significantly improved OS (Figure 1). In groups 1, 2, 3, and 4 median OS was 13.0 months, 21.0 months, 22.0 months, and 28.0 months, respectively (p=0.004). The significant impact of higher dose was confirmed by multivariate analysis (HR: 0.46, 95%CI: 0.27-0.78, p= 0.005).

**Figure 1: Overall survival versus chemoradiation dose**  
(< 45 Gy, ≥ 45 Gy and < 50 Gy, ≥ 50 Gy and < 55 Gy, ≥ 55 Gy).

### Conclusion

Despite its retrospective nature this analysis shows a significant impact of CRT dose on OS. This can explain the conflicting results of randomized trials on adjuvant CRT in PAC in which doses < 45 Gy were generally used.

### Purpose or Objective

In the last years, several prognostic and predictive models (PMs) for locally advanced rectal cancer (LARC) patients (pts) have been developed. Aim of this study was to update the previous PMs [1] developed for local recurrence (LR), distant metastases (DM) and overall survival (OS) at 2, 3, 5 and 10 years based on a more copious pooled set of LARC pts.

### Material and Methods

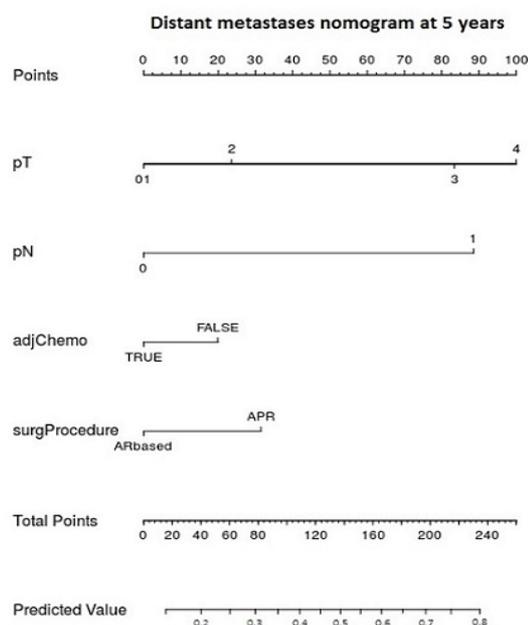

The PMs were developed using the data of the following LARC trials: Accord 12/0405, EORTC 22921, FFD 9203, CAO/ARO/AIO-94, CAO-ARO-AIO-04, INTERACT, I-CNR-RT and TROG 01.04. Pts were selected applying the following exclusion criteria: neoadjuvant and adjuvant oxaliplatin based chemotherapy, no surgery procedure, short-course radiotherapy and no neoadjuvant radiotherapy. As the current pooled dataset contains different trials, we used 20% of the data (stratified per trial) as a validation dataset. Due to variable influence over time, a logistic regression model was used. Follow-up times (2, 3, 5 and 10 years) for the survival outcomes (LR, DM and OS) were used as the model outcome. Variable selection was performed using a stepwise Akaike's information criterion (AIC) feature selection to determine the optimal subset of

covariates and nomograms developed as a visual representation. The nomogram shows only significant covariates ( $p < 0.01$ ). According to the TRIPOD [2], all PMs were validated using external validation of type 2b. The models performance was evaluated using the Area under the Receiver Operating Curve (AUC) and the brier score.

### Results

Three thousand seven hundred seventy patients out of 7612 patients in this pooled dataset satisfied the inclusion criteria and were analyzed in this study. For each outcome (LR, DM and OS) performance of training and validation models, in terms of AUC and brier score were shown in table 1. Nomograms were generated for each outcome (LR, DM and OS) at 2, 3, 5 and 10 years. Furthermore as an example we have reported the new distant metastases nomogram at 5 years obtained (Figure 1).

FUP (years)	Outcomes	AUC training model	AUC validation model	Brier score
2	LR	0.73	0.77	0.06
	DM	0.73	0.74	0.14
	OS	0.71	0.75	0.07
3	LR	0.74	0.75	0.08
	DM	0.74	0.73	0.16
	OS	0.73	0.76	0.12
5	LR	0.75	0.77	0.13
	DM	0.74	0.75	0.19
	OS	0.72	0.76	0.19
10	LR	0.75	0.80	0.2
	DM	0.74	0.77	0.19
	OS	0.73	0.79	0.19

### Conclusion

The logistic regression models performed with AUC values always higher than 0.7. The AUC higher in validation than in training would need further investigation. Nomograms will be totally showed at the conference.

Radiation Oncology MAASTRO-GROW School for Oncology and Development Biology, Maastricht, The Netherlands

<sup>3</sup>Besançon University Hospital J Minjot, Department of Radiation Oncology, Besançon, France

<sup>4</sup>Unicancer Centre Antoine Lacassagne, Radiotherapy, Nice, France

<sup>5</sup>Peter MacCallum Cancer Centre, Division of Radiation Oncology, Melbourne, Australia

<sup>6</sup>Goethe University Frankfurt, Department of Radiotherapy and Oncology, Frankfurt am Main, Germany

### Purpose or Objective

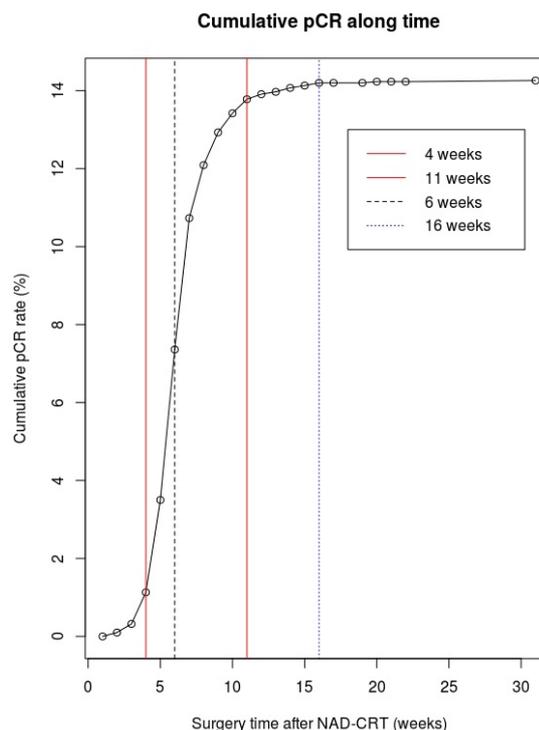

Optimal timing of surgery after neoadjuvant chemoradiotherapy (NAD-CRT) is still controversial. Literature data suggest an improvement in pathological complete response (pCR) after prolongation of surgical interval (SI) after NAD-CRT. The aim of this study was to evaluate the effects of SI on pCR in a pooled dataset of locally advanced rectal cancer (LARC) patients (pts) coming from 7 randomized trials.

### Material and Methods

Pts data were extracted from the following LARC trials: Accord 12/0405, EORTC 22921, FFCO 9203, CAO/ARO/AIO-94, CAO-ARO-AIO-04, INTERACT and TROG 01.04. Inclusion criteria for pts selection were: LARC (clinical tumor stage (cT) 3-4, clinical nodal stage (cN) 0-1-2 and no distant metastases) and NAD-CRT followed by surgery. The SI was calculated from the end of NAD-CRT. Pts were divided into two groups according to median of the surgery time (MST): shorter interval group (SIG) (pts who had surgery before MST) and longer interval group (LIG) (pts who had surgery after MST). The primary outcome was to determine the rate of pCR related to SI. The secondary outcome was to compare post-surgical complications in two groups and the impact of pCR rates on local recurrence (LR), metastases-free survival (MFS) and overall survival (OS). Pearson's Chi-squared test, Kaplan-Meier curves and univariate logistic regression model (uLRM) were used for data analysis. A p-value <= 0.05 was considered significant.

### Results

This pooled dataset included 5247 pts; 3078 pts satisfied the inclusion criteria and were analyzed in this study. Recruitment in the period investigated by the study took place as follows: 453 pts from 1993 to 1998, 613 from 1999 to 2003, 1023 from 2004 to 2008 and 996 from 2009 to 2014. 440 (14%) pts had pCR. The cumulative pCR rate rose significantly when time between NAD-CRT and surgery was increased, until reaching a plateau at 16 weeks (Figure 1). MST was 6 weeks (range 1-31, range interquartile 5-7). The SIG and the LIG had 1953 and 1132 pts, respectively. pCR rates were significantly higher in the LIG as compared to the SIG (19% vs 11.6%, p<0.01). cT, cN, surgery procedure and post surgical complications were distributed equally between the two groups. The results of uLRM are summarized in table 1. Finally, considering only the pCR events there was no statistically significant difference in term of LR, MFS and OS between the two groups. Comparing the two groups, considering pCR and no pCR pts, there was no statistically significant difference in term of LR, MFS and OS between them.

**Table 1: Significant covariates of univariate logistic regression model**

Covariates	Coefficients	P-Value	Outcome
Surgery time after NAD-CRT (weeks)	0,019	<0.01	An increase of weeks after NAD-CRT increases pCR rate
Radiotherapy Dose	0,007	<0.01	An increase in radiotherapy dose increases pCR rate
Neoadjuvant chemotherapy Oxaliplatin based	0,056	<0.01	Neoadjuvant chemotherapy Oxaliplatin based increases pCR rate
Longer interval group	0,072	<0.01	Have surgery after 6 weeks increases pCR rate
Surgery time after NAD-CRT (weeks)	-0,015	<0.01	An increase of weeks after NAD-CRT decreased post-surgical complications

### Conclusion

The results of these pooled analyses confirm that the prolongation of SI after the end of NAD-CRT increased the rate of pCR in LARC pts. The cumulative pCR rate reached a plateau at 16 weeks; moreover longer SI has no impact on post surgical complication rates. No statistically significant difference was observed in term of survival outcomes between the SIG and the LIG in pCR pts.

### OC-0429 Neoadjuvant chemoradiotherapy or 5x5 Gy followed by chemotherapy in rectal cancer: the RAPIDO trial

C. Marijnen<sup>1</sup>, For the cooperative group of the RAPIDO trial<sup>2</sup>

<sup>1</sup>Leiden University Medical Center LUMC, Department of Radiotherapy, Leiden, The Netherlands

### Purpose or Objective

Current standard for the most locally advanced rectal cancers is preoperative chemoradiotherapy (CRT), and, variably per institution, postoperative adjuvant chemotherapy. Short-course preoperative radiation with delayed surgery induces tumour downstaging in both randomized and observational studies. In the RAPIDO trial, the value of short-term preoperative radiotherapy with 5x5 Gy followed by neoadjuvant chemotherapy is investigated in a randomized fashion.

### Material and Methods

Patients with rectal cancer with high risk features for systemic or local failure on magnetic resonance imaging were eligible. Randomization took place between a standard arm A: long course chemoradiotherapy followed

by TME surgery and optional postoperative chemotherapy and an experimental arm B: short course 5 x 5 Gy radiation followed by six cycles of full-dose CAPOX or nine cycles of FOLFOX and TME surgery.

#### Results

A total of 920 patients were included between June 2011 and June 2016. At randomisation, 302 were cT4 and 828 were cN+, of whom 621 were considered cN2 disease and 137 as extramesorectal pelvic lymphnodes. Based on MRI, extramural vascular invasion was diagnosed in 275 patients, whereas the mesorectal fascia was threatened in 564 patients.

Preliminary data show that median time between randomization and surgery was 15,9 weeks for arm A and 25,3 weeks for arm B. In arm B, 100% of the patients who started, completed the radiotherapy and 72% of patients completed all scheduled cycles of neoadjuvant chemotherapy after 5x5 Gy. Another 9% of patients completed the last course(s) without oxaliplatin. In arm A, 96% received all scheduled radiotherapy fractions and 94% of the patients received 5 weeks of preoperative capecitabine combined with radiotherapy. Open surgery was performed in 59% of the patients and 35% underwent an APR. In total, 19% of patients had a ypT0N0. For 4% of all patients a wait & watch strategy was applied. Of the operated patients, 89% had a negative circumferential resection margin (> 1 mm).

#### Conclusion

Compliance for neoadjuvant treatment was good in both treatment arms. Given the locally advanced state of most tumors, the ypT0N0 rate can be considered satisfactory. Final data and details concerning differences in pre-treatment characteristics and treatments between the two arms will be presented.

### Joint Symposium: ESTRO-ESR: Radiomics and imaging databases for precision radiation oncology

---

#### SP-0430 Radiomics in radiology, what are the parameters of interest for different imaging modalities?

H. Ahlström<sup>1</sup>

<sup>1</sup>*Uppsala University, Dept of Radiology, Uppsala, Sweden*

CT, MRI, PET, PET-CT and PET-MRI datasets contain huge amounts of spatially detailed morphological, functional and metabolic information. Today, when analysed, these detailed datasets are typically heavily reduced to a few measurements of a priori specified measurements of interest (e.g. volumes, areas, diameters, average/maximum tracer concentrations etc.) and/or visually - and therefore inevitably subjectively - assessed by a human operator. As a result, normality/non-normality can only be assessed on these measurements and not on the entire data collected, and statistical interaction with non-imaging parameters can also be assessed only on these a priori specified measurements. In order to utilise the full potential of these image datasets, new analysis tools included in the concept Radiomics, that allow objective or quantitative assessment of all imaging data (including e.g. previously discarded information about texture), are needed. Radiomics can be divided into distinct processes: (a) image acquisition and reconstruction, (b) image segmentation and rendering, (c) feature extraction and feature qualification and (d) databases and data sharing with non-imaging data (e.g. different "omics" and clinical data) for (e) informatics analyses. Statistical knowledge of the normal range of Radiomics features are needed for the analyses. These analyses are anticipated to bring out new associations and understandings that traditional approaches could not achieve. Radiomics features can, together with non-imaging data, be included in models that have shown to

provide valuable diagnostic, prognostic or predictive information for oncological diseases. This information aims at improving individual patients' outcomes by a better treatment selection.

#### SP-0431 Radiomics in radiotherapy. How is it used to personalise treatment and to predict toxicity and/or tumour control

C. Gani<sup>1</sup>

<sup>1</sup>*University Hospital Tübingen Eberhard Karls University Tübingen, Radiation Oncology Department, Tübingen, Germany*

Radiomics is defined as the automated or semi-automated extraction of a large number of features from imaging datasets resulting an individual "imaging phenotype". These features and the imaging phenotype can then be correlated with a variety of other parameters: from genetic phenotypes to oncological outcome data. Radiomics as a non-invasive procedure is of particular interest for the radiation oncologist in times of precision radiation oncology: The radiomics phenotype might help to identify patients at high risk for treatment failure and therefore candidates for more aggressive treatment. Furthermore radiomics can also be a helpful tool to predict the risk for radiation-induced toxicities and guide the dose distribution within normal tissues. This lecture will give an overview about the existing data on radiomics in the field of radiation oncology.

#### SP-0432 Uncertainties in imaging -how they should be reported and propagated in prediction models using radiomics

L. Muren

<sup>1</sup>*Aarhus University Hospital - Aarhus University, Medical Physics, Aarhus, Denmark*

Abstract not received

#### SP-0433 Imaging biobanks: challenges and opportunities

A. Van der Lugt<sup>1</sup>

<sup>1</sup>*Erasmus MC University Medical Center Rotterdam, Department of Radiology, Rotterdam, The Netherlands*

An imaging biobank can be defined as an organised database of medical images and associated imaging biomarkers (radiology and beyond) shared among multiple researchers, and linked to other biorepositories. An imaging biobank is designed for scientific use. Image data are systematically analysed visually, manual, or (semi)-automated with the main aim to extract imaging biomarkers than can be related to patient characteristics like medical history, genomic data, and outcome or disease characteristics like genomic data, biomaterials or response to treatment. The data storage is structured in a way that the database can be queried and retrieved based on available metadata. In order to exploit the available information interactions with other databases are a prerequisite. General requirements with respect to the data collection are therefore a database facilitating storage of image data and metadata, storage of derived image-based measurements, and storage of associated non-imaging data, taking into account the need to deal with longitudinal data, and to cope with multiple file formats. Finally, automated retrieval is needed for image analysis pipelines that extract image features for radiomics signatures or for hypothesis free deep learning algorithms.

**Symposium with Proffered Papers: Novel approaches in prostate tumour control**

---

**SP-0434 State of the art in prostate tumour****radiobiology**C. Peitzsch<sup>1,2</sup><sup>1</sup>*OncoRay - Center for Radiation Research in Oncology, University Hospital Carl Gustav Carus- Technische Universität Dresden, Dresden, Germany*<sup>2</sup>*Nationales Centrum for Tumor diseases NCT- Dresden, German Cancer Center DKFZ- Heidelberg, Dresden, Germany*

Prostate tumorigenesis is a multistep process from intraepithelial neoplasia (PIN) and localized adenocarcinoma, to castration-resistant prostate cancer (CRPC) and further into an invasive and metastatic disease stage with poor prognosis. Several driver and passenger mutations e.g. within the androgen receptor (AR), *ETS*, *TP53*, *PTEN*, *BRCA1/2*, *CTNNB1* or *ATM* were identified, so far, to be involved in this developmental process. Beside this specific genetic features of prostate cancer cells, cellular heterogeneity within prostate cancer describes the observation that malignant cells differ within their phenotypic features and functional properties. This tumor heterogeneity and cellular plasticity of tumor cells are the main driving forces for tumor growth, metastasis and therapy resistance and can be explained by the cancer stem cell (CSC) hypothesis in combination with clonal evolution and epigenetic regulation. CSC-specific molecular mechanisms of radioresistance mainly based on increased DNA repair capacity, enhanced reactive oxygen species (ROS) scavenging and induced epithelial-mesenchymal transition (EMT) and is regulated e.g. by the androgen-receptor signaling, the tumor microenvironment, growth factors and cytokines. Data from our own group indicating that ionizing radiation itself is modulating epigenetic mechanisms in prostate cancer cells and thereby cellular plasticity. To translate these basic research findings into clinically relevant data primary model systems and mouse models can be used for pre-clinical validation of radiosensitizer and biomarker discovery.

**SP-0435 Novel developments in molecular targeting of prostate cancer**R. Bristow<sup>1</sup><sup>1</sup>*Princess Margaret Cancer Centre University Health Network, Radiation Oncology - Room 5-964, Toronto, Canada*

Prostate cancer (CaP) remains the most common male malignancy worldwide. Although some localized cancers can be indolent, others can manifest aggressive biology with abnormal cancer metabolism and genetic instability. These men need intensified treatment to prevent metastatic castrate-resistant disease (mCRPC). Recent studies have started to define the genomic landscape of prostatic cancer heterogeneity in which mCRPC is associated with increasing androgen receptor aberrations, DNA repair deficiencies, mutations in PI3K and tumour suppressor gene pathways, aberrant WNT-beta-catenin signaling and defects in cell cycle control. For localized disease amenable to radiotherapy, we have previously shown that genetic instability and hypoxia are strong prognostic factors for prostate cancer outcome. Subsequently, we have gone on to analyze the whole-genomes and methylomes of 194 men and the exomes of 479 men to discover multimodal genetic signatures for responders and non-responders following precision radiotherapy and surgery. We observed that intermediate risk prostate cancers have a paucity of clinically-actionable mutations; in distinct contrast to that reported

for mCRPC. However, all patients with an DDR-associated ATM mutation failed therapy. A significant proportion of tumours harbour recurrent non-coding aberrations, important genomic rearrangements, and a novel mechanism of PTEN inactivation whereby a local inversion represses transcription of genes within its boundaries. Chromothripsis and kataegis is evident in one fifth of these tumours and can be associated with more aggressive disease. Using driver mutations, copy-number alterations and methylation, we were able to categorize patients into prognostic categories which has less than 5% or greater than 50% probability of relapse. The use of genomic markers as prognostic factors for local failure and for systemic disease are therefore novel risk-stratification tools which help to triage patients to existing treatment options, and potentially identification of molecular targets for therapy. However, our data also suggest that novel therapeutic approaches focus on recurrent non-mutation targets. This new approach could then prevent castrate-resistance by targeting genetic instability earlier on the natural history of the disease when fewer driver events are operational.

**OC-0436 Cytokine-dependent regulation of prostate cancer stem cell maintenance in response to irradiation**C. Peitzsch<sup>1,2</sup>, M. Baumbach<sup>1</sup>, M. Cojoc<sup>1</sup>, L. Hein<sup>1</sup>, I.Kurth<sup>1,2</sup>, M. Baumann<sup>1,2,3,4,5</sup>, M. Krause<sup>1,3,4,5</sup>, A.Dubrovskaja<sup>1,3,4</sup><sup>1</sup>*OncoRay - Center for Radiation Research in Oncology, Faculty of Medicine and University Hospital Carl Gustav Carus- Technische Universität Dresden, Dresden, Germany*<sup>2</sup>*National Center for Tumor Diseases NCT, German Cancer Research Center DKFZ, Dresden, Germany*<sup>3</sup>*German Cancer Consortium DKTK, German Cancer Research Center DKFZ, Dresden, Germany*<sup>4</sup>*Institute of Radiation Oncology, Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany*<sup>5</sup>*Department of Radiation Oncology, Faculty of Medicine and University Hospital Carl Gustav Carus- Technische Universität Dresden, Dresden, Germany***Purpose or Objective**

According to the cancer stem cell hypothesis prostate cancer is driven by a malignant subpopulation with stem-like properties. These cancer stem cells (CSC) contribute to tumor-initiation, metastasis, therapy-resistance and tumor relapse. In parallel, genetic mutations accumulate over time and CSC subclones evolve. Therapeutic interventions like radiotherapy provide selective pressure for the expansion of resistant subclones with genetic diversification. We hypothesize that the determination of CSC-related biomarker in prostate cancer biopsies is correlating with clinical parameter and can be used for patient stratification and treatment selection to improve personalized radiotherapy.

**Material and Methods**

We generated isogenic radioresistant prostate cancer cell lines with a high expression of CSC marker, an epithelial-to-mesenchymal transition (EMT) phenotype, higher self-renewal properties, higher tumorigenicity and enhanced DNA repair capacity. We applied comparative genomic, proteomic, metabolomic, epigenomic and secretome analysis to identify novel biomarker for prostate cancer radioresistance and to unravel contributing molecular mechanisms. Novel biomarkers were validated using the Cancer Genome Atlas (TCGA) database and correlated with the tumor-free survival of prostate cancer patients after anti-cancer therapy including radiotherapy using SUMO software calculation.

**Results**

Within our first proof-of-principle study, we could show that ALDH-positive CSCs are radioresistant and maintained directly by the Wnt/ $\beta$ -catenin signaling pathway. In

addition, we found that irradiation is inducing CSC marker and CSC properties in a dose- and time-dependent manner. This irradiation-induced CSC-plasticity was attributed to the modulation of the histone methylation code. Within the present study we analyzed a panel of secreted cytokines and their corresponding cytokine receptors in the radioresistant prostate cancer sublines, in a s.c. xenotransplantation model, in ex vivo irradiated primary prostate cancer biopsies and in blood samples of prostate cancer patients during the course of radiotherapy and found, for example, the CXCR4-CXCL12 signaling to be involved in the CSC maintenance and the induction of prostate cancer radioresistance.

#### Conclusion

Our studies suggest that the combination of irradiation with cytokine signaling modulation, especially the CXCR4-CXCL12 signaling, may increase the cytotoxic effects of irradiation in prostate cancer cells. The expression profiling of proteins involved in the cytokine signaling can be used to predict clinical outcome of prostate cancer patients after radiotherapy.

#### Proffered Papers: New technologies for imaging and therapy

##### OC-0437 Scatter imaging: promising modality for image guided ablation radiotherapy for lung cancer patients

J. Chu<sup>1</sup>, G. Redler<sup>1</sup>, G. Cifter<sup>1</sup>, K. Jones<sup>1</sup>, J. Turian<sup>1</sup>  
<sup>1</sup>Rush University Medical Center, Department of Radiation Oncology, Chicago IL, USA

#### Purpose or Objective

Early stage lung cancers can be effectively treated by stereotactic ablation radiation therapy (SABR). Successful treatment requires hypofractionation and large dose per fraction (up to 20 Gy) while maintaining a high level of accuracy ( $\leq 1.0$ mm). By imaging the photons that are Compton-scattered out of the treatment beam, real-time, non-invasive monitoring of the tumor location may be possible. To assess the potential of this modality, we have obtained scatter images of static and movable tumor phantoms, and calculated images from CT-based Monte Carlo simulations.

#### Material and Methods

Compton scatter is a natural by-product of external beam radiation therapy. The scattered radiation contains information about the patient anatomy and the transient tumor location. An embedded tumor in a Quasar respiratory motion phantom (Modus Medical Devices Inc.) was programmed to move linearly over 2.5cm. While irradiating the embedded tumor using a 6MV Varian TrueBeam linear accelerator, experimental scatter images were measured with a Varian PaxScan flat panel detector and a pinhole collimator. Tumor centroid locations were then measured from various scatter images and compared with the expected values. Monte Carlo N-Particle (MCNP) code was used to simulate scatter images from phantoms and patient CT images using 10 - 1000MU, or 0.5 - 50 second time scales. The quality of the images was assessed to determine their potential for tumor localization during treatment.

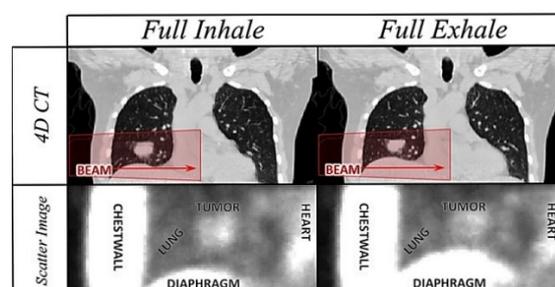

#### Results

The measured tumor centroid locations agreed with the expected values to within 1mm, which is adequately accurate for clinical tumor tracking. Lung tumor phantom images showed excellent signal and contrast. The contrast-to-noise ratio ranged from 3.4 to 15.1 for scatter images acquired with 0.5 to 50s. The attached figures below show CT and simulated scatter images (corresponding to the red shaded region in CT) for both inhale and exhale breathing phases. The scatter images clearly show variation of tumor and diaphragm locations for two breathing phases. Other pertinent anatomical

structures, such as chest wall, heart, and lung are also clearly visible.

#### Conclusion

This study has demonstrated the feasibility of using scatter imaging to track lung tumor movement during SABR treatments. The potential benefits may include real-time, good quality image guidance without additional radiation. We are optimistic that improvements in the detector and collimation system, will lead to better image quality, more accurate tumor localizations, and possible 3D reconstruction of patient's anatomy within the irradiated region.

##### OC-0438 The impact of a 1.5 T MR-Linac fringe field on neighbouring linear accelerators.

T. Perik<sup>1</sup>, J. Kaas<sup>1</sup>, F. Wittkamper<sup>1</sup>

<sup>1</sup>The Netherlands Cancer Institute, Department of Radiation Oncology, Amsterdam, The Netherlands

#### Purpose or Objective

In our institution a clinical prototype of the MR-Linac(MRL)(Elekta AB, Stockholm, Sweden) was installed in an existing treatment room. The MRL, which has a field strength of 1.5 T, is neighbored by 3 clinical Elekta accelerators at a distance (isocenter MRL to gun linac) of 7.5 and 5.5 and 11 meters. The peripheral magnetic field outside of the magnet core of the MRL, the fringe field, may influence the beam steering of accelerators in adjacent treatment rooms. This influence for a pre-clinical prototype was described by Kok et al. in 2009. The aim of this study is to investigate the influence of the significantly reduced fringe field of the clinical prototype on the beam steering of its neighbouring accelerators.

#### Material and Methods

A STARCHECK MAXI detector array (PTW Freiburg, Germany) was mounted on all the neighbouring accelerators with a frame that puts the array on isocentre height. An inclinometer was attached to the gantry to acquire a gantry rotation signal. For every available energy, two 360 degree arcs (clockwise and counter clockwise) were irradiated with a 40x40 field. A measurement of beam profile was acquired in movie mode at a frame rate 2.5 Hz. Beam symmetry (IEC) was determined for every frame.

These measurements were done before and after ramping up the MRL magnet, and a 3<sup>rd</sup> time after adjusting the look-up tables (LUT) which correct the beam steering by applying a gantry-angle dependent current to the steering coils (2R and 2T). These LUTs were adjusted using the accelerator internal monitor chamber.

#### Results

A change in beam symmetry as a function of gantry angle, before and after ramping the magnet, of up to 4% (Linac A) and 1% (Linac B) is observed, causing beam symmetry on both linacs to be out of tolerance (IEC 102%). Linac C did not show any significant change. Figure 2 shows the LUT before ramping the magnet (pre) and after adjustment (post) and the difference for Linac A for the 10 MV beam. After adjustment of the beam steering on Linac A and B, the symmetry was within tolerance for all gantry angles. Adjusting the LUTs took 1.5 hours per linac.

#### Conclusion

The influence of the MRL fringe field is less than described by Kok for the pre-clinical prototype, but does still influence the beam steering of the accelerators in adjacent treatment rooms. The LUTs of 2 accelerators, that were situated the closest to the MRL, but outside the 0.5 Gauss line, needed to be adjusted in order to get beam parameters within tolerances. Adjusting the LUTs fully corrected the influence of the magnetic fringe field of the MRL. In case of an unexpected ramp down of the magnet (i.e. quench) both neighbouring accelerators cannot be used clinically before the LUTs are adjusted to the new situation. Adjustment of the LUT can be done in a short time by experienced personnel, without a dedicated measurement device.

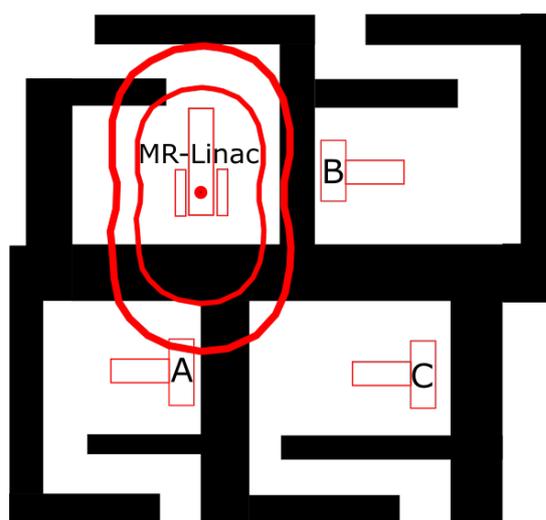

Figure 1. Graphical representation of the treatment room layout with the position of the neighbouring Linacs A, B and C, and the 0.5 G (outer) and 2 G (inner) fringe field strengths.

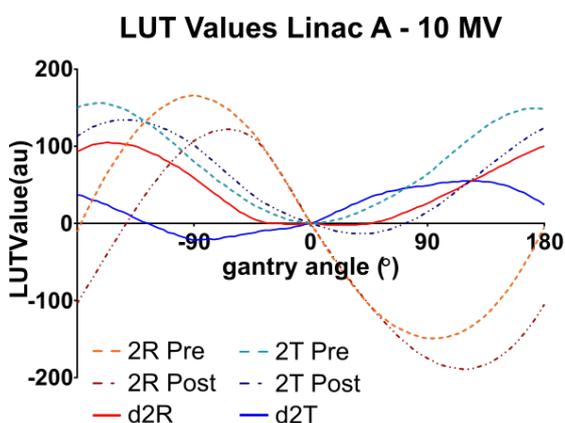

Figure 2. LUT values before (Pre) ramping the magnetic field to 1.5 T, after correction (Post) of beam symmetry and the difference between Pre and Post (d2R, d2T)

#### Purpose or Objective

Dynamic Wave Arc (DWA) is a system-specific non-coplanar arc technique that combines synchronized gantry-ring rotation with D-MLC optimization. This paper presents the clinical workflow, quality assurance program, and reports the geometric and dosimetric results of the first patient cohort treated with DWA.

#### Material and Methods

The RayStation TPS was clinically integrated on the Vero SBRT platform for DWA treatments. The main difference in the optimization modules of VMAT and DWA relates to angular spacing, where the DWA optimization algorithm does not consider the gantry spacing, but only the Euclidian norm of the ring and gantry angle. To support DWA deliveries, the Vero system required some additional upgrades: an MLC secondary feedback unit upgrade allowing faster dynamic MLC leaf movement of up to 4 cm/s at isocenter level, and a machine controller offering gantry-ring synchronous rotations.

The first 15 patients treated with DWA represent a broad range of treatment sites: breast boost, prostate, lung SBRT and bone metastases, which allowed us to explore the potentials and assess the limitations of the current site-specific DWA template solution. Table 1 provides further information for each patient case including the corresponding DWA plan information, while Figure 1 presents the most common used DWA trajectories. For the DWA verification a variety of QA equipment was used, from 3D diode array to an anthropomorphic end-to-end phantom. The geometric accuracy of each arc was verified with an in-house developed method using fluoroscopy images.

Table1. Summary of patient diagnoses, dose prescription and DWA plan parameters

Patient Nr.	Indication	Fractionation	DWA template	Nr. of MPs	Nr. of CPs	Nr. kV images	Nr. MU	Delivery time (min)
1	Right breast boost	8 x 2Gy	B3	6	59	195	505	1,60

Abbreviations: LLL=left lower lobe; RML=right middle lobe; RUL=right upper lobe; MP= Manipulation Points i.e. gantry-ring angle positions where the direction of the ring rotation can change; CP= Control Points, i.e. gantry-ring angle positions spaced every 4° where the beam aperture shaped by the MLC can change; Nr. kV images=fluoroscopic images acquired during DWA QA delivery for the gantry-ring geometric verification; Delivery time=measured beam-on delivery time.

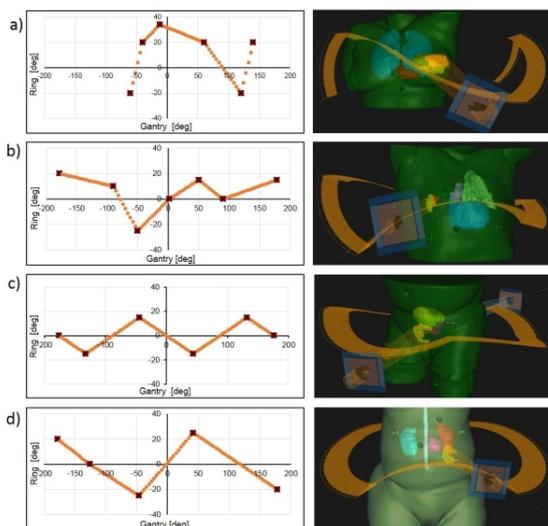

Figure 1. DWA trajectories for a) left breast boost, b) right lung, c) prostate and d) bone metastases. The diagrams present the 2D gantry-ring rotational positions with highlighted turning points (square red markers), while the images present the DWA curve in 3D view.

## Results

The average beam-on delivery time was 3min, ranging from 1.22min to 8.82min. The average  $\gamma$  (3%,3mm) passing rate for film measurements was  $97.0 \pm 1.6\%$  (range from 93.3 to 98.8%), while the Delta<sup>4</sup> measurements presented an average  $\gamma$  (2%,2mm) of  $97.7 \pm 1.4\%$  (range from 95.3 to 99.6%) respectively. The average isocentre point dose ratio was  $99.9 \pm 1.2\%$  (range from 98.0 to 102.8%). For the lung SBRT verifications with the CIRS phantom, an average local  $\gamma$  of  $97.0 \pm 1.0\%$  and  $93.1 \pm 2.0\%$  was obtained during the coronal and sagittal film analysis, whereas the average isocentre point dose ratio was  $100.0 \pm 1.4\%$ . An overall mean gantry-ring geometric deviation of  $0.04^\circ \pm 0.46^\circ$  and  $0.19^\circ \pm 0.26^\circ$  was obtained, respectively.

## Conclusion

DWA has been successfully added to the non-coplanar rotational IMRT techniques' arsenal, allowing additional flexibility in dose shaping while preserving dosimetrically robust delivery. In a short period of time, it has become a standard treatment technique on the Vero system in our department.

## OC-0440 Characterization and clinical evaluation of a novel CT reconstruction to derive electron densities

B. Van der Heyden<sup>1</sup>, M. Ollers<sup>1</sup>, C. Loon Ong<sup>1</sup>, F.

Verhaegen<sup>1</sup>, W. Van Elmpt<sup>1</sup>

<sup>1</sup>School for Oncology and Developmental Biology- Maastricht University Medical Centre, Department of Radiation Oncology MAASTRO- GROW, Maastricht, The Netherlands

## Purpose or Objective

Radiotherapy dose calculations are almost exclusively performed on CT images. In a clinical workflow, the Hounsfield Units (HU) are converted into electron density (ED) by using a CT to ED conversion curve calibrated for a typically fixed tube potential (e.g. 120 kV). Recently, a novel CT image reconstruction algorithm (DirectDensity<sup>TM</sup>, Siemens Healthcare GmbH, Germany) was developed that directly reconstructs the ED, independent of the tube potential of the CT scanner. This allows the elimination of a conversion curve for each tube potential. Our study describes the accuracy in terms of dose calculation of the reconstruction algorithm based on phantom measurements and shows the application in a clinical radiation therapy workflow for different tube potentials.

## Material and Methods

The accuracy of the novel reconstruction algorithm to derive ED was validated in a Gammex RMI 467 phantom (Gammex, USA) using different tissue mimicking inserts.

The phantom was scanned at different tube potentials (80 kV, 120 kV and 140 kV) with a novel SOMATOM Confidence<sup>®</sup> RT Pro scanner (Siemens Healthcare GmbH, Germany). Images were reconstructed both into HU and ED for each tube potential. Next, the usability of the reconstruction algorithm was evaluated in a clinical workflow. Five patients with an abdominal lesion (e.g. rectal or prostate cancer) were scanned using the clinically used tube potential of 120 kV and an additional dual-spiral dual-energy CT acquisition was made at 80 kV and 140 kV. Dose distributions (Eclipse<sup>TM</sup>, Varian, USA) of the ED images of the 80 kV, 120 kV, 140 kV acquisitions using the novel reconstruction algorithm were then compared with the clinical plan based on the 120 kV acquisition using the clinical CT to ED curve with the standard HU image of the 120 kV scan. The difference in mean doses delivered to the planning target volume were quantified (i.e. relative difference  $\pm 1$  SD).

## Results

The CT to ED conversion curve for the HU images depended on the tube potential of the CT scanner. The novel reconstruction algorithm produced ED values that had a residual from the identity line of  $-0.1\% \pm 2.2\%$  for all inserts and energies and is shown in Figure 1.

The dose distributions between the standard and the novel reconstruction algorithm were compared for different energies. The relative differences in target dose ranges were small and ranged from -0.2% to 0.7% for 80 kV, -0.1% to 1.1% for 120 kV, and 0.1 to 1.0% for 140 kV.

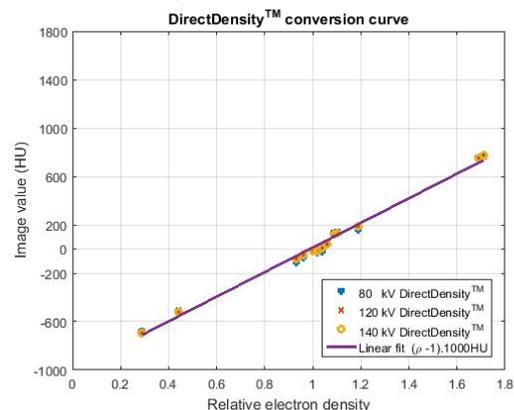

Figure 1: The linear conversion curve (fitted) of the novel reconstruction algorithm.

## Conclusion

A novel reconstruction algorithm to derive directly relative electron density irrespective of the tube potential of the CT scanner was evaluated. A single identity curve for the CT to ED could be used in the treatment planning system. This reconstruction algorithm may enhance the clinical workflow by selecting an optimal tube potential for the individual patient examination that is not restricted to the commonly used 120 kV tube potential.

## OC-0441 Dose Prescription Function from Tumor Voxel Dose Response for Adaptive Dose Painting by Number

D. Yan<sup>1</sup>, S. Chen<sup>2</sup>, G. Wilson<sup>1</sup>, P. Chen<sup>1</sup>, D. Krauss<sup>1</sup>

<sup>1</sup>Beaumont Health System, Radiation Oncology, Royal Oak MI, USA

<sup>2</sup>Beaumont Health System, Radiation Oncology, Royal Oak, USA

## Purpose or Objective

Dose-painting-by-number (DPbN) needs a novel Dose Prescription Function (DPF) which provides the optimal clinical dose to each tumor voxel based on its own dose response. To obtain the DPF for adaptive DPbN, a voxel-by-voxel tumor dose response matrix needs to be constructed during the early treatment course. The study demonstrated that the voxel-by-voxel tumor dose

response can be quantified and predicted using Tumor Metabolic Ratio (TMR) matrix obtained during the early treatment weeks from multiple FDG-PET imaging.

#### Material and Methods

FDG-PET/CT images of 15 HN cancer patients obtained pre- and weekly during the treatment were used. TMR was constructed following voxel-by-voxel deformable image registration. TMR of each tumor voxel,  $v$ , was a function of the pre-treatment SUV and the delivered dose,  $d$ , such as  $TMR(v, d) = SUV(v, d)/SUV(v, 0)$ . Utilizing all voxel values of TMR in the controlled tumor group at the last treatment week, a bounding function between the pre-treatment SUV and TMR was formed, and applied in early treatment days for all tumor voxels to model a tumor voxel control probability (TVCP). At the treatment week  $k$ , TVCP of each tumor voxel was constructed based on its pre-treatment SUV and TMR obtained at the week  $k$  using the maximum likelihood estimation on the Poisson TCP model for all dose levels. The DPF at the week  $k$  was created selecting the maximum TVCP at each level of the pre-treatment SUV and TMR measured at the week  $k$ . In addition, 150Gy was used as an upper limit for the target dose.

#### Results

TVCP estimated in the early treatment week, i.e. week 2, had their  $D_{50} = 13-65\text{Gy}$ ;  $g_{50} = 0.56-1.6$  respectively with respect to  $TMR = 0.4-1.2$ ; Pre-treatment SUV = 3.5-16. Figure 1 shows the TVCP estimated using the TMR measured at the week 2 with different levels of pre-treatment SUV, as well as TVCP at different weeks, the week 2 - week 4. Large dose will be required to achieve the same level of tumor control for the same level of TMR appeared in the later week of treatment. Figure 2 shows the corresponding DPF for the week 3 TMR, as well as the prescribed tumor dose distribution for the 3 failures.

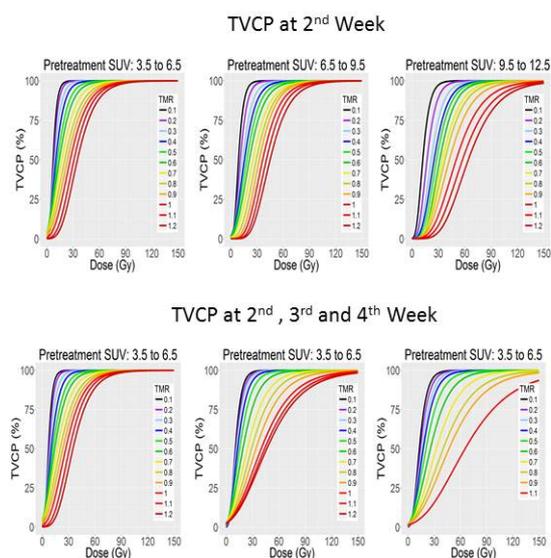

Figure 1

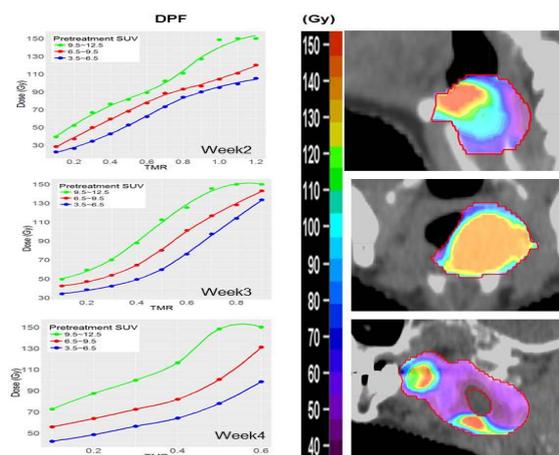

Figure 2

#### Conclusion

DPF can be estimated and constructed adaptively voxel-by-voxel in human tumor using multiple FDG-PET imaging obtained during the treatment course. DPF provides a potential quantitative objective for adaptive DPBN to plan the best clinical dose, escalate or de-escalate, in human tumor based on its own radiosensitivity or radioresistance.

#### OC-0442 Intensity based synthetic CT generation from standard T2-weighted MR images with three MR scanners

L. Koivula<sup>1</sup>, L. Wee<sup>2</sup>, J. Dowling<sup>3</sup>, P. Greer<sup>4</sup>, T. Seppälä<sup>1</sup>, J. Korhonen<sup>1</sup>

<sup>1</sup>Comprehensive Cancer Center- Helsinki University Central Hospital, Department of radiation oncology, Helsinki, Finland

<sup>2</sup>Danish Colorectal Cancer Center South, Vejle Hospital, Vejle, Denmark

<sup>3</sup>Commonwealth Scientific and Industrial Research Organisation CSIRO, CSIRO ICT Centre, Brisbane, Australia

<sup>4</sup>Calvary Mater Newcastle Hospital, Radiation Oncology, Newcastle, Australia

#### Purpose or Objective

Recent studies have shown feasibility to conduct the entire radiotherapy treatment planning workflow relying solely on magnetic resonance imaging (MRI). Yet, few hospitals have implemented the MRI-only workflow into clinical routine. One limiting issue is the requisite construction of a synthetic computed tomography (sCT) image. The majority of published sCT generation methods necessitate inclusion of extra sequences into the simulation imaging protocol. This study aims to develop an intensity-based sCT generation method that relies only on image data from standard T2-weighted sequence. The work includes images derived from three different manufacturers' MR scanners. The primary target group was prostate, for which T2-weighted images are already used as standard target delineation images.

#### Material and Methods

The study utilized a total of 30 standard T2-weighted images acquired for prostate target delineation in three different clinics. The imaging was conducted with MR scanners (GE Optima 1.5T, Philips Ingenia 1.5T, and Siemens Skyra 3.0T) of each participating clinic by using their typical clinical settings. Intensity value variations of the obtained images were studied locally, and compared to corresponding Hounsfield units (HUs) of a standard CT image. The data of 21 of the 30 prostate patients was used to generate conversion models for bony and soft tissues to transform the MR image into sCT. The models were optimized separately for the images obtained by each MR platform. The sCT generation was tested for 9 of the 30

prostate patients by acquiring the conversion algorithms within and outside an automatically contoured bone outline. The quality of the produced sCT images was quantified by HU and dose distribution comparisons against standard CT images. The treatment planning was conducted with VMAT.

### Results

Figure 1 shows examples of the constructed sCTs with the original MR images of each scanner. The mean HU difference for the sCTs was 11 HUs and 90 HUs in the soft and bone tissue volumes, respectively (n=9). The target volume dose differences compared to the CTs were within 0.8% in all cases ( $0.2 \pm 0.5\%$  [average  $\pm$  SD, n=9]). Table 1 presents the HU and dose distribution differences between the sCTs and the actual CT images.

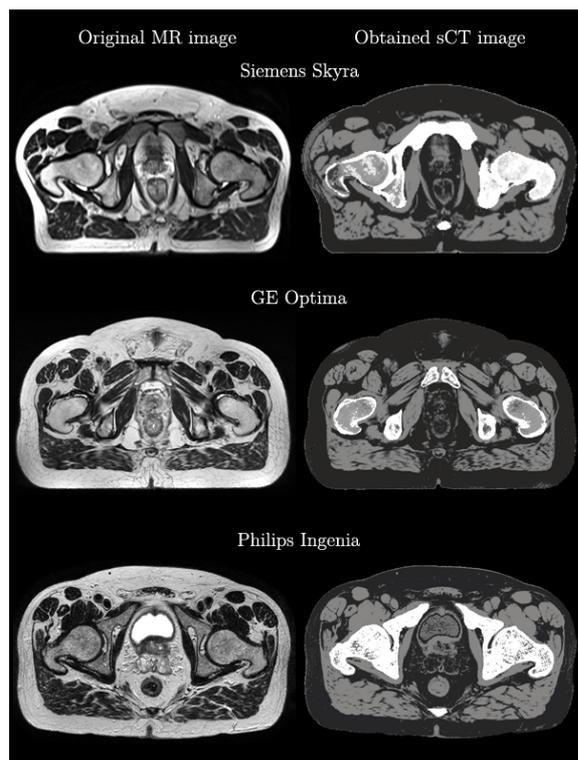

Table 1. Average HU and relative PTV dose differences (CT-sCT) between sCT images and standard CT images as mean  $\pm$  SD

Scanner	GE Optima 1.5 T	Siemens Skyra 3.0 T	Philips Ingenia 1.5 T
Soft tissue	12 $\pm$ 3 HU's	6 $\pm$ 6 HU's	13 $\pm$ 6 HU's
Bone tissue	-54 $\pm$ 49 HU's	-105 $\pm$ 37 HU's	-112 $\pm$ 60 HU's
Mean PTV dose diff.	0.6 $\pm$ 0.2 %	0.2 $\pm$ 0.2 %	-0.1 $\pm$ 0.6 %

### Conclusion

This study revealed the feasibility of generating high quality sCTs directly from intensity values of standard T2-weighted MR images. The applied sCT generation method is adjustable for images applied by multiple manufacturers' scanners with different clinical settings. This work can further contribute to wider clinical implementation of MRI-only based radiotherapy treatment planning.

**Proffered Papers: Optimisation algorithms for treatment planning**

### OC-0443 Robust optimization of VMAT in head and neck patients

D. Wagenaar<sup>1</sup>, R.G.J. Kierkels<sup>1</sup>, J. Free<sup>1</sup>, J.A. Langendijk<sup>1</sup>, E.W. Korevaar<sup>1</sup>

<sup>1</sup>UMCG University Medical Center Groningen, Department of Radiation Oncology, Groningen, The Netherlands

### Purpose or Objective

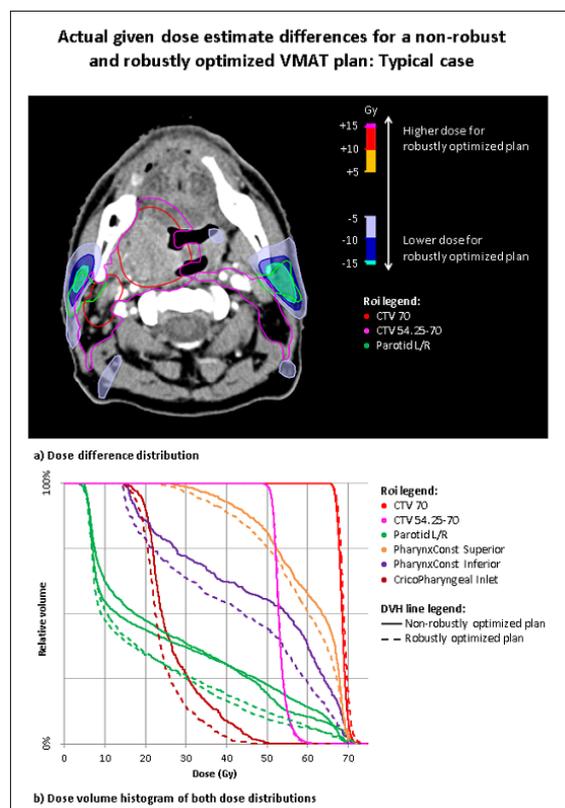

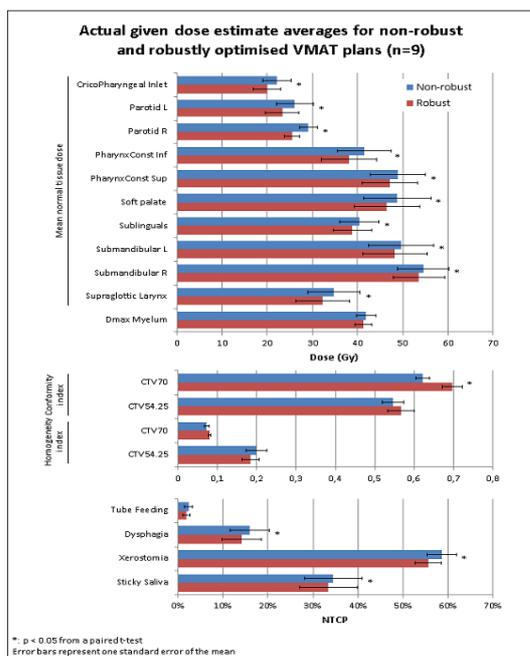

In the Netherlands, a subgroup of patients eligible for proton therapy will be selected using the model-based approach. So far, patients were selected by comparing robustly optimized proton plans to non-robustly optimized photon plans. However, using non-robust optimization for photon plans may not explore the full potential of this technique, possibly leading to an unfair comparison. The main objective of this study was to investigate the benefit of robust optimization for head and neck using photon techniques.

### Material and Methods

A cohort of nine head and neck cancer patients clinically treated with VMAT were included. Their non-robustly optimized (i.e. PTV-based) VMAT plans were copied and their objectives were altered to create robustly optimized (i.e. CTV-based) VMAT plans. Plans were re-optimized with worst case robust objectives for the targets. Hence, the actual given dose was estimated by calculating the dose on 35 daily cone beam CT (CBCT) scans after position correction, deforming the dose distributions to the planning CT and summing doses from all fractions. All estimated actual given dose distributions were inspected and approved by a physician with experience in head and neck radiotherapy. Treatment plan quality was evaluated using dosimetric parameters and normal tissue complication probability (NTCP) values using previously published models for tube feeding dependence, grade 2-4 dysphagia, xerostomia and sticky saliva, 6 months after treatment.

### Results

Robustly optimized plans resulted in a lower actual given dose estimation for all organs at risk (figure 1). The difference in dose distribution and dose volume histograms of a typical case are displayed in figure 2. The average NTCP values were lower for the robustly optimized plans by 0.5% (p = 0.07) for tube feeding dependence, 1.8% (p = 0.04) for dysphagia, 3.0% (p = 0.01) for xerostomia and 1.1% (p = 0.02) for sticky saliva. Moreover, target dose conformity slightly improved using robustly optimized VMAT optimization.

### Conclusion

Robust CTV-based VMAT optimization in head and neck patients resulted in improved estimated actual given dose distributions with lower normal tissue dose and equal target coverage compared to non-robustly optimized plans. This is the first study to compare robustly optimized photon plans to non-robustly optimized photon plans in terms of dose accumulation using daily CBCT images. The differences in dose are deemed clinically relevant and are expected to lead to an improved method of patient selection for proton therapy.

### OC-0444 Pareto-optimal plans as ground truth to validate a commercial knowledge-based DVH-prediction system

E. Cagni<sup>1</sup>, A. Botti<sup>1</sup>, Y. Wang<sup>2</sup>, M. Iori<sup>1</sup>, S.F. Petit<sup>2</sup>, B.J. Heijmen<sup>2</sup>

<sup>1</sup>Arcispedale S. Maria Nuova - IRCCS, Medical Physics Unit, Reggio Emilia, Italy

<sup>2</sup>Erasmus MC Cancer Institute, Department of Radiation Oncology, Rotterdam, The Netherlands

### Purpose or Objective

The purpose of the current study was two fold. First, to evaluate the DVH prediction accuracy of RapidPlan (Varian Medical Systems, Palo Alto) using a large database of Pareto optimal treatment plans. These were consistently generated with automated prioritized multi-criterial treatment plan optimization, independent of RapidPlan, and therefore can be considered as an unbiased, ground truth of achievable plan quality. Second, to determine the importance of the size/variability of the plan database on the accuracy of the RapidPlan DVH predictions. Using the automatically generated plans, the prediction accuracy of RapidPlan could be investigated without an impact of unavoidable plan quality variations related to manual planning.

### Material and Methods

A previously published database of 115 Pareto-optimal prostate VMAT plans, consistently generated with automatic prioritized planning, was used in this study [Wang et al, PMB, 2016]. Separate Rapidplan prediction models were generated for training groups consisting of 20, 30, 45, 55, or 114 randomly selected plans, the latter using a leave-one-out technique. In a second experiment, Model-20 was also built for 4 other groups of randomly selected training patients. Prediction accuracy of all models was assessed using a fixed, independent validation group of 60 plans and comparing predicted dose parameters (rectum Dmean, V65, and V75, anus Dmean, and bladder Dmean) with the achieved values of the Pareto optimal plans.

### Results

For Model-114, the absolute (relative) prediction errors (mean±SD), for rectum Dmean, V65, and V75 were 1.8±1.4Gy (6.9±5.6%), 1.0±0.9% (8.9±13.4%), and 1.6±1.4% (36.3±62.2%), respectively. For anus and bladder Dmean, these errors were 2.2±1.7Gy (18.3±21.3%) and 1.8±1.3Gy (4.9±4.2%), respectively. For 63.3% of the validation plans, Model-114 predicted a lower rectum V65 than could actually be achieved. Because of the prioritized optimization used for generating the input Pareto-optimal plans, this can only be realized by underdosing the target. In 36.7% of plans, the predicted V65 was higher than obtained in the input plan, possibly losing an opportunity for lower rectum dose. Table 1 demonstrates equal prediction accuracies for model-114 and the smaller models (only first Model-20 included). Table 2 compares Model-114 with all 5 investigated Models-20, showing significant differences in performance of the Models-20.

Table 1

	Model-20 (*)	Model-30	Model-45	Model-55	Model-114

(\*) Model-20 Group #1

Table 2

	Models-20	Group #1	Group #2	Group #3	Group #4	Group #5
<i>Absolute differences between Models-20 and Model-114 (p values)</i>						
Rectum $D_{mean}$ [Gy]	0.18	<0.01	0.01	0.47	<0.01	<0.01
Rectum $V_{95\%}$ [%]	0.22	<0.01	0.14	<0.01	<0.01	<0.01
Rectum $V_{75\%}$ [%]	0.20	0.61	0.88	0.10	0.15	0.15
Anus $D_{mean}$ [Gy]	0.19	0.15	<0.01	0.23	<0.01	<0.01
Bladder $D_{mean}$ [Gy]	0.39	<0.01	<0.01	0.26	0.09	0.09

## Conclusion

Rapidplan DVH prediction is a useful tool to guide treatment plan generation, although significant prediction inaccuracies may occur, even when the training database consists of as many as 114 treatment plans. Since all plans to train and validate RapidPlan DVH prediction were Pareto optimal, prediction errors for a database of manually optimized treatment plans are likely larger than presented here. For models based on a small number of plans (N=20), prediction performance depends strongly on the selected training patients, therefore larger models are recommended.

## OC-0445 Probabilistic optimization of the dose coverage - applied to treatment planning of cervical cancer

D. Tilly<sup>1,2</sup>, A. Holm<sup>2</sup>, E. Grusell<sup>1</sup>, A. Ahnesjö<sup>1</sup>

<sup>1</sup>Uppsala University Hospital, Department of Immunology- Pathology and Genetics, Uppsala, Sweden

<sup>2</sup>Elekta, R&D, Stockholm, Sweden

### Purpose or Objective

Probabilistic optimization is an alternative to margins for handling geometrical uncertainties in treatment planning of radiotherapy where the uncertainties are explicitly incorporated into the plan optimization through sampling of treatment scenarios and thereby better exploit patient specific geometry. In this work, a probabilistic method is presented based on statistical measures of dose coverage, similar to the basis for margin based planning. The idea is that the dose planner requests a dose coverage to a specified probability, which the algorithm then fulfils.

### Material and Methods

The van Herk margin recipe is designed to deliver sufficient target dose coverage in 90% of the treatments. The probability is however rarely specified. We generalize this prescription approach to include the probability explicitly through the concept of *Percentile Dose Coverage* (PDC), i.e. the dose coverage that is at least fulfilled to a specified probability. The PDC used in this work for target minimum dose criterion is the probability for the dose-volume criteria  $D_{98\%}$  to be fulfilled with 90% probability which we denote as  $D_{98\%,90\%}$ . For optimization, we make use of the *Expected Percentile Dose Coverage* (EPDC), defined as the average dose coverage below a given PDC. The EPDC is, in contrast to PDC, a convex measure which allows for standard optimization techniques to be used for finding an optimal treatment plan. We propose an iterative method where a treatment optimization is performed at each iteration and

the EPDC constraint tolerance is adjusted gradually until a desired PDC is met.

We have tested our probabilistic planning method based on datasets containing multiple imaging for four cervical cancer patients treated with VMAT (2 Gy, 23fx). The datasets formed the basis for a statistical shape model (SSM) that provided the scenario specific sampled deformations. A set of 100 scenarios sampled from the SSM was included in the probabilistic optimization. A final iteration using 400 scenarios was performed to increase the resulting precision. A set of 1000 independent scenarios not part of the optimization was used to verify that the requested PDC was met.

### Results

For all patients in this work, the iterative process of finding the EPDC tolerance to fulfil the requested PDC converged in less than 10 iterations to within 0.1 Gy of the requested PDC (95% of 46 Gy = 43.7 Gy), see figure 1. The verification calculations showed that the requested PDC was met within 1.3%, see table 1.

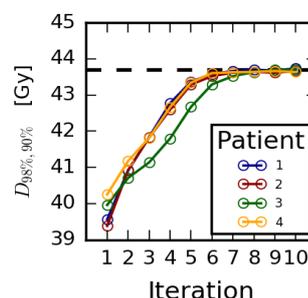

Figure 1. The convergence of  $D_{98\%,90\%}$  per iteration towards the requested indicated by the dashed line. A full probabilistic optimization is performed per iteration.

Table 1. The  $D_{98\%,90\%}$  after optimization and verification calculations.

Patient	PDC optimization [Gy]	PDC verification [Gy]
1	43.4	43.2
2	43.8	43.8
3	43.4	43.4
4	43.1	43.1

### Conclusion

We proved that a probabilistic planning algorithm can be formulated such that the dose planner can request a PDC which the algorithm attempts to fulfil. Results for datasets of four cervical cancer patients indicate that the requested PDC was fulfilled within 1.3%.

## OC-0446 A Fully Automated VMAT Planning System with Site-Configurable Algorithm

M. Chu<sup>1</sup>, R. Maggs<sup>1</sup>, M. Smyth<sup>1</sup>, R. Holmes<sup>1</sup>, D.G. Lewis<sup>1</sup>,

J. Staffurth<sup>2</sup>, E. Spezi<sup>3</sup>, A.E. Millin<sup>1</sup>, P.A. Wheeler<sup>1</sup>

<sup>1</sup>Velindre Cancer Centre, Medical Physics, Cardiff, United Kingdom

<sup>2</sup>Cardiff University, School of Medicine, Cardiff, United Kingdom

<sup>3</sup>Cardiff University, School of Engineering, Cardiff, United Kingdom

### Purpose or Objective

One of the key benefits to automation of the treatment planning process is that consistency in plan quality can be maintained, regardless of user experience. To ensure that the plans are fully optimal, however, the system should allow incorporation of clinical experience and knowledge of the oncologist. This work presents an automated planning system that can be configured via a novel Pareto navigation process. A retrospective study was performed with thirty patients across three sites: Prostate & Seminal

Vesicles (PSV), Prostate & Pelvic Nodes (PPN) and Head & Neck (HN).

#### Material and Methods

A fully automated VMAT planning system has been developed using the scripting functionality of RayStation (RaySearch Laboratories, Stockholm, Sweden). For each treatment site, a set of clinical priorities is determined as a list of constraints and 'tradeoffs'. The system is designed to ensure constraints are met while optimization of the prioritized tradeoffs is guided by an *a priori* calibration process. This process involves optimizing for the first priority trade-off with a range of objective weights. A GUI allows the user to navigate through these plans using the DVH and dose-distribution to determine the optimal weight. This weight is then stored and the process is repeated for the next priority. When all trade-offs have been optimized, the whole process is repeated to refine the set of objective weights.

As the underlying automated-planning algorithm tailors the base plan to individual patient anatomy, a single set of configuration data can be used for all patients of a given site and plan can be generated with no user interaction.

Ten patients of each configured site were planned using the automated system and compared against the clinically approved manual plan. Quantitative comparisons were made using relevant DVH metrics and qualitative comparisons of dose distributions.

#### Results

A selection of the DVH metrics, averaged across all patients in each site, is listed in Table 1. A set of representative dose distributions is provided in Figure 1. The tabulated data shows that the automated plans tend towards improved OAR sparing. For PSV and PPN, this was at the expense of target coverage. For HN plans, the automated plans improved coverage while also reducing OAR doses.

Visual comparisons of dose distributions showed that, for all three sites, the automated plans were of equal or better quality relative to manually optimized plans. All plans met local clinical DVH constraints and were deemed to be clinically acceptable.

Table 1: DVH metrics for Automated and Manual plans, averaged over all patients in category with standard deviations listed in parentheses. The PTV metrics are given as the percentage dose (relative to local prescription) received by a specified volume. OAR metrics are given as the volume receiving the specified dose.

ROI	Metric	PSV		PPN		HN	
		Automated	Manual	Automated	Manual	Automated	Manual
PTV1	D98%	96.2% (0.2)	96.5% (0.5)	96.2% (0.3)	96.5% (0.5)	96.0% (0.3)	95.1% (1.1)
	D2%	102.7% (0.1)	103.0% (0.3)	102.6% (0.1)	103.3% (0.3)	103.8% (0.1)	103.8% (0.4)

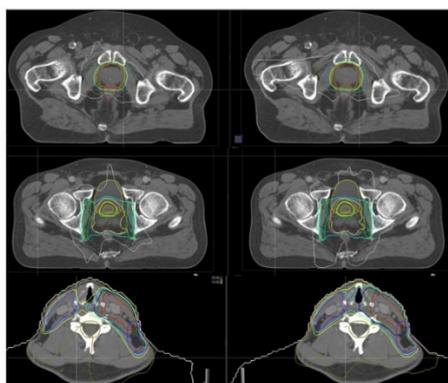

Figure 1: Representative dose distributions for PSV (top), PPN (middle) and HN (bottom) with automated plans to the left and manually optimized plans to the right

#### Conclusion

A fully automated planning system has been developed that allows configuration by expert treatment planners and oncologists. The evaluative study presented shows high quality plans can be produced with no user input, following the initial site-specific configuration process. This simple process allows high-quality automated plans to be produced for new treatment sites in an efficient manner.

#### OC-0447 CyberArc: a 4 $\pi$ -arc optimization algorithm for CyberKnife

V. Kearney<sup>1</sup>, J. Cheung<sup>1</sup>, T. Solberg<sup>1</sup>, C. McGuinness<sup>1</sup>

<sup>1</sup>University of California UCSF, department of radiation oncology, San Francisco CA, USA

#### Purpose or Objective

To demonstrate the feasibility of 4 $\pi$ -arc radiotherapy using CyberKnife for decreased treatment delivery times.

#### Material and Methods

A novel 4 $\pi$ -arc optimization algorithm (CyberArc) was developed and evaluated in 4 prostate and 2 brain cancer patients previously treated with CyberKnife using Iris collimation. CyberArc was designed for continuous radiation delivery between beam and node positions using 4 $\pi$  treatment geometry. During beam delivery, the isocenter and Iris collimator diameter are allowed to freely move within machine tolerances. For comparison purposes, new plans were generated using the same total number of beams and range of Iris collimation. Dose calculation was based on the MatRad pencil beam algorithm, modified using the machine commissioning data to fit the CyberKnife flattening filter free beam profiles and percent depth doses. An initial 4 $\pi$  library of beam coordinates is cast over the allowed delivery space. A constrained subplex-based optimization algorithm then selects from an initial library of 6 node positions for each beam coordinate using a 5mm x 5mm fluence map resolution to obtain the first set of beam/node/collimator configurations. A preliminary monitor unit calculation is performed, and beam/node/collimator positions that fall under a threshold are discarded. A 3D traveling salesman problem is solved using a genetic algorithm to obtain the paths between beams (Figure 1). From the second set of beam/node/collimator positions, intermediate beam/node/collimator coordinates are calculated along the path between neighboring coordinates using cubic interpolation. A third set of continuous intermediate beam/node/collimator doses are calculated every 2° along the arc path with a 2mm x 2mm fluence map resolution. MUs are calculated for each beam/node/collimator position using an L-BFGS-B optimization engine. All plans were normalized to the 70% dose volume of the PTV for comparison.

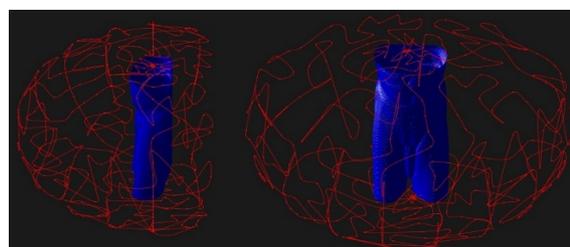

Figure 1. The set of final beam positions and their corresponding paths for prostate patient 3.

#### Results

Among the six patients analyzed, the average difference in PTV min dose, max dose, and V95 was  $2.47\% \pm 2.13\%$ ,  $4.11\% \pm 2.62\%$ , and  $1.63\% \pm 3.01\%$  respectively. The average conformity index (CI) was  $1.09 \pm 0.07$  for the brain patients and  $1.12 \pm 0.09$  for the prostate patients. Figure 2 shows the plan comparison DVHs for a prostate and brain

patient. On average CyberArc decreased treatment times by  $1.76x \pm 0.23x$  for the prostates cases and  $1.62x \pm 0.13x$  for brain patients, not taking into consideration the gantry speed limitations. Staying within the tolerance of the machine speed specifications, the average time decrease was  $1.56x \pm 0.19x$  for prostate patients and  $1.39x \pm 0.11x$  for brain patients.

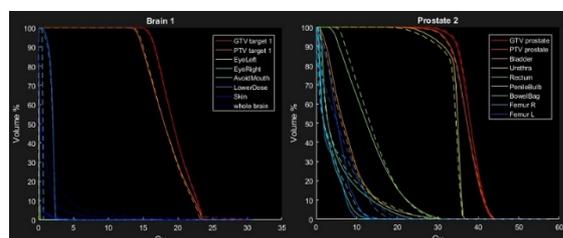

Figure 2. DVH comparison between the original CyberKnife plan (solid line) and the corresponding CyberArc plan (dashed line).

#### Conclusion

CyberArc is able to deliver plans that are dosimetrically comparable to their CyberKnife counterparts, while reducing treatment times considerably.

#### OC-0448 Near real-time automated dose restoration in IMPT to compensate for daily tissue density variations

T. Jagt<sup>1</sup>, S. Breedveld<sup>1</sup>, S. Van de Water<sup>1</sup>, B. Heijmen<sup>1</sup>, M. Hoogeman<sup>1</sup>

<sup>1</sup>Erasmus MC Cancer Institute, Radiation Oncology, Rotterdam, The Netherlands

#### Purpose or Objective

Intensity-modulated proton therapy (IMPT) allows for very localized dose deposition, but is also highly sensitive to daily variations in tissue density along the pencil beam paths, induced for example by variations in organ filling. This potentially results in severe deviations between the planned and delivered dose. To manage this, we developed a fast dose restoration method that adapts the treatment plan in near real-time.

#### Material and Methods

The dose restoration method consists of two steps: (1) restoration of the geometrical spot positions (Bragg peaks) by adapting the energy of each pencil beam to the new water equivalent path length (Figure 1), and (2) re-optimization of pencil beam weights by minimizing the dosimetric difference with the planned dose distribution, using a fast and exact quadratic solver.

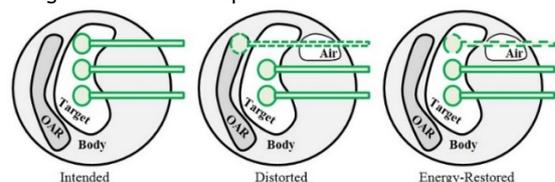

Figure 1 Restoring spot positions. Left: The intended spot positions. Middle: An air cavity causes a displacement and a change in spot shape (not depicted). Right: The energy of the pencil beam has been adapted to restore the spot position.

The method was evaluated on 10 prostate cancer patients, using 8-10 repeat CT scans; 1 for planning and 7-9 for restoration. The scans were aligned based on intra-prostatic markers. Prostate, lymph nodes and seminal vesicles were delineated as target structures. Dose was prescribed according to a simultaneously integrated boost scheme assigning 74 Gy to the high-dose planning target volume (PTV) (prostate + 4 mm) and 55 Gy to the low-dose PTV (lymph nodes and seminal vesicles + 7 mm).

#### Results

While substantial dose deviations were observed in the repeat CT scans without restoration, clinically acceptable dose distributions were obtained after restoration (Figure

2). This resulted in PTV  $V_{95\%} \geq 98\%$  and  $V_{107\%} \leq 2\%$  for all scans. For the bladder, the differences between the restored and intended treatment plans were below 2 Gy and 2%-point. The rectum differences were below 2 Gy and 2%-point for 90% of the scans. In the remaining scans the rectum was filled with air and partly overlapped with the PTV, resulting in unavoidably higher rectum doses.

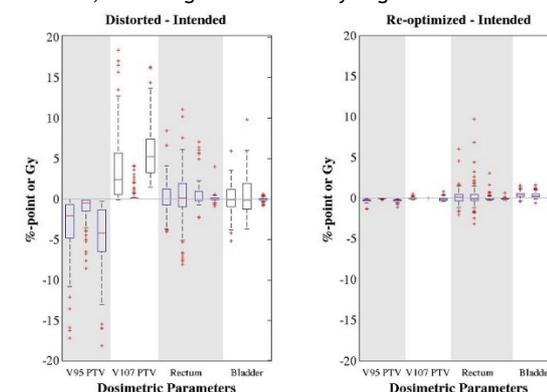

Figure 2 Boxplots showing differences in dosimetric parameters between the distorted and intended (left) and re-optimized and intended dose distributions (right) for all 80 scans. Left to right, rectum parameters:  $D_{mean}$ ,  $V_{45Gy}$ ,  $V_{60Gy}$ ,  $V_{75Gy}$  and bladder parameters:  $D_{mean}$ ,  $V_{45Gy}$ ,  $V_{65Gy}$ .

The mean time needed for energy adaptation was 5.4 seconds (3.5-10.6). The re-optimization time was on average below 5 seconds (maximum 9.0). The most time consuming and currently limiting operation was calculating the dose distribution matrix (average 4.3 minutes (2.4-9.6)), performed once between the two steps.

#### Conclusion

The impact of density variations on the pencil beam path in IMPT can be reduced by performing an automated dose restoration consisting of a water equivalent path length correction of the pencil beams, followed by a re-optimization of the pencil beam weights.

#### Proffered Papers: Planning and quality assurance

#### OC-0449 A novel and objective plan evaluation for limb sarcomas IMRT in the IMRiS phase II trial

R. Simões<sup>1</sup>, H. Yang<sup>1</sup>, R. Patel<sup>1</sup>, F. Le Grange<sup>2</sup>, S. Beare<sup>3</sup>, E. Miles<sup>1</sup>, B. Seddon<sup>2</sup>

<sup>1</sup>Mount Vernon Cancer Centre, National Radiotherapy Trials Quality Assurance RTTQA Group, London, United Kingdom

<sup>2</sup>University College Hospital, Sarcoma Unit, London, United Kingdom

<sup>3</sup>University College of London, Cancer Research UK & University College London Cancer Trials Centre, London, United Kingdom

#### Purpose or Objective

IMRiS (Clinicaltrials.gov id:NCT02520128) is a multicentre phase II trial of intensity modulated radiotherapy (IMRT) in soft tissue and bone sarcomas. IMRT was implemented in the UK for limb soft tissue sarcomas (STS) in the context of this trial, which opened to recruitment in March 2016. As limb STS volumes are very variable, there are several ways of optimising the plans. It is often difficult to assess plan quality without understanding fully if the presented plan has been well optimised. We describe novel metrics used to evaluate IMRT plan quality for limb STS.

#### Material and Methods

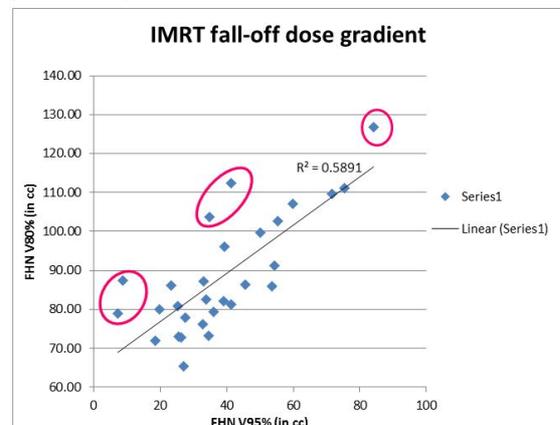

A case of liposarcoma of the left thigh was available to the 29 IMRiS participating centres. The prescription was 50Gy in 25 fractions. The clinical target volumes and the

relevant organs at risk (OAR) were pre-contoured. The planning target volume (PTV) was derived at each centre (5-10 mm). All plans were checked, PTV conformity (PTV  $V_{95\%}/PTV_{V_{total}}$ ) and PTV compromise (OAR  $V_{95\%}/OAR \& PTV_{V_{Total\ overlap}}$ ) indexes were also calculated. The relevant OAR for this case were the femoral head and neck (FHN) and the femur in treatment field (FTF). The IMRT dose fall-off gradient for FHN (FHN  $V_{95\%}/FHN_{V_{80\%}}$ ) was also assessed. Normal tissues and the joint were not analysed, as their tolerances were easily met for this specific case.

### Results

19 centres completed 20 IMRT plans. The plan quality of 9/20(45%) submissions was suboptimal and had to be repeated. The results (see table) include the resubmitted cases (total 29 plans). The case was particularly challenging near FHN and FTF, due to an overlap of OARs with the PTV. Depending on PTV margins, overlapping FHN volumes varied from 13.8% (for PTV margins of 5mm) to 33.0% (for PTV margins of 10mm). FTF overlapping volume with PTV ranged from 24.7% to 51.1%. Plans were very conformal to PTV; however, the PTV conformity index was not useful for areas where PTV overlapped with OAR. We therefore calculated a compromise index for the PTV areas overlapping with FHN and FTF, which support the visual assessment of plans. The graph below highlights plans in which  $V_{80\%}$  was suboptimal in relation to the  $V_{95\%}$  (in total 5 plans had a suboptimal IMRT fall-off dose gradient).

Assessment method	Recommended	Mean (range; Standard deviation)	Suboptimal plans based on the assessment method
PTV coverage	$V_{95\%} > 95\%$	98.28% (94.53%-113.37%; $\pm 3.11\%$ )	0
PTV conformity index	(as close to 1 as possible)	0.98 (0.95-1.00; $\pm 0.1$ )	0
Femoral Head and Neck	Mean dose < 40Gy	40.26Gy (37.22-45.56; $\pm 1.86$ )	9
Femur in treatment field	$V_{50Gy} < 50\%$	8.27% (0.02-33.31; $\pm 8.11$ )	9
PTV compromise index near FHN	(as close to 1 as possible)	1.32 (0.17-2.80; $\pm 0.57$ )	9 plans excessively covered FHN 3 plans under covered PTV
PTV compromise index near FTF	(as close to 1 as possible)	1.44 (0.00-2.64; $\pm 0.57$ )	14 plans excessively covered FTF 2 plans under covered PTV

### Conclusion

Limb STS tumours are a heterogeneous group of tumours with significant variation in PTV shape and size. Evaluating the plans for a newly implemented technique can be challenging, particularly when determining if a plan is optimal. We developed an objective assessment method that is applicable to all limb STS. The first planning results show that 45% of plans had either compromised PTV coverage in favour of meeting OAR dose constraints, or had not created a steep enough dose gradient near the OAR. We attribute this to a change in the planning technique paradigm, as many of the centres were using IMRT for limb STS for the first time.

### OC-0450 Geometric variation of the axillary lymph node region in locoregional breast/chest wall irradiation.

K.N. Goudschaal<sup>1</sup>, N. Bijker<sup>1</sup>, A. Bel<sup>1</sup>, N. Van Wieringen<sup>1</sup>, M. Kamphuis<sup>1</sup>

<sup>1</sup>Academic Medical Center, Radiotherapie, Amsterdam, The Netherlands

### Purpose or Objective

Image-guided radiation therapy (IGRT) for patients who will be treated to both the breast/chest wall and the axillary lymph node region (ALNR) is performed with Conebeam-CT (CBCT). The position verification is based on the breast/chest wall registration. The current planning technique is a combination of a quarter field fast-forward intensity modulated radiation therapy (IMRT) for the breast/chest wall with an AP-PA beam technique for the ALNR. This technique is robust for the daily position variation of the ALNR but is not very conformal. We are planning to introduce a volumetric arc therapy (VMAT) technique which is highly conformal but the margins to account for daily position variation are not known. The aim of this study is to determine the daily positional variation of the ALNR relative to the breast.

### Material and Methods

The study population consisted of 20 female patients treated with locoregional radiotherapy for stage II to IV breast cancer. For all 20 patients the target volume was the breast/chest wall and the ALNR level 1 and 2 or level 1 to 4, depending on the TNM classification. A standard clinical target volume (CTV) to planning target volume (PTV) margin of 5 mm is used for the entire axilla area and the delineated breast is the PTV. The patient positioning was supine with both arms up on a CQual breastboard including a wedge position combined with a knee support (CIVCO, USA). The clinical IGRT protocol with CBCT is based on the position variation of the breast/chest wall. A bony registration with a region of interest (ROI) on bony anatomy (ribs and sternum) is used as a surrogate for the breast position (XVI 4.5, Elekta).

For this study 138 CBCTs were retrospectively registered on level 1 to 3 and 66 CBCTs on level 4. The CBCT analysis was based on:

1. registration of the breast/chest wall using a ROI (figure 1) on bony anatomy of the ribs and sternum;
2. registration of the ALNR using shaped ROI (SROI, figure 1) around level 1, 2, 3 and 4. The SROI is a ROI that can be designed in the shape of each level separately. No bony elements were included in these SROIs. The geometric variation was expressed as the displacement of the ALNR relative to the breast. The mean, systematic and random setup errors of the displacement of level 1 to 4 were calculated.

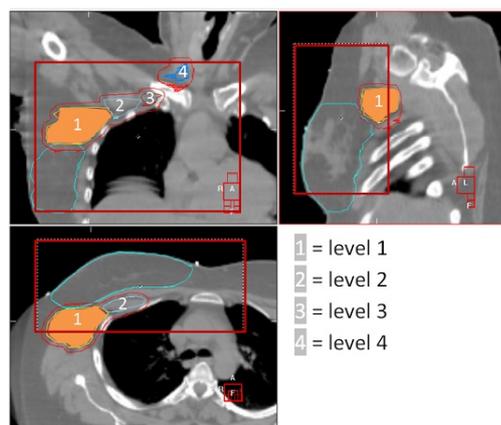

Figure 1: reference CT with ROI in red and an example of a SROI of level 1 in orange. SROI of level 2,3, and 4 are not shown in figure 1.

### Results

The mean displacement for each level of the ALNR is small (table 1). Considerable geometric variation was found for Level 1 in ventral-dorsal (VD) direction. This may be due

to variation in arm / shoulder positioning on the breastboard armrests.

Level	# CBCTs	Geometric variation	LR (mm)	CC (mm)	VD (mm)
Level 1	N=138	Mean	0.2	0.1	-0.7
		Systematic error $\Sigma$	1.3	<b>2.5</b>	<b>4.2</b>
		Random error $\sigma$	1.3	<b>2.7</b>	<b>3.4</b>
Level 2	N=138	Mean	-0.0	1.0	-0.6
		Systematic error $\Sigma$	<b>1.6</b>	1.4	1.4
		Random error $\sigma$	<b>1.4</b>	1.2	1.4
Level 3	N=138	Mean	-0.5	0.7	-0.3
		Systematic error $\Sigma$	1.4	1.0	1.2
		Random error $\sigma$	1.0	1.2	1.2
Level 4	N=66	Mean	-0.3	0.9	0.8
		Systematic error $\Sigma$	0.9	1.6	1.1
		Random error $\sigma$	0.9	1.0	1.2

Table 1: results of the geometric variation (1 SD) of the ALNR Level 1 to 4 relative to the breast. LR=left-right (X), CC=cranio-caudal (Y) and VD=ventro-dorsal (Z) direction in mm. In bold the highest errors of each direction.

### Conclusion

With the current patient set up there is a considerable geometric variation in Level 1 in VD direction. Introducing a highly conformal technique requires adaptation of currently used margins for adequate target coverage of both the breast/chest wall and the ALNR.

### OC-0451 Effect of cardiac motion on displacement of LAD artery in gated left breast treatment using MRI

S.Y. Ng<sup>1</sup>, W.K. Fung<sup>1</sup>, K.M. Ku<sup>1</sup>, O.L. Wong<sup>2</sup>, G. Chiu<sup>1</sup>

<sup>1</sup>Hong Kong Sanatorium & Hospital, Department of Radiotherapy, Hong Kong, Hong Kong SAR China

<sup>2</sup>Hong Kong Sanatorium & Hospital, Medical Physics & Research Department, Hong Kong, Hong Kong SAR China

### Purpose or Objective

Respiratory control has been promoted to minimize dose to heart during left sided breast radiotherapy. However, there is limited data to address the effect of intrinsic cardiac motion during actual treatment. This study quantified the effect of both cardiac motion and respiratory motion on variation in distance between left anterior descending artery (LAD) and chest wall,  $D_{LAD}$ , for gated left-sided breast radiotherapy using MRI.

### Material and Methods

Eighteen healthy female volunteers aged  $32.1 \pm 5.0$  were scanned in a 1.5T MR simulator (MAGNETOM Aera, Siemens Healthcare) with cine mode for respiratory motion (images<sub>resp</sub>) and cardiac triggered cine mode for cardiac motion (images<sub>card</sub>), at the middle slice locations of three equal segments of LAD (proximal, middle and distal). The images were sorted into 10 phases for respiratory cycle and cardiac cycle respectively.  $D_{LAD}$  was measured in each slice of images<sub>resp</sub> as shown in Figure 1. The maximum LAD displacement along the direction of  $D_{LAD}$  ( $Maxdisp_{LAD}$ ) was measured in images<sub>card</sub>.

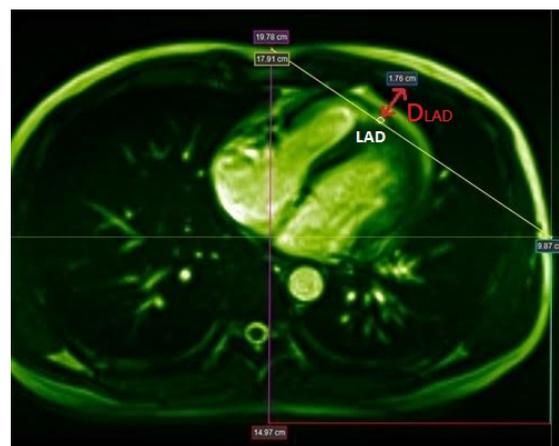

Figure 1: Measurement of  $D_{LAD}$

### Results

For proximal, middle and distal LAD, 78%, 72% and 61% of subjects had both the longest  $D_{LAD}$  in end-inspiratory (90-10%) phase and shortest  $D_{LAD}$  in end-expiratory (40-60%) phase. The average  $D_{LAD}$  in end-inspiratory phase and end-expiratory phase were  $13.1 \pm 2.0$ mm,  $12.7 \pm 1.8$ mm,  $11.6 \pm 1.5$ mm and  $10.9 \pm 1.5$ mm,  $10.5 \pm 1.4$ mm,  $9.5 \pm 1.3$ mm for proximal, middle and distal LAD respectively. While the  $D_{LAD}$  decreased from proximal to distal portion of LAD in both phases, the extension of  $D_{LAD}$  from end-inspiratory phase to end-expiratory phase were similar in all LAD portions (proximal:  $2.1 \pm 0.9$ mm; middle:  $2.2 \pm 0.8$ mm; distal:  $2.1 \pm 0.5$ mm). The average  $Maxdisp_{LAD}$  due to cardiac motion were also similar in proximal, middle and distal portion, which were  $2.6 \pm 0.6$ mm,  $2.4 \pm 0.5$ mm and  $2.6 \pm 0.7$ mm respectively. When accounting both cardiac and respiratory motions,  $D_{LAD}$  could be shorter than expected. To account the effect of both cardiac and respiratory motions, the shortest distance between LAD and chest wall ( $D_{LAD} - 0.5 \times Maxdisp_{LAD}$ ) was estimated for end-inspiratory and end-expiratory phase. The averages were  $11.8 \pm 2.1$ mm,  $11.5 \pm 1.8$ mm,  $10.3 \pm 1.6$ mm and  $9.6 \pm 1.7$ mm,  $9.3 \pm 1.4$ mm,  $8.2 \pm 1.4$ mm for proximal, middle and distal LAD respectively.

### Conclusion

Most patients could be benefited from gated radiotherapy using end-inspiratory phase (90-10%). However, the distance between LAD and chest wall could be shorter than expected due to random cardiac motion during actual treatment delivery. Special attention should be put on distal portion of LAD as it had the closest proximity to chest wall. A minimum clearance of 2mm ( $-0.5 \times Maxdisp_{LAD}$ ) from the LAD to the high dose zone during treatment planning is recommended to compensate for LAD displacement due to cardiac motion for patient receiving gated left breast radiotherapy.

### OC-0452 Evaluation of a novel field placement algorithm for tangential internal mammary chain radiotherapy

<sup>1</sup>Royal Marsden Hospital Trust & Institute of Cancer Research, Clinical Oncology, London, United Kingdom

<sup>2</sup>Edinburgh Cancer Centre, Clinical Oncology, Edinburgh, United Kingdom

<sup>3</sup>Royal Marsden Hospital Trust & Institute of Cancer Research, Physics, London, United Kingdom

<sup>4</sup>Royal Marsden Hospital Trust, Radiotherapy, London, United Kingdom

<sup>5</sup>Portsmouth Hospital NHS Trust, Clinical Oncology, Portsmouth, United Kingdom

<sup>6</sup>Cambridge University Hospitals NHS Trust, Clinical Oncology, Cambridge, United Kingdom

### Purpose or Objective

Published data demonstrate an overall survival benefit associated with including the internal mammary chain (IMC) in the radiotherapy target volume (TV) for women with node positive breast cancer. Implementation of IMC-RT will be facilitated by development of resource efficient techniques. However, even relatively simple techniques rely on time consuming clinician outlining of lymph nodes to achieve adequate dose to the TV (not well covered by standard fields based on bony landmarks). In order to reduce the resource burden of nodal contouring, an anatomical point based algorithm for guiding field placement was developed and tested for its ability to ensure TV coverage.

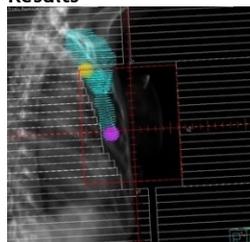

### Material and Methods

Point	Description
Point 1 (Sup_AF): Cranial border of the anterior field (previously called 'SCF field')	2.5cm point with its central axis at the superior border of the subclavian artery arch.
Point 2 (Med_AF): Medial border of the anterior field	2cm point with central axis at medial edge of the internal jugular vein.
Point 3 (Lat_AF): Lateral border of the anterior field	The lateral aspect of the field should be dictated by the nodal levels requiring treatment. E.g. To cover Level 3 - Place a 2cm point with its central axis at the medial edge of pectoralis minor muscle (at its superior aspect).
Point 4 (Med_Tangs): Posterior border of tangential fields (Medial aspect)	At the superior border of tangents (1 CT slice below the match line), place a 2cm point with its central axis on the internal mammary artery.
Point 5 (Lat_Tangs): Posterior border of tangential field (Lateral aspect)	The lateral aspect of the field edge will be dictated by the lateral tattoo and breast tissue as normal. If treating Level 1 place a 1cm point with its posterior border abutting the anterior edge of the latissimus dorsi muscle at the level of the 4th rib (in the mid axillary line).
Point 6 (Inf_IMC): Inferior border of the IMC (used to inform cardiac/lung shielding)	Place a 2cm point centred on the internal mammary vein at the cranial edge of the 4th rib (at its intersection with the sternum).

Table 1: Table of points and abridged description

We identified six points, representative of regional lymph node level borders according to ESTRO consensus guidelines, and tested these for their ability to inform field placement adequately covering the TV (Table 1). Written instructions were developed and a cohort of 20 cases identified as a validation group. 'Gold standard' nodal volumes (Levels 1-4 and IMC) were delineated according to ESTRO consensus guidelines by four clinical oncologists with experience in locoregional breast radiotherapy. Six independent testers (three clinicians and three radiographers blinded to the nodal volumes) were invited to place points and consequently fields on the cases. In four cases a clinician placed both the points and fields, in eight cases a clinician placed the points and radiographer applied the fields and in eight cases points and fields were placed by a radiographer. Cases were planned using forward planned techniques. The dose objective to the nodal PTV was  $V_{32Gy} \geq 90\%$ .

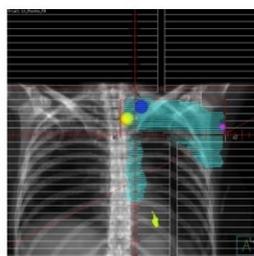

### Results

Right anterior oblique beam

Figure 1: Digitally reconstructed radiographs demonstrating points placed according to the algorithm, fields placed according to these points and coverage of the 'gold standard' nodal volumes (light blue)

Note: The superior border of the right anterior oblique field will be matched to the inferior border of the anterior field

Anterior field

Fourteen of 20 cases met the dose objectives when testers followed the written algorithm alone (Figure 1). Of the remaining six cases, four failed due to the subclavian vein being mistaken for the subclavian artery. Two failed due to point 3 being placed at the inferior part of the pectoralis minor muscle resulting in insufficient coverage of level 3. When the points were re-placed correctly nodal TVs were well covered.

### Conclusion

The results suggest that, in the majority of cases, by following the algorithm clinicians and radiographers can appropriately place fields which result in acceptable nodal

TV coverage. To avoid the common mistakes encountered, a new approach to training including verbal instructions is being developed for testing. Our aim is to demonstrate benefits in clinical workflow and expand validation to other RT centres.

### OC-0453 Stereotactic radiosurgery for multiple brain metastases: Results of multi-centre benchmark studies

D.J. Eaton<sup>1</sup>, J. Lee<sup>1</sup>

<sup>1</sup>Radiotherapy Trials QA group RTTQA, Mount Vernon Hospital, Northwood, United Kingdom

### Purpose or Objective

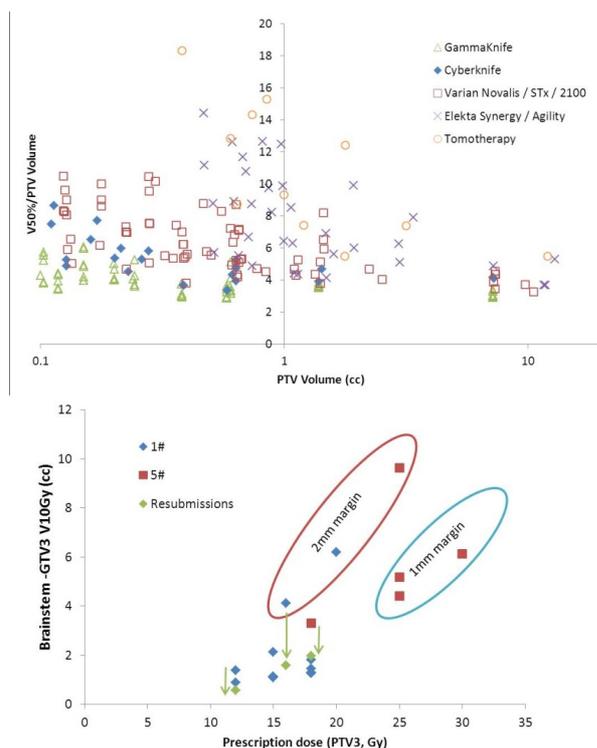

Stereotactic radiosurgery (SRS) is strongly indicated for treatment of multiple brain metastases. Various treatment platforms are available, and comparisons have been made between modalities, but mostly in single centre studies. A pre-requisite for all providers selected as SRS/SRT centres in England was to participate in a quality assurance process, informed through collaboration between the national trials QA group and a multidisciplinary expert advisory group. All clinical centres undertook planning benchmark cases, providing a unique dataset of current practice across a large number of providers and a wide range of equipment. This was used to facilitate sharing of best practice and support centres with less experience.

### Material and Methods

Two brain metastases cases were provided, with images and structures pre-drawn, involving three and seven lesions respectively. Centres produced plans according to their local practice, and these were reviewed centrally using metrics for target coverage, selectivity, gradient fall-off and normal tissue sparing.

### Results

38 plans were submitted, using 21 different treatment platforms, including Gamma Knife, Cyberknife, Varian (Novalis / Truebeam STx / 2100), Elekta (Synergy / Versa HD using Beam Modulator / Agility MLC) and Tomotherapy. 6 plans were subsequently revised following feedback, and review of 4 plans led to a restriction of service in 3 centres. Prescription doses were typically 18-25Gy in 1 fraction (or 27/3fr), except for a lesion within the brainstem, which was prescribed 12-20Gy in 1 fraction (or 18-30Gy/5fr). All centres prioritised coverage, with the prescription isodose covering  $\geq 95\%$  of 208/209 lesions. Selectivity was much more variable, especially for smaller lesions, and in some cases this was combined with high gradient index, resulting in large volumes of normal tissue being irradiated. Both Tomotherapy submissions were outliers in terms of either selectivity or gradient index, but all other platforms were able to give plans with relatively low gradient indices for larger lesion volumes, although there was more variation among Varian and Elekta plans, than for Gamma Knife and Cyberknife (first figure). There were also larger differences for the smaller volumes, with increasing variation both inter- and intra-treatment-platform. Doses to normal brain and brainstem were highest when PTV margins were applied, but substantial improvements were possible by re-planning, even without changing margin size (second figure).

### Conclusion

These benchmarking exercises give confidence in the safe and consistent delivery of SRS services across multiple centres, but have highlighted areas of different priorities, and potential for service improvement. The data can be used to progress standardisation and quality improvement of national services in the future, and may also provide useful guidance for centres worldwide.

### OC-0454 End-to-end QA methodology for proton range verification based on 3D-polymer gel MRI dosimetry

E. Pappas<sup>1</sup>, I. Kantemiris<sup>2</sup>, T. Boursianis<sup>3</sup>, G. Landry<sup>4</sup>, G. Dedes<sup>4</sup>, T.G. Maris<sup>3</sup>, V. Lahanas<sup>5</sup>, M. Hillbrand<sup>6</sup>, K. Parodi<sup>4</sup>, N. Papanikolaou<sup>7</sup>

<sup>6</sup>Rinecker Proton Therapy Center, Department of Medical Physics, Munich, Germany

<sup>7</sup>University of Texas Health Science Center, Department of Radiation Oncology-, San Antonio- Texas, USA

### Purpose or Objective

In clinical proton therapy, proton range measurements are associated with considerable uncertainties related to : a) imaging, b) patient set-up, c) beam delivery and d) dose calculations. A sophisticated QA process that can take into account all the mentioned sources of uncertainties is required in clinical practice. In this work, cubic phantoms filled with VIPAR polymer gels have been used towards this aim. An investigation of the gels dosimetric performance and their potential use for proton dosimetry purposes and as an end-to-end QA method for proton range verification has been implemented.

### Material and Methods

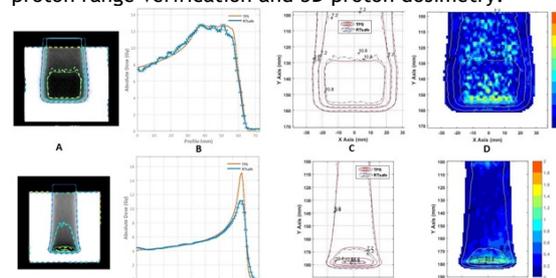

Three hollow plexiglass cubes filled with VIPAR polymer gel were produced and used in this study. Planning CT scans of each one of the gel filled cubes and arbitrary RStructures have been used for treatment planning. Cube-1 was planned to be irradiated with mono-energetic proton beams (90MeV & 115MeV) avoiding overlapping of the irradiated gel areas (Max Dose : ~ 15 Gy). Cube-2 was planned to be irradiated with a multi-energetic beam forming a spread-out Bragg peak (SOBP) (Max Dose : ~ 13 Gy). Cube-3 was planned to be irradiated with two opposing beams (Max Dose : ~ 13 Gy) each delivering an overlapping and uniform SOBP. Set-up and irradiation of each cube followed. One day post-irradiation each cube was MRI scanned in order to derive high spatial resolution 3D-T2 maps that were subsequently co-registered to the corresponding planning-CT scans and DICOM-RT Dose and Structure data. Assuming a linear gel dose response, 1D, 2D and 3D dose measurements were derived and compared against corresponding TPS data.

### Results

VIPAR gel response seem to be non-dependent on LET for LET values < ~6 keV/μm implying that their use for most clinical cases is acceptable. No matter their LET dependence, the protons range can be well verified. Even if uncertainties related to imaging, set-up, beam delivery, dose calculations, co-registration, gels LET dependence were incorporated, the range measured by the proposed method was within ~ 1 mm to that calculated by TPS. Moreover, the corresponding ranges at the 80% value of the maximum dose point for both TPS and polymer gels derived percentage depth dose profiles (pdds) were equal within ~1 mm. Additionally, for the opposed beams experiment (cube-3), the proposed methodology results in even more accurate dosimetry due to the reduced LET values inside the SOBP compared to the high LET values present in the irradiated schemes of cubes 1 and 2.

### Conclusion

The proposed End-to-End Quality Assurance method based on polymer gel dosimetry, provides valuable outcomes for proton range verification and 3D proton dosimetry.

### PV-0456 Volumetric Modulated Arc Therapy for patients with bilateral breast cancer

S. Lutjeboer<sup>1</sup>, J.W.A. Rook<sup>1</sup>, G. Stiekema<sup>1</sup>, A.P.G. Crijns<sup>1</sup>, N.M. Sijtsema<sup>1</sup>, E. Blokzijl<sup>1</sup>, J. Hietkamp<sup>1</sup>, J.A. Langendijk<sup>1</sup>, A.J. Borden van der<sup>1</sup>, J.H. Maduro<sup>1</sup>

<sup>1</sup>UMCG University Medical Center Groningen, Radiation Oncology, Groningen, The Netherlands

### Purpose or Objective

The objective was to study the differences in target coverage and dose-volume parameters for heart and lung between Deep Inspiration Breath Hold (DIBH) 3D Conformal Radiation Therapy (3D-CRT), DIBH Volumetric Modulated Arc Therapy (VMAT) and free breathing Intensity Modulated Radiation Therapy (IMRT) in patients treated with synchronous bilateral breast cancer.

### Material and Methods

This planning comparative study was conducted in nine patients previously treated for synchronous bilateral breast cancer. These patients were treated with either DIBH 3D-CRT or IMRT in free breathing. All patients were treated with whole breast irradiation and those requiring a boost were given a simultaneously integrated boost (SIB). Three treatment plans were constructed for each patient individually; a DIBH 3D-CRT plan, a DIBH VMAT plan and an IMRT plan in free breathing. DIBH IMRT is clinically not feasible due to the extended duration of treatment. Three patients were treated without a boost, three were treated with unilateral SIB and the remaining patients were treated with double sided SIB. DIBH 3D-CRT plans were created using tangential fields for both breasts and up to three boost fields for each breast, if a boost was required. IMRT plans were created using 14 fields around the patient, 24° apart, covering both breasts and simultaneously covering the boost target in one or both breasts. DIBH VMAT plans without boost targets were created using eight 30° arcs, four on each side, oriented in a tangential design. Four 60° arcs, in a tangential design, were used in patients with boost targets, two for each breast, with an additional semi-circle arc on either side covering the boost targets. The parameters reviewed were V95% (percentage of volume receiving 95% of the prescription dose) PTV1 and PTV2 coverage, with PTV1 being the elective target and PTV2 the boost target, the mean heart dose and heart left ventricle V5 (percentage of volume receiving 5 Gy), mean lung dose, lung V5 and lung V20. The parameters were compared using the paired T-test for normally distributed data and the Wilcoxon signed rank-test for not normally distributed data. Three statistical analyses were performed on each parameter, therefore the Bonferroni correction was applied.  $P \leq 0.016$  was considered statistically significant in this study.

### Results

Target coverage of PTV1 and PTV2 were comparable between the three techniques (table 1), except the V95% PTV1 left. All dose volume parameters of the heart and lung were lower for the DIBH VMAT technique (table1) in comparison with the DIBH 3D-CRT and free breathing IMRT technique.

	DIBH 3D-CRT x ± σ	IMRT x ± σ	DIBH VMAT x ± σ	3D-CRT vs IMRT (p-value)	3D-CRT vs VMAT (p-value)	IMRT vs VMAT (p-value)
<b>Lung</b>						
Mean (Gy)	9,44 ± 3,06	8,64 ± 1,67	7,63 ± 2,07	0,258	0,031	0,053
V20v (%)	17,22 ± 6,82	14,01 ± 4,12	12,83 ± 4,83	0,068	0,015	0,341
<b>Heart</b>						
Mean (Gy)	4,77 ± 1,60	4,57 ± 1,10	3,31 ± 1,03	0,535	0,005	0,014
Left Ventricle V5v (%)	12,45 ± 11,24	18,53 ± 7,52	8,78 ± 7,73	0,088	0,084	0,008
<b>PTV1</b>						
Right V95v (%)	95,20 (1,34)	94,48 (1,94)	96,04 (1,61)	0,678	0,086	0,021
Left V95v (%)	95,08 (3,34)	94,84 (3,46)	95,12 (1,20)	0,214	0,678	0,011
<b>PTV2</b>						
Right V95v (%)	94,46 (1,33)	95,50 (2,23)	96,73 (0,97)	0,374	0,140	0,089
Left V95v (%)	91,22 (3,39)	94,74 (5,59)	97,49 (1,62)	0,715	0,068	0,068
<b>Lung</b>						
V5v (%)	38,79 (9,87)	36,24 (12,34)	31,47 (10,09)	0,374	0,110	0,011

### Conclusion

DIBH VMAT is the most optimal radiation technique in the treatment for patients with synchronous bilateral breast cancer. Both PTV coverage and the sparing of the organs at risk give better results for DIBH VMAT in comparison with DIBH 3D-CRT and IMRT in free breathing.

### PV-0457 Delay between planning and stereotactic radiotherapy for brain metastases: margins still accurate?

C. Bonnet<sup>1</sup>, A. Dr Huchet<sup>1</sup>, E. Blais<sup>1</sup>, J. Dr Benech-Faure<sup>1</sup>, R. Dr Trouette<sup>1</sup>, V. Dr Vendrely<sup>1</sup>

<sup>1</sup>Hopital Haut Leveque, Radiotherapy, Pessac, France

### Purpose or Objective

Advances in intracranial stereotactic radiotherapy have led to high gradient dose between tumor and normal tissue and to dramatically reduced Planning Target Volume (PTV) margins. Accurate definition of the gross tumor volume (GTV) for stereotactic radiotherapy of brain metastases is an essential key for the treatment planning. However, its underestimation due to tumor growth during the delay between planning and stereotactic radiotherapy may lead to treatment failure.

Our purpose was to evaluate the tumor growth kinetics and its impact during the delay before treatment of brain metastasis secondary to lung cancer (LC) or melanoma (ML).

### Material and Methods

This retrospective monocentric study included all consecutive patients (pts) treated for brain metastases secondary to LC or ML between June 2015 and May 2016. Margins from GTV to PTV were 2 mm. Imaging at diagnosis of brain metastasis and preplanning imaging were compared; GTV corresponding to the contrast enhancement was analyzed. Linear extrapolation was used to determinate the n minimum theoretical time leading the diameter of the tumor to increase more than 4 mm (T4mm).

### Results

Out of 103 pts treated for brain metastasis by stereotactic radiotherapy, 50 were treated for metastases secondary to LC (n=26) or ML (n=24). Six pts were excluded because of lack of imaging data. Median age was 68 years old (range: 25-92). RPA status was 1 for 1 patient (2%), 2 for 33 pts (79%) and 3 for 8 pts (19%). Systemic treatment was given at diagnosis for 19 pts (45 %). Radiotherapy was delivered according to a monofraction scheme for 8 pts (3 LC and 5 ML metastasis), 3-fraction scheme (23 LC, 18 ML) or 5-fraction scheme (2 LC, 3 ML).

A hundred and eight brain imaging (84 MRI, 24 CT-scan) were analyzed. Comparison of imaging at diagnosis and preplanning treatment showed bleeding inside metastasis for one patient with primary LC; increased tumor volume for 40 pts (ML n=25 ; LC n=15) ; stability for 11 pts (ML n=1 ; LC n=10) and decreased volume for one LC patient.

Median delay between brain imaging at diagnosis and pretreatment planning were: 28 days (range 8-107) for ML pts and 31.5 days (range 7-70) for LC pts. Median Volumes of GTV at diagnosis were 0.5 cm<sup>3</sup> (range 0.05-8.6cm<sup>3</sup>) for ML pts and 0.45cm<sup>3</sup> (range 0.05-6.1cm<sup>3</sup>) for LC pts; median volumes of preplanning treatment GTV were 1.55 cm<sup>3</sup> (range: 0.2-9.9cm<sup>3</sup>) for ML pts and 0.85 (range 0.2-10.4cm<sup>3</sup>) for LC patients. Linear extrapolation revealed a median increase of tumor volume of 0.16 cm<sup>3</sup>/wk (range 0-0.8 cm<sup>3</sup>/wk) for ML and 0.06 cm<sup>3</sup>/wk (range 0-0.5 cm<sup>3</sup>/wk) for LC. Shorter T4mm was 15 days for ML patients and 17 days for LC pts.

### Conclusion

Maximal delay for treatment appeared to be 15 days for ML patients and 17 days for LC patients to ensure that tumor radius has grown less than to 2 mm. Above this delay, clinicians should reconsider planning of treatment.

### PV-0458 FMECA of Cyberknife process: two years' experience for improvement

S. Cucchiario<sup>1</sup>, D. Dechambre<sup>1</sup>, T. Massoz<sup>1</sup>, N. Gourmet<sup>1</sup>, D. Boga<sup>1</sup>, N. Jansen<sup>1</sup>, P. Coucke<sup>1</sup>, M. Delgaudine<sup>2</sup>

<sup>1</sup>C.H.U. - Sart Tilman, Radiotherapy Departement, Liège, Belgium

<sup>2</sup>C.H.U. - Sart Tilman, STA Quality Departement, Liège, Belgium

### Purpose or Objective

Failure Modes Effects and Criticality Analysis (FMECA) is a risk analysis allowing the identification of causes and

effects of a potential problem and the prioritization of actions that can reduce this dysfunction. Our Radiation Therapy Department used the FMECA as a strategy tool to continuously improve treatment quality and safety. This FMECA approach was applied to our Cyberknife (CK) workflow process.

#### Material and Methods

Using the FMECA methodology, the CK workflow process was defined with a flow chart and responsibility map including a description of every step of prescription, treatment preparation and treatment delivery. The identification of possible risks was then carried out with their origins and consequences. The evaluation was based on 3 criteria: Severity (S), frequency of Occurrence (O) and probability of Detection (D). Finally, we calculated the Criticality Index (CI = S x O x D) for each of the identified risks. The rating for each criterion is based on a scale from 1 to 4. The Criticality Index can span a range of 1 to 64.

#### Results

We defined 10 stages, with corresponding failure modes presented in a table. At each stage, identified failures with possible causes and consequences are listed and the risk level assessed. A detailed scoreboard was obtained presenting the risks and enabling easier identification of priority actions to be undertaken. The board showed 66 possible failure modes. 8 of the top-ranked failure modes were considered for process improvements. We also crossed the scoreboard obtained with the adverse events most often reported on 2015. We found 2 correspondences between failure modes and adverse events reported. We therefore also considered that in the implementation of preventive/improvement actions to take. A review of this analysis was done in September 2016. Therefore, at this moment, a reevaluation of the process, failures, ratings and implemented actions was performed with each members of the CK team. The correlation with reported adverse events was also made. We had one failure mode that has to be changed from a moderate to an unacceptable level because an incident was reported following a non-update procedure. New improvement actions have been implemented directly. In order to continue our proactive approach to risk analysis a systematic annual review of this analysis is now introduced in routine. All this, in relation to the reported adverse events. The figure shows an extract of the FMECA scoreboard obtained for CT

#### simulation and contouring stage.

Extract of the FMECA scoreboard Cyberknife process (CT Simulation and contouring)

N°	Process activity	Potential failure modes	Potential causes	Potential Effects	First evaluation 08/2015			CI	Second evaluation 09/2016			CI2	
					Detection	Severity	Occurrence		Detection	Severity	Occurrence		
1	CT Simulation and contouring	Error in patient positioning	Lack of information concerning patient position, wrong contouring, wrong patient data	Wrong treatment definition, endanger the integrity of the patient	2	4	2	16	Picture of patient positioning, standard CT acquisition protocol and RTT's training	2	4	1	8
2		Wrong CT images acquisition	Wrong sequence used, insufficient limits, injection of contrast agent forgotten	Redo the simulation, unnecessary exposure to radiation for the patient	2	3	2	12	Standard CT acquisition protocol, RTT's training, update procedures	2	2	2	8
3		Error in Image fusion (MRI, PET)	Using the wrong sequence, misuse of the software, lack of experience	Wrong target volume and OARs delimited, wrong dosimetry and DVH	2	4	2	16	Verification Checklist, realization of the exam(MRI, PET) in treatment condition	1	4	2	8
4		Patient motion	lack of information given to the patient, cramps, sneeze	Postponing simulation, bad images acquired for treatment	2	3	2	12	Explanatory booklet for the patient	2	2	2	8
5		Inadequate contouring the target volume/OARs	Lack of information concerning pathology anatomy	Error in treatment planning	2	4	3	24	Integrity check contours, medical rigor	2	4	2	16
6		Lack of information on previous treatment	Incomplete or missing medical data	Risk of excessive resection, overdose, endanger the integrity of the patient	3	4	4	48	Electronic prescription with required tabs, workflow manager software	2	4	3	24

#### Conclusion

The analysis of the potential failures, their causes and effects allowed us to increase the quality and the safety in the CK workflow process. The FMECA technique provides a systematic method to target vulnerabilities before they generate an error. This framework analysis can naturally incorporate further quantification and monitoring. The FMECA method is an effective tool for the management of risks in patient care.

#### PV-0459 Prostate CBCT dose optimization : from an iterative mAs reduction to a systematic exposure reduction

E. Jaegle<sup>1</sup>, M.E. Alayrach<sup>1</sup>, A. Badey<sup>1</sup>, V. Bodez<sup>1</sup>, C. Khamphan<sup>1</sup>, P. Martinez<sup>1</sup>, R. Garcia<sup>1</sup>

<sup>1</sup>Institut Sainte Catherine, Physique, Avig non, France

#### Purpose or Objective

A daily repositioning Cone Beam Computed Tomography image (CBCT) for prostate radiotherapy is realized using exposure templates (mAs, kV) which affect image quality and imaging dose. Settings should be optimized to minimize patient exposure while maintaining sufficient image quality to register the initial planning CT with CBCT using soft tissue matching.

#### Material and Methods

20 prostate patients (without hip prosthesis) with daily CBCT (40 fractions) acquired on a TrueBeam™ (Varian Medical Systems) machine were selected. After the first fraction using the standard pelvis template (125 kV 1080 mAs CTDIw 14 mGy), the therapists manually applied, day after day, a low mAs reduction and assessed if the CBCT image quality was good enough for patient repositioning. The iterative process stopped when image quality was assessed too bad and the last proper mAs were selected. The link between the mAs reduction and corpulence (patient volume inside CBCT FOV) was studied. For one example patient, 23 therapists registered CBCT images with CT for 3 fractions : the first fraction (S<sub>0%</sub>), a fraction with 50% mAs reduction (S<sub>-50%</sub>) and the fraction with maximum mAs reduction (S<sub>-71%</sub>). Fisher's test was applied to every direction, to compare the variance between S<sub>0%</sub> / S<sub>-50%</sub> and S<sub>0%</sub> / S<sub>-71%</sub>.

## Results

The median mAs reduction for all patients was 64% (13% to 85%). Patient corpulence was not correlated to the mAs reduction achieved (Spearman's correlation  $r_s = 0.465$ ). Variance analysis, for every direction, shows no significant difference ( $p < 0.05$ ) between  $S_{0\%} / S_{-50\%}$  and  $S_{0\%} / S_{-71\%}$ .

**Table 1 : For 3 fractions, the variance in matching from 23 therapists and Fisher's test results**

	Fraction 1	Fraction 50% reduction		Fraction max reduction	
	$\sigma^2 S_{0\%}$	$\sigma^2 S_{-50\%}$	$\sigma^2 S_{0\%} = \sigma^2 S_{-50\%} ?$	$\sigma^2 S_{-71\%}$	$\sigma^2 S_{0\%} = \sigma^2 S_{-71\%} ?$
Vert.	0.086	0.064	Yes $p=0.184$	0.109	Yes $p=0.28$
Long.	0.074	0.074	Yes $p=0.972$	0.081	Yes $p=0.666$
Lat.	0.049	0.045	Yes $p=0.716$	0.050	Yes $p=0.900$

## Conclusion

mAs reductions recorded across the 20 patients are highly variable, due to the subjective assessment of CBCT image quality, but a median reduction of 64% indicates a great potential for reducing imaging dose.

For one patient it has been demonstrated that image quality deterioration has no impact on interobserver variability.

A 50% mAs reduction for the Pelvis CBCT template is therefore considered.

## PV-0460 Comparison of 3 Image-guided Adaptive Strategies for Bladder Radiotherapy

V. Kong<sup>1</sup>, A. Taylor<sup>2</sup>, T. Craig<sup>1</sup>, P. Chung<sup>1</sup>, T. Rosewall<sup>1</sup>

<sup>1</sup>Princess Margaret Cancer Centre, Radiation Medicine Program, Toronto, Canada

<sup>2</sup>Sheffield Hallam University, Faculty of Health & Well-being, Sheffield, United Kingdom

## Purpose or Objective

Due to the significant variation of bladder volume observed throughout the course of treatment, various adaptive strategies have been developed to improve the quality of bladder radiotherapy. The aim of this study was to use deformable registration and dose accumulation processes to compare the dosimetric differences of a population-based PTV approach and three proposed adaptive strategies: Plan of the Day (POD), Patient-Specific PTV (PS-PTV) and daily reoptimization (ReOpt).

## Material and Methods

Bladder patients (n=10) were included in this retrospective investigation. Patients were planned and treated with a full bladder in supine position. Planning CT and the CBCTs were retrieved and imported into treatment planning system. After delineating the bladder and the pelvic lymph node (PLN) on the planning CT, an expansion of 1.5 cm and 0.5 cm was applied to generate the population-based Standard PTV<sub>WB</sub> and PTV<sub>PLN</sub>, respectively. A 7-field IMRT distribution was designed to deliver a prescription dose of 46Gy in 23 fractions. Each adaptive strategy was applied according to published guidelines. After simulating the execution of each strategy using the daily CBCTs, daily dose was computed on all CBCTs and then total dose was summed on the planning CT using the output from the CT-CBCT deformable image registration. The volume receiving 95% of prescription dose ( $V_{95}$ ) was compared against the Standard for each of the adaptive strategies.  $p < 0.05$  was considered statistically significant.

## Results

Mean  $V_{95}$  (cm<sup>3</sup>) were 1410 (SD: 227), 1212 (SD: 186), 1236 (SD: 199), and 1101 (SD: 180) for Standard, POD, PS-PTV and ReOpt, respectively. All adaptive strategies significantly reduced the irradiated volume, with ReOpt demonstrating the greatest reduction compared to the Standard (-25%). This was followed by a mean reduction of 16% with PS-PTV and 12% with POD. The difference in the magnitude of reduction between ReOpt and the other 2 strategies reached statistical significance ( $p = 0.0006$ ).

## Conclusion

Previous comparisons between bladder adaptive strategies have been limited due to the inability to account for the effect of daily motion of the bladder and surrounding organs. When deformable registration is used to reconstruct dose in the presence of organ motion, ReOpt is the best adaptive strategy at reducing the irradiated volume due to its frequent adaptation based on the daily geometry of the bladder. However the resource burden associated with this strategy needs to be quantified to further assess the feasibility of clinical implementation.

## PV-0461 Integrating diagnostic MRI in radical bladder cancer radiotherapy: Challenges in image registration.

C.L. Eccles<sup>1</sup>, H. McNair<sup>1</sup>, D. McQuaid<sup>2</sup>, K. Warren-Oseni<sup>2</sup>, V.N. Hansen<sup>2</sup>, A. Sohaib<sup>3</sup>, M.D. Koh<sup>4</sup>, R. Huddart<sup>4</sup>, S. Hafeez<sup>4</sup>

<sup>1</sup>The Royal Marsden NHS Foundation Trust and The Institute of Cancer Research, Radiotherapy, London, United Kingdom

<sup>2</sup>The Royal Marsden NHS Foundation Trust and The Institute of Cancer Research, Radiotherapy Physics, London, United Kingdom

<sup>3</sup>The Royal Marsden NHS Trust, Radiology, London, United Kingdom

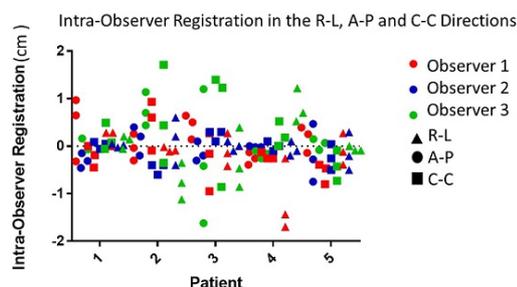

<sup>4</sup>The Royal Marsden NHS Foundation Trust and The Institute of Cancer Research, Radiotherapy and Imaging, London, United Kingdom

## Purpose or Objective

Radiographer led soft tissue matching has been fundamental for implementation of adaptive strategies in bladder cancer. Integrative MRI technology has the potential to improve tumour and normal soft tissue visualisation at treatment planning and delivery. This work investigates the degree of inter and intra observer variation in image registration between experts, using a biological target volume (BTV) defined on diffusion weighted MRI (DW-MRI), in patients muscle invasive bladder cancer.

## Material and Methods

Twenty-two patients with muscle invasive bladder cancer recruited prospectively to a phase I image guided radiotherapy protocol (NCT01124682). Prior to radiotherapy, all patients underwent MRI on a 1.5T magnet prior to to acquire T1-weighted, and T2-weighted DW-MRI with b values of 0, 50, 100, 250, 500 and 750s/mm<sup>2</sup>. The BTV was delineated on b 750 s/mm<sup>2</sup> images and transferred to the treatment planning system (Pinnacle v9.6, Philips Medical Systems), where DW-MR images were registered to the corresponding ADC map and planning CT by three observers (one oncologist and two radiographers). Registration was guided using the bladder, and BTV.

## Results

Nineteen of the 22 patients accrued to the study had BTVs visible on DW MRI and were included in this analysis. The most notable inter-observer variation in image registration of the BTV occurred in the caudal-cranial (C-C) direction with a mean difference of 5.4 mm (standard deviation (sd) 4.7 mm), followed by the anterior-posterior (A-P) direction (mean 4.5 mm, sd 4.9 mm). The inter-

observer registration variation was minimal in the right-left (R-L) direction (mean, 2.8mm, sd 2.4 mm). Overall, on Anova analysis, there were no statistically significant differences in inter-observer registration ( $p = 0.8214$ ,  $0.3136$ , and  $0.3270$ , in the R-L, A-P and C-C directions respectively). To determine intra-observer variability, each observer performed repeat image registrations on 5 patients at 3 separate time-points. The observers mean reproducibility of  $\leq 4$ mm, 2.5 mm and 5 mm in all directions, respectively (Figure 1).

#### Conclusion

Despite the limitations in geometric fidelity of DW MRI, it is a potentially useful tool for the generation of BTV and image registration for adaptive bladder radiotherapy. In this study we quantified the inter-observer variation to  $<5$ mm  $\pm$  5mm, in image registration of BTV generated using DW-MRI to planning CT. Current application to clinical practice may necessitate revision of PTV margins but further quantification of geometric distortions and validation is on going.

We acknowledge NHS funding to the NIHR Biomedical Research Centre for Cancer and to Cancer Research UK (CRUK).

#### PV-0462 E-learning in the Radiotherapy Department-Ortello

J.P. De Jong<sup>1</sup>, P. De Boer<sup>1</sup>, D. Ages<sup>2</sup>, F. Telgenhof<sup>3</sup>, D. Hasken<sup>3</sup>

<sup>1</sup>Netherlands Cancer Institute Antoni van Leeuwenhoek Hospital, Radiotherapy, Amsterdam, The Netherlands

<sup>2</sup>Leiden University Medical Center, Radiotherapy, Leiden, The Netherlands

<sup>3</sup>University Medical Center Utrecht, Radiotherapy, Utrecht, The Netherlands

#### Purpose or Objective

In 2006 four Radiation therapy technologist (RTT) heads of Radiation Oncology departments agreed to create an E-learning environment. Their goal was to introduce a learning method for RTTs involved in new radiation techniques for whom the learning environment would be easily accessible, relatively cheap and offer new teaching and learning techniques.

#### Material and Methods

From 2006 till 2008 a dedicated group of four RTTs created a web-based environment called "Ortello". By December 2015 Ortello had been fully revised and updated to current website standards. In 2008 Ortello started with 8 Radiotherapy case studies (CS), 3 games and a multiple-choice test. Radiotherapy was highlighted in these CS, but other treatment modalities, such as surgery and chemotherapy, were also represented. Each CS consists of a patient's pathway during their cancer treatment. Ortello now contains 21 different E-learning CS, which are categorized in Radiotherapy, Techniques, Imaging, and Radiobiology, coupled to 21 multiple-choice tests to examine the gained knowledge. The e-learning environment is linked to the Dutch Register for Paramedics to automatically register credit points obtained after completing a CS and the corresponding test. Every 2 years, reapplication for accreditation is required to guarantee the quality and relevance of each CS.

#### Results

Since its introduction, Ortello has gained more than 1100 users in 21 departments; 19 in The Netherlands and 2 in Suriname and Curacao. Each year new CS are launched on the website. Up to now, Ortello contains 11 CS in the category Radiotherapy: prostate-, oropharyngeal-, larynx carcinoma, 2 in the category Technique: "Photons vs electrons" and "Teaching & Brachytherapy", 2 in the category Imaging: MRI and MRI & bone tumors and 3 in the category Radiobiology: Radiobiology, Linac & Radioactivity and Radiotherapy side effects. Currently, Ortello is no longer exclusive for RTTs, but can also be used by Diagnostic radiographers.

#### Conclusion

The E-learning environment Ortello is fully operational. On the Ortello website, RTTs can train their skills, maintain their knowledge, learn newly introduced technologies, and have the opportunity to learn techniques used in other departments. Furthermore, Ortello provides CS with the accreditation points to ensure RTTs continuous competence.

#### OC-0463 In vitro prediction of DNA repair defects reveals association with poor clinical outcome in HNSCC

P. Essers<sup>1</sup>, C. Verhagen<sup>1</sup>, M. Van der Heijden<sup>1</sup>, M. Van den Brekel<sup>2</sup>, H. Bartelink<sup>3</sup>, M. Verheij<sup>3</sup>, C. Vens<sup>1</sup>

<sup>1</sup>Netherlands Cancer Institute Antoni van Leeuwenhoek Hospital, Division of Biological Stress Response, Amsterdam, The Netherlands

<sup>2</sup>Netherlands Cancer Institute Antoni van Leeuwenhoek Hospital, Department of Head and Neck Surgery / Department of Maxillofacial Surgery, Amsterdam, The Netherlands

<sup>3</sup>Netherlands Cancer Institute Antoni van Leeuwenhoek Hospital, Department of Radiation Oncology, Amsterdam, The Netherlands

#### Purpose or Objective

Recent studies highlight the relevance of DNA repair defects in genome instability and tumour development. Little is known about the impact of DNA repair aberrations on patient prognosis or treatment outcome. However, new targeted treatment options, such as PARP inhibitors, can exploit these repair defects if present. Here we tested whether gene expression analysis could identify DNA repair defects, with the ultimate aim to determine an association with clinical outcome and identify patients for targeted treatments.

#### Material and Methods

Mitomycin C (MMC) or PARP inhibitor olaparib hypersensitivity is a hallmark of functional homologous recombination (HR) or Fanconi anaemia (FA) pathway DNA repair defects. We determined whole transcriptome expression and sensitivity to MMC and olaparib in a panel of 28 patient derived head and neck squamous cell carcinoma (HNSCC) cell lines. Based on their sensitivity (IC50 values), cell lines were classified as *Normal (N)*, hypersensitive to both drugs (*MOS*) or hypersensitive to mitomycin C but not olaparib (*MS*). To establish a "DNA repair defect" signature, relevant genes were extracted by differential expression analysis and used as input to various machine learning algorithms. Performance was evaluated using 20 repetitions of 5-fold internal cross validation.

Probabilities of defects calculated by these models were used in a multivariate cox proportional hazard model to determine their prognostic capacity in a cohort of 84 HNSCC tumours, treated with chemo-radiation, and the TCGA HNSCC cohort.

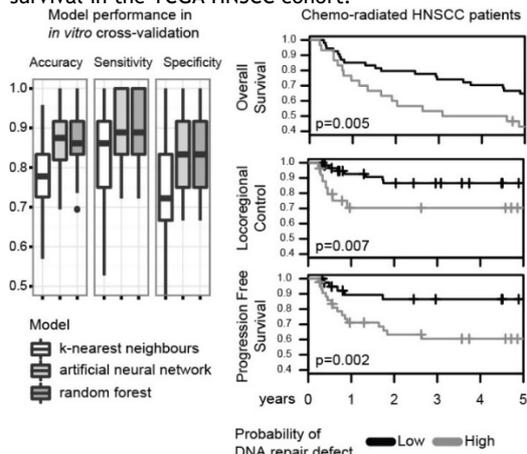

#### Results

Expression analysis of the three groups yielded genes enriched for targets of transcription factors involved in DNA damage response, including p53, demonstrating its relevance to the system under study. The random forest model performed best, achieving a high sensitivity of 0.91 and specificity of 0.86.

We validated our model in the Cancer Genome Project dataset of drug sensitivities in cell lines. The predicted repair defected groups had significantly lower IC50 values for DNA damage inducing agents, including cisplatin ( $MS: p=5.9e-05$ ;  $MOS: p=0.042$ ).

Encouraged by this data, we used our model in the patient data sets. Increased probabilities of DNA repair defects

were associated with increased mortality, recurrence and disease progression in chemo-radiated patients with advanced tumours in our cohort (shown in figure) and with survival in the TCGA HNSCC cohort.

### Conclusion

We developed a model that exposes DNA repair defects as it predicts hypersensitivity to DNA crosslinking agents caused by such defects *in vitro*. The model successfully predicted sensitivity in an independent dataset. We found that increased probabilities of DNA repair defects were associated with poorer outcome in patients, possibly a result of the impact on genomic instability.

#### OC-0464 Validation of a fully automatic real-time liver motion monitoring method on a conventional linac

J. Bertholet<sup>1</sup>, R. Hansen<sup>1</sup>, E.S. Worm<sup>1</sup>, J. Toftegaard<sup>1</sup>, H. Wan<sup>2</sup>, P.J. Parikh<sup>2</sup>, M. Høyer<sup>1</sup>, P.R. Poulsen<sup>1</sup>

<sup>1</sup>Aarhus University Hospital, Department of oncology, Aarhus C, Denmark

<sup>2</sup>Washington University- School of Medicine, Department of Radiation Oncology, St-Louis, USA

#### Purpose or Objective

Intrafraction motion is a challenge for accurate liver radiotherapy delivery. Real-time treatment adaptation (gating, tracking) may mitigate the detrimental effects of motion, but requires reliable target motion monitoring. In this study, we develop and validate a framework for fully automatic monitoring of thoracic and abdominal tumors on a conventional linac by combining real-time marker segmentation in kV images with internal position estimation by an external correlation model (ECM). The validation is based on experiments and simulations using known external and internal motion for 10 liver SBRT patients.

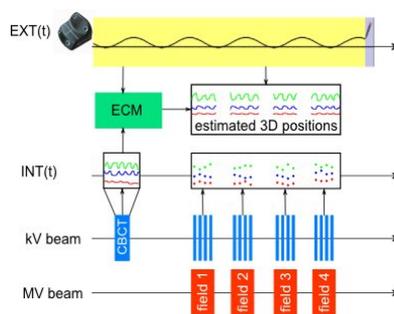

#### Material and Methods

A fully automatic real-time motion monitoring framework was developed. The framework combines auto-segmentation of arbitrarily shaped implanted fiducial markers in CBCT projections and intra-treatment kV images with simultaneous streaming of an external optical motion signal. Fig. A illustrates the workflow: A pre-treatment CBCT is acquired with simultaneous recording of the motion of an external block on the abdomen. The markers are segmented in every CBCT projection and a 3D voxel model of each marker is generated. The 3D marker motion is estimated from the observed 2D motion and used to optimize an ECM of the 3D internal marker motion INT(t) as a function of the external motion EXT(t). During treatment, INT(t) is estimated from EXT(t) at 20Hz, while MV-scatter-free kV images are acquired every 3s during beam pauses. The markers are segmented in real-time

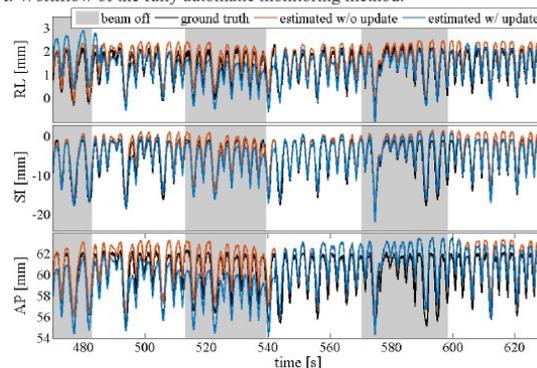

using the ECM to determine the search area and projections of the 3D voxel model as templates. The ECM is continuously updated with the latest estimated 3D marker position. The method was validated using Calypso-recorded internal motion and simultaneous camera-recorded external motion of 10 liver SBRT patients. The validation included both experiments with a programmable motion stage and simulations hereof for the first patient as well as simulations for the remaining patients. The real-time estimated 3D motion was compared to the known tumor motion. For comparison, the position estimation error was also calculated without ECM updates.

### Results

The segmentation rate was 90% with a mean 2D segmentation error of 1.5pixels. Fig. B compares the estimated and actual target motion for a portion of the phantom experiment for Patient 1. The simulations agreed with the experimental root-mean-square error within 0.4mm (Table 1). For all patients, the mean 3D root-mean-square error was 1.74mm with ECM updates and 2.47mm without ECM updates (Table 1).

A. Workflow of the fully automatic monitoring method.

B. 3D marker position. The ground truth is shown in black along the right-left (RL), superior-inferior (SI) and antero-posterior (AP) axis. The red line shows the estimated position without model update. The blue line shows the estimated position with model update. The shaded areas indicate when the MV beam was off.

Mean root-mean-square position estimation error [mm]	Patient 1 (Experiment/simulation)		Patients 1-10 (simulation)	
	Without update	With update	Without update	With update
Right-Left	0.31/0.36	0.45/0.27	0.82	0.69
Superior-Inferior	1.39/1.15	1.08/0.86	1.86	1.10
Anterior-Posterior	0.89/0.76	0.89/0.61	1.07	1.04
3D	1.68/1.43	1.47/1.09	2.47	1.74

### Conclusion

A real-time 3D tumor motion monitoring method was established and validated in experiments and simulations using known Calypso-recorded liver tumor motion. The method is fully automatic and can be used for arbitrarily shaped fiducial markers in the thorax or abdomen on a conventional linac without additional time or hardware. The internal position estimation can also be performed for non-coplanar fields where there is no room to deploy the kV imaging system.

<sup>16</sup>CHU de Bordeaux- Hopital Pellegrin, Gironde, Bordeaux, France

<sup>17</sup>CHU de Bordeaux- USMR, Gironde, Bordeaux, France

#### Purpose or Objective

The objective was to compare local excision (LE) and total mesorectal excision (TME) in patients with a good response after radiochemotherapy for low rectal cancer.

#### Material and Methods

Patients with T2-T3 low rectal carcinoma, maximum size 4 cm, received neoadjuvant radiochemotherapy. Good clinical responders (residual tumor  $\leq$  2 cm) were randomized between LE and TME. In the LE group, a completion TME was required if ypT2-3. The primary end point was a composite outcome including death, recurrence, morbidity and after-effects at 2 years. Secondary outcomes were pathologic response, 3-year local recurrence and survival.

#### Results

A hundred forty eight good clinical responders to radiochemotherapy were randomized, 3 were excluded and 145 were analyzed: 74 in the LE group and 71 in the TME group. In the LE group, 26 patients had a completion TME. At 2 years, significant events occurred in 56% in the LE group and 48% in the TME group ( $p=0.320$ ). In intention-to-treat analysis, there was no difference between LE and TME in all components of the composite outcome. Per protocol analysis showed a lower morbidity (11%/21%/48%,  $p=0.001$ ) and fewer after-effects (17%/29%/62%,  $p<0.001$ ) according to type of surgery LE, TME and completion TME. Pathologic results showed a low rate of positive lymph nodes in ypT0-1 (0%) and ypTx/cN0 (2%). 3-year local recurrence (5%) and overall survival (92%) were similar between LE and TME groups.

#### Conclusion

LE is oncologically safe as compared to TME. Globally it is not superior to TME, due to a high rate of completion TME that increases morbidity and after-effects. A better patient selection removing unnecessary completion TME (ypT2/cN0) will improve the strategy.

#### OC-0466 Brachytherapy for conservative treatment of penile carcinoma: prognostic factors and outcome

A. Escande<sup>1</sup>, C. Haie-Meder<sup>1</sup>, R. Mazeron<sup>1</sup>, P. Castelnaud-Marchand<sup>1</sup>, P. Maroun<sup>1</sup>, A. Cavalcanti<sup>2</sup>, F. Marsolat<sup>1</sup>, K.

Doyeux<sup>1</sup>, R. De Crevoisier<sup>3</sup>, F. Martinetti<sup>1</sup>, I. Dumas<sup>1</sup>, E. Deutsch<sup>1</sup>, C. Chargary<sup>1</sup>

<sup>1</sup>Gustave Roussy Cancer Campus, Brachytherapy Unit-Radiation Oncology, Villejuif, France

<sup>2</sup>Gustave Roussy Cancer Campus, Department of Surgery, Villejuif, France

<sup>3</sup>Eugene Marquis Cancer Center, Radiation Oncology, Rennes, France

#### Purpose or Objective

Penile carcinoma is a very rare disease, for which total glansectomy is frequently proposed as first intent treatment. However, functional sequelae of surgery have prompted to look at organ sparing strategies. Here is reported the largest experience of brachytherapy as a conservative approach.

#### Material and Methods

We examined the outcome of 201 patients treated in our Institution over 45 years for a histologically confirmed invasive squamous cell carcinoma of the penile glans, with emphasis on long-term complications and probability to achieve organ preservation. All had undergone circumcision prior to brachytherapy. Low dose rate or pulse dose rate interstitial brachytherapy was used. Median dose of brachytherapy was 65 Gy (36.5 to 76 Gy).

#### Results

With a median follow-up of 10.7 years, local relapses were reported in 38 patients (18.9%) and 22/29 (75.9%) patients with local failure only were in complete remission after salvage surgery or second brachytherapy. At last follow-up, 18 (12.9%) underwent partial surgery and eight (4%) total penectomies for relapse. Fifty patients (25%) presented urethral stenosis requiring at least one dilatation and 13 (6%) required limited surgeries for toxicities. A tumour diameter  $>$  4cm and a dose  $<$  62 Gy correlated with a higher probability of local relapse ( $p = 0.009$  and  $p = 0.015$ , respectively). At five years, overall survival rate and local-failure free survival were 79% (95%CI: 76-82%) and 82% (95%CI: 79-85%), respectively. Presence of inguinal lymph node metastasis correlated with a poorer overall survival ( $p = 0.02$ ). Neutrophilia at diagnosis correlated with a higher probability of distant relapse ( $p = 0.014$ ). The risk of complication correlated with the dose, treated volume, and dose rate. At five years, the probability of surviving while preserving the penile was 85% (95%CI: 82-88%), taking into account the need for surgery for complications.

#### Conclusion

This large institutional experience confirms the high local control achieved with brachytherapy with the advantage of organ preservation in selected patients. Most local relapses are efficiently salvaged by second intent surgery.

#### OC-0467 Investigating reporting-and-learning systems of Irish radiation therapy: Can standards be improved?

K. Dowling<sup>1</sup>, C. Poole<sup>1</sup>, L. Mullaney<sup>1</sup>, S. Barrett<sup>1</sup>

<sup>1</sup>Trinity College Dublin, Discipline of Radiation Therapy, Dublin, Ireland

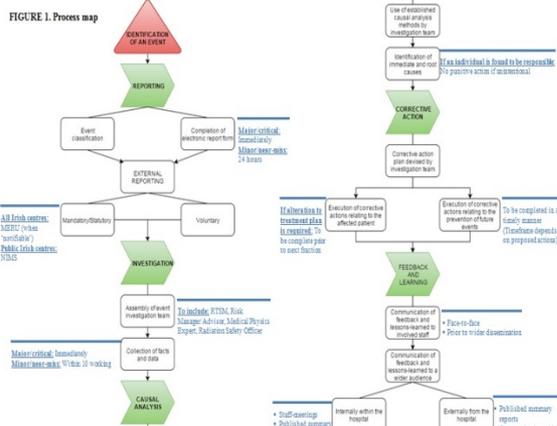

#### Purpose or Objective

Wide variation exists between event (incidents and near-misses) reporting-and-learning systems utilised in the field of radiation oncology. Due to the high potential for error associated with this field of medicine, evidence-based and rigorous systems are imperative. The implementation of such systems facilitates the reactive enhancement of patient safety following an event. This research study was undertaken so as to evaluate Irish event reporting-and-learning procedures and to propose recommendations as to how the national standard can be improved to the optimal standards outlined in the literature. The methodology used to undertake this research was developed with the aim of ensuring its applicability to

international practice, allowing for further similar studies to be performed in other countries.

**Material and Methods**

An evidence-based event reporting-and-learning process map was developed from recommendations in the literature [see Figure 1], followed by a questionnaire to assess a radiation therapy centre's compliance with this map. Radiation Therapy Service Managers of Irish radiation therapy centres (n=12) were invited to participate in the anonymous online questionnaire. Frequency analysis of closed-ended questions and thematic analysis of open-ended questions was performed to assess the data.

**Results**

A 91.7% response rate was achieved. The following improvements were found to be most in need of occurring: decreased variation in event classification and taxonomy, expanded use of external reporting systems, and heightened dissemination of lessons-learned to wide audiences. A recommendations table was developed to present methods in which required standardisation and enhancement of practice can be achieved [see Table 1].

Table 1. Recommendations for improving the standard of event-reporting-and-learning systems

Process Stage	How can the standard be improved?	Recommendations
Event Classification	Increased uniformity in taxonomy and classification systems	<ul style="list-style-type: none"> <li>Implement a standardised event classification system nationally. Use of a well-accepted, international system is recommended so that harmonisation also occurs on a global level.</li> <li>Complete adherence to the taxonomy guidelines recently published by the European Commission regarding event reporting-and-learning</li> </ul>
Electronic versus paper-based reporting	Use of electronic reporting systems only	<ul style="list-style-type: none"> <li>Replace paper-based reporting with the implementation of electronic reporting systems</li> </ul>
Timeframe for initial report	Shortened timeframes within which the initial reporting of events must occur	<ul style="list-style-type: none"> <li>Establish protocols that require staff members to report major/critical incidents immediately, and minor incidents/near-misses within twenty-four hours</li> <li>Print physical copies of protocols and keep them in easily seen/accessible locations within centres</li> </ul>
External Reporting	Increased correct use of mandatory reporting systems Increased rates of reporting to voluntary reporting systems	<ul style="list-style-type: none"> <li>Educate staff thoroughly on the protocols of what constitutes a reportable event for both MERU and NIRS, emphasising the benefits associated with increased participation</li> <li>Print physical copies of protocols and keep them in easily seen/accessible locations within centres</li> <li>Encourage reporting of incidents and near-misses to voluntary systems, such as SAFRON or ROSIS, educating staff on the importance and benefits of doing so</li> <li>A potential method of increasing report rates is the establishment of a reward system to encourage staff to report</li> </ul>
Investigation	Increased compliance with established guidelines on the make-up of investigation teams Shortened timeframes between the occurrence and the investigation of minor incidents/near-misses	<ul style="list-style-type: none"> <li>Include the Radiation Safety Officer as a permanent member of event investigation teams</li> <li>Include a Risk Manager/Advisor as a permanent member of event investigation teams</li> <li>Establish protocols that require the investigation process for minor incidents/near-misses to be performed within ten working days of the event's occurrence</li> </ul>
Causal Analysis	Increased use of established reactive causal analysis tools Increased implementation of no-blame culture	<ul style="list-style-type: none"> <li>Until further research has been shown to support the retrospective use of FMEA, use established reactive methods of causal analysis</li> <li>Do not take punitive action when a staff member is unintentionally responsible for an event</li> <li>If a staff member is repeatedly causing similar events, provide retraining when applicable, rather than taking disciplinary action</li> <li>Ensure staff are aware of this no-blame culture</li> </ul>
Corrective Action	Shortened timeframes within which compensatory action to patient plans must be taken Shortened timeframes between investigations and the implementation of corrective actions for preventing future events	<ul style="list-style-type: none"> <li>Establish protocols that require possible compensatory corrective actions to treatment plans to be assessed and implemented prior to further irradiation</li> <li>Print physical copies of protocols and keep them in easily seen/accessible locations within centres</li> <li>Ensure that corrective actions for preventing future events are implemented in a timely manner</li> </ul>
Feedback and Learning	Improved and increased dissemination of lessons-learned to the wider audience	<ul style="list-style-type: none"> <li>Publish summary reports at regular intervals</li> <li>Share summary reports with other centres</li> <li>Regularly report incidents and near-misses to voluntary systems</li> </ul>

**Conclusion**

This study identified aspects of Irish event reporting-and-learning systems wherein improvements are necessary. The recommendations made can be utilised to optimise the national standard of incident and near-miss management in Ireland. Due to their evidence-based nature, they can also be applied to the field of radiation

therapy across the globe. With such developments, a worldwide enhancement of the safety-culture in the field of radiation therapy can occur.

**Symposium: Non-rectal GI tumours: key open questions to be answered from (and for) the radiation oncologist!**

**SP-0469 Radio(chemo)therapy in oesophageal cancer: can we do better?**

M. Hulshof<sup>1</sup>  
<sup>1</sup>Academic Medical Center, Dept Radiation Oncology, Amsterdam, The Netherlands

The indications for radiation in esophageal cancer have increased dramatically in the last 15 years, and the developments of chemoradiation for esophageal cancer can be defined as a success story: Preoperative chemoradiation became standard since phase III trials have shown that overall survival did increase in resectable stage of disease and the results from studies with definitive chemoradiation for irresectable/inoperable case has changed the treatment intent from palliative to curative. The indications for palliative radiotherapy remained unchanged. Thus the vast majority of esophageal cancer patients will get radiotherapy somewhere in their disease tract. This recent change is the reason that improvements in radiation accuracy for esophageal tumors are running behind compared to longer existing indications like prostate. Improving radiation accuracy in esophageal tumors is challenging because of its mobility by breathing effects, the anatomical changes that can occur during the treatment period and the difficulties of accurate delineation of macroscopical tumor borders on a CT scan. This challenge becomes even larger because the impact of all these uncertainties have shown to differ between the different levels of the esophagus, i.e. proximal, mid versus distal. Use of fiducials, 4 D imaging, cone beam verification, non-uniform margins, IMRT and adaptive radiotherapy are tools to improve accuracy and to decrease dose to healthy surrounding tissue, but are not yet routinely applied in most institutes. Still, improving radiation accuracy will probably not have a large impact on tumor control and survival. In contrast to the preoperative treatment, in which dose schedules are well defined and locoregional control is good after surgery, locoregional control in definitive chemoradiation is still disappointing and warrants improvements. Prospective studies are needed and currently running to analyze the effect of dose escalation in definitive chemoradiation. If dose escalation is effective, treatment techniques to adequately deliver the boost dose will become more important (4 D CT scans, fiducials, and CBCT verification). The sensitizing effect of chemotherapy during radiotherapy is well established, but addition of new targeted drugs are expected to increase the treatment response during chemoradiation. The first studies on combining monoclonal antibodies with CRT have been executed with so far somewhat disappointing results. But new drugs are in development and studies on combinations with immune therapeutic agents like PD-L1 inhibition are being conducted. So yes, we can do better, both in terms of accurate dose delivery and improving tumor response. Efforts by radiation oncologists are necessary to provide that the success story of chemoradiation in esophageal cancer has not ended yet.

**SP-0470 Does radiotherapy still have a role in the management of pancreatic cancer?**

E. Fokas<sup>1</sup>  
<sup>1</sup>Goethe University Frankfurt, Department of Radiotherapy and Oncology, Frankfurt, Germany

The role of radiotherapy in pancreatic ductal adenocarcinoma (PDAC) remains controversial. In contrast to the notion that all patients with PDAC die of metastatic disease, at least a 20% suffer and die from local recurrence. The latter provides a strong rationale for improving local control using radiotherapy, including dose escalation with SBRT. The advent of modern RT and imaging technology can reduce toxicity without compromising efficacy. International consensus on the definition of R1-resection in primarily and borderline resectable PDAC is needed to better define radiotherapy indications. SBRT and chemoradiotherapy (CRT) have to be tested in the context of more efficient chemotherapy regimens, such as FOLFIRINOX and Gemcitabine/Nab-paclitaxel if it is to unmask the importance of improved local control. The development of molecular signatures to differentiate patients with high risk of developing only local recurrence from those likely to die of distant metastases is urgently needed. Preclinical and patient data indicate testing the efficacy of immunotherapeutics in combination with (C)RT in future clinical trials.

**SP-0471 Standard treatment in anal cancer: where do we stand and where should we go?**

R. Muirhead<sup>1</sup>

<sup>1</sup>CRUK/MRC Oxford Institute for Radiation Oncology, Oncology, Oxford, United Kingdom

**Introduction** - Anal cancer is a rare disease but the incidence is increasing rapidly. Despite its rarity there is significant research, development and interest in this topic with large phase III trials involving hundreds of patients' completed, and literature on anal cancer regularly on the "most read" list of radiotherapy journals. The initial phase III trials investigated the use of concurrent chemotherapy with radiotherapy, confirming the benefit of concurrent chemoradiotherapy using Mitomycin and Fluorouracil. These trials changed the standard treatment in anal cancer from APR with permanent stoma to CRT. Subsequent phase III trials have investigated diverse concurrent chemotherapy regimens and the different settings of systemic therapy; namely the role of neo-adjuvant and adjuvant chemotherapy and different concurrent regimens. However these strategies failed to demonstrate significant impact on outcome, and the optimal concurrent regimen remains Mitomycin and Fluorouracil. The ESMO-ESSO-ESTRO and NCCN guidelines support the use of capecitabine as an alternative to fluorouracil, however phase III evidence supporting this recommendation is not available. The phase I and II studies, multicentre and single centre data supporting this regimen, highlight the different toxicity profiles. Due to a failure to demonstrate improved outcomes in recent phase III trials investigating different systemic strategies, moving forward we will need to consider how improving the radiotherapy component of our treatment can improve both cancer outcomes and the late toxicity of this toxic but effective treatment.

**Radiotherapy Technique** - The RTOG 0529, a phase II study investigating the acute toxicity of IMRT in comparison to the historical RTOG 9811, raised some important questions regarding the challenges of implementation of IMRT in anal cancer. The central review of volumes revealed a large numbers of revisions required in contouring. In addition there is a correlation between plans that fail to meet the recommended dose constraints and G3 toxicity. In implementing IMRT, thought has to be given to volumes to be included, doses and fractionations, margins used and organ at risk constraints; each of these issues alongside the relevant literature will be discussed in the context of designing the UK IMRT guidance.

**Late toxicity and Quality of Life** - Until recently there was minimal literature on the late toxicity of this treatment despite cure rates of >70%. With the requirement to

quantify late toxicity in order to design studies to improve morbidity and increasing awareness of cancer survivorship; there is renewed interest in this topic. A number of recent series have reported the late toxicity following IMRT using a combination of physician recorded and patient reported outcome measures. While there is recovery of the majority of acute side effects and quality of life 3 months after completing treatment, diarrhoea, urinary incontinence and dyspareunia persisted beyond 1 year. These adverse effects were reported following "modern" CRT techniques therefore it is arguable that to see an improvement in these outcomes, we will need to explore individualising treatment dose to minimise late effects.

**RT stratification according to stage** - Although there has always been much interest in increasing doses with external beam or brachytherapy boosts in all stages of anal cancer until recently there was no dose response data available. The RTOG 0529 study set a precedence for stratifying dose delivered according to tumour stage. This lecture will discuss the dose response model which reports while there was a dose response in both early and locally advanced stages of tumour, the improved local control rates achieved by dose escalating in locally advanced tumours far exceeds what can be achieved by dose escalating in early tumours.

**Future international trials** - The UK led PLATO study trial (ISRCTN88455282) is funded by Cancer Research UK and incorporates many of the themes of the teaching lecture. PLATO is a unique "umbrella" trial addressing a number of radiotherapy questions in the loco-regional management of anal cancer. It incorporates 3 individual trials: ACT3 - for T1N0 anal margin tumours, evaluating a strategy of selective reduced dose chemoradiotherapy after local excision, within a single arm phase II trial; ACT4 - for T1-2 N0 ( $\leq 4$ cm) tumours, evaluating reduced dose chemoradiotherapy to the primary tumour, in a randomised 2:1 phase II study, with the aim of reducing toxicity and maintaining efficacy; ACT5 - for T2 N1-3, T3/4 Nany, evaluating dose escalation within a seamless randomised trial design moving from pilot to phase II to phase III, with the aim of reducing locoregional failure. The primary endpoint for all 3 trials is 3 year local regional failure, key secondary outcomes will focus on patient reported outcome measures.

---

**SP-0472 The pros, cons, process and challenges for achieving better radiotherapy through data -an introduction**

L.C. Holloway<sup>1,2,3,4</sup>

<sup>1</sup>Ingham Institute and Liverpool and Macarthur Cancer Therapy Centres, Medical Physics, Sydney, Australia

<sup>2</sup>University of Wollongong, Centre for Medical Radiation Physics, Wollongong, Australia

<sup>3</sup>University of Sydney, Institute of Medical Physics, Sydney, Australia

<sup>4</sup>University of New South Wales, South West Sydney Clinical School, Sydney, Australia

The magnitude and use of data is expanding in many areas including medicine. The opportunities for using data to improve our knowledge and understanding are many and varied including demographic, disease and outcome investigations. Within current radiotherapy practice data may be collected in a very rigorous approach within for instance a clinical trial framework and data is also collected in an ongoing fashion during standard clinical practice. It is possible for us to gain knowledge from both rigorously collected data and clinical practice data. The gold standard of randomised clinical trial (RCT)

evidence is only provided from 2-3% of retrospective patients who have been enrolled in RCTs and is only directly applicable to a limited number of patients due to strict trial eligibility criteria, necessary to ensure trial rigour. Clinical practice data may provide us with the opportunity to develop additional evidence to support evidence from RCTs, utilising data from potentially all previous patients and including patients who do not fit RCT eligibility criteria. Considering data from both RCTs and clinical practice may also enable us to learn from the differences between the two. Different approaches to learning from data have been undertaken. These range from include common statistical approaches to machine learning approaches. All data learning approaches require the development and then validation of models. Validation must be undertaken carefully to ensure that the developed model is validated on independent datasets. To utilise data we need data; ideally large datasets from multiple treatment centres with varied clinical practice and of high quality. Achieving this requires a number of challenges to be addressed. Collecting large datasets can be very challenging in the medical field due to ethics, privacy and national and international regulations as well as the practical and technical challenges of collecting large datasets (e.g. when using multiple medical images). One approach to addressing this is termed 'distributed learning' where datasets remain within the local treatment centres. Computer algorithms can then be used to both assess (as in practice comparison and demographic studies) and learn from (as in model development providing evidence for future treatment decisions) these datasets. The requirement for varied clinical practice generally requires international datasets where local treatment guidelines may vary between countries. This requires collaboration between centres and an active effort to 'translate' between practices to ensure that data items considered are consistent between the datasets. Translation is necessary for simple items such as language differences but also more challenging differences such as different scoring scales or different approaches to normalisation in quantitative data. The use of a standard ontology which may need to be actively developed can help streamline this.

Data quality will be an ongoing challenge. Ideally every parameter within a dataset will be correctly recorded, curated and with minimal variation in any scoring scales or assessment criteria. Particularly within clinical practice datasets it is highly unlikely that every parameter within a dataset is correct although this varies both between and within centres. There are two practical issues to be considered, the first that of missing data where particular parameters are not recorded for all patients or not recorded for some patients and the second that of incorrect data entries. Although a complete full quality dataset is always preferred imputation approaches can be used successfully to address missing data, increase dataset size and thus increase model confidence. Incorrect data entries are more challenging, however if incorrect data entries are random and datasets are large then the impact of this will be minimised and seen primarily in model confidence parameters.

Although it is important to be aware of the limitations and challenges of use of data, there is growing evidence that use of data can improve our knowledge and understanding of radiotherapy.

#### **SP-0473 From Genomics and Radiogenomics data to a better RT**

**A. Vega<sup>1</sup>**

<sup>1</sup>*Fundación Pública Galega Medicina Xenómica, Hospital Clínico Santiago de Compostela, Santiago de Compostela, Spain*

The completion of The Human Genome Project in 2001, after more than 10 years of international collaborative

efforts along with progress in technology, heralded an era of enormous advances in the field of genetics. The study of the genetic susceptibility behind the different response of the irradiated tissue of patients treated with radiotherapy, known today as Radiogenomics, is an example of this. One of the major aims of Radiogenomics is to identify genetic variants, primarily common variation (SNPs), associated with normal tissue toxicity following Radiotherapy. A large number of candidate-gene association studies in patients with or without Radiotherapy side-effects have been published in recent years. These studies investigated SNPs in genes related to radiation pathogenesis, such as DNA damage, DNA repair, tissue remodeling and oxidative stress. Most of the studies suffered from methodological shortcomings (small sample sizes, lack of adjustment for other risk factors/covariates or multiple testing). The Human Genome Project and the subsequent International HapMap Project, provided extremely valuable information on the common variation of human DNA in different populations. This information and the development of high-density SNP arrays, in which all genome variability is considered (from 500000 to a few million SNPs), enabled Genome Wide Association Studies (GWAS) and an hypothesis-free case-control approach. GWASs are a major breakthrough in the attempts to unravel the genetics of common traits and diseases. Simultaneous analysis of thousands of variants requires a large sample size to achieve adequate statistical power. The need for a large number of samples makes it essential to collaborate and share data. A Radiogenomics Consortium (RGC) was established in 2009 with investigators from throughout the world who shared an interest in identifying the genetic variants associated with patient differences in response to radiation therapy. To date, RGC collaborative large-scale projects have led to statistically-powered gene-association studies, as well as Radiogenomic GWASs. The recent availability of Next Generation Sequencing (NGS) and advances in Bioinformatics, have promoted major initiatives such as The 1000 Genomes Project and The Cancer Genome Atlas (TCGA) that are providing unprecedented information about the human genome. NGS has the potential to identify all kinds of genetic variation (not only SNPs) at base-pair resolution throughout the human genome in a single experiment. The identification of rare genomic variants through these new sequencing technologies, should allow us to unravel the heritability of complex traits, such as radiation sensitivity. The genetic variants identified through Radiogenomic studies could lead to the development of an assay to predict a patient's risk of toxicity. Such an assay could help to individualize radiotherapy protocols leading to safer and more effective outcomes.

#### **SP-0474 From radiotherapy & dosimetry data to better plans**

**M. Hoogeman<sup>1</sup>, S. Breedveld<sup>1</sup>, R. Bijman<sup>1</sup>, B. Heijmen<sup>1</sup>**  
<sup>1</sup>*Erasmus MC Cancer Institute, Department of Radiation Oncology, Rotterdam, The Netherlands*

In radiotherapy patients are treated with a personalized treatment plan, which optimizes the linear accelerator settings for the delivery of a curative dose to the target while sparing surrounding healthy tissues. Those settings are calculated following a mathematical optimization, balancing the treatment goals as specified by the physician regarding target prescription dose and tolerable doses to healthy tissues.

The generation of a radiotherapy treatment plan is a complex procedure. The quality is not only highly dependent on the planner skills, but also on the physician or institutional preferences regarding the prioritization of the sparing of organs-at-risk in relation to the coverage of the planning target volume. A complicating factor is that the semi-automated optimization can take up to hours or

even a day to complete and that it is often not known a priori what can be ultimately achieved in the trade-off between organs-at-risk sparing and target coverage. Another challenge in treatment planning is that the quality of a treatment plan is only partly captured by quantitative metrics such as DVH parameters and that prediction models of toxicity are not yet integrated in the process of treatment planning.

In this presentation the above challenges will be addressed. It will be discussed if (big) radiotherapy data of plans and dosimetry can make treatment plans better. Prediction models combined with comparative treatment planning can be used for decision making and further personalizing the treatment. Some practical examples will be presented regarding the selection of patients for proton therapy. In addition, we will address to what extent the accuracy of the prediction models impact such clinical decisions. Finally, the role of treatment-plan automation will be discussed in improving the quality of treatment planning and different approaches of automation will be compared.

#### **SP-0475 Moving Big Data into Clinical Practice - A positive outlook**

S. Vinod<sup>1</sup>

<sup>1</sup>Liverpool Hospital, Cancer Therapy Centre, Liverpool BC, Australia

The evidence-base underlying treatment of oncology patients is derived from the 2-3% of patients enrolled in prospective clinical trials. Outcomes in these highly selected patients are then applied to the general patient population. However, adherence to guideline treatment varies from 44% in lung cancer to 91% in breast cancer due to clinician uncertainty about the efficacy and toxicity of evidence-based treatments in individual patients. An alternative source of evidence is Big Data. This is what we already collect in routine clinical practice including clinical data, imaging data and genomic data. The type and nature of data collected and the platform of collection varies, however current systems can overcome this to successfully enable distributed learning. Multi-institutional data can be used to develop predictive models relating outcomes to specific patient, tumour and treatment characteristics. The strength of Big Data is in the sheer number of patients and hence applicability of findings to the general clinic population. Moving Big Data into clinical practice requires translation of model outputs to decision support systems to enable shared decision making between clinicians and patients. It also requires trust of the model by patients and clinicians. There is a need to demonstrate that model predictions based on objective parameters are superior to clinician's subjective judgement alone. Clinical trials of decision support systems are necessary to evaluate whether Big Data can change clinical practice. Only then can we truly deliver personalised medicine tailored to an individual patient's specific parameters.

#### **SP-0476 Personalised local and locoregional radiotherapy in breast cancer**

T. Tramm<sup>1</sup>

<sup>1</sup>Aarhus University, Department of Clinical Medicine - The Department of Pathology, Aarhus, Denmark

Genomic profiling has unveiled the heterogeneity of breast cancer, and revealed prognostic differences and prediction on benefit from systemic therapy. Although the literature on gene expression profiles related to prediction for response to different systemic treatment strategies has been substantial, only a limited number of

studies have described molecular signatures associated with local control and benefit from radiotherapy (RT). The use of single markers or combinations of immunohistochemical markers to divide patients according to risk of LRR is potentially easily applicable in a daily clinical setting.

Especially, the immunohistochemical approximations of the intrinsic subtypes (based on e.g. ER, PR, HER2 and Ki67) have attracted attention. Most consistently, the Luminal A subtype has been associated with a low risk of loco-regional recurrence (LRR). In a subgroup analysis of the Canadian hypofractionation trial, it has also been examined, if different treatment schemes may be more or less suitable for the various subtypes, but no interaction between hypofractionation and intrinsic subtypes was found.

A number of molecular signatures prognostic of LRR have also been identified, but until recently, the majority of these signatures have failed to validate in independent cohorts. Two studies by a Dutch group did not succeed in identifying a specific gene-set predicting risk of recurrence after breast conserving therapy (BCT), though a gene-profile based on the wound response signature was described as being of independent prognostic value. Later, the same group developed a 111-gene signature, but it did not show independent prognostic value in multivariate analysis, and lost prognostic impact when tested in other cohorts. A Swedish gene-profile aiming to identify patients developing LRR despite of RT after BCT has also not been independently validated.

The ideal setting for identification of a prognostic factor is in a non-treated study population. Gene profiles predicting LRR after BCT are, however, not strictly prognostic, but include an element of prediction of benefit from RT, since the vast majority of patients treated with BCT have been treated with RT. A few prognostic gene-expression profiles predicting risk of LRR after mastectomy have, however, also been published. One of these, the 18-gene classifier, was developed from 135 non-irradiated patients treated with mastectomy. The 18-gene classifier was found to be an independent predictor of LRR in multivariate analysis regardless of ER status and nodal stage. The performance of the classifier has been tested in 87 patients treated with BCT, but the index is not yet validated and holds no predictive information in terms of postmastectomy radiotherapy (PMRT). The DBCG-RT profile has, however, been found to hold both prognostic information in terms of LRR and predictive impact in regard to PMRT. The gene profile was derived from a training set 191 high-risk breast cancer patients treated with mastectomy and randomized to PMRT or not, and independently validated in another 112 patients. Among non-irradiated patients in the training set, the profile attained prognostic impact by identifying two groups with a significant 6-fold difference in LRR risk. Furthermore, the DBCG-RT profile showed a predictive impact, since PMRT could be seen to reduce the risk of LRR in the "High LRR risk" patients, whereas the "Low LRR risk" patients experienced no additional benefit from PMRT. More recently, a radiation sensitivity signature has been derived from breast cancer cell lines, and has been found to accurately identify patients with LRR among 185 breast cancer patients. The latter two signatures have been found to be independent of the intrinsic subtypes.

Finally, exploring the heterogeneity of the tumormicroenvironment may lead to targets that can affect radiosensitivity or reverse radioresistance. Hypoxic areas may leave possibilities for potential therapeutic targets, and a more profound understanding of the interaction between the immune system and RT (including different treatment schemes) may lead to an increased understanding of non-targeted effects.

The progress towards integrating molecular profiling into precision radiation oncology is currently in its infancy, but

recent discoveries have been promising. The identification and validation of prognostic and predictive genes and gene profiles needs, however, to take into account the various treatment regimes as the prognostic information may potentially not be applicable in all treatment settings.

**SP-0477 Where should we place radiotherapy: before or after surgery?**

L.J. Boersma<sup>1</sup>, S. Lightowlers<sup>2</sup>, B.V. Offerse<sup>3</sup>, A.N. Scholten<sup>4</sup>, N. Somaiah<sup>5</sup>, C. Coles<sup>6</sup>

<sup>1</sup>MAASTRO Clinic, Dept. Radiation Oncology, Maastricht, The Netherlands

<sup>2</sup>Cambridge University NHS Foundation Trust, Oncology Centre, Cambridge, United Kingdom

<sup>3</sup>Aarhus University Hospital, Oncology, Aarhus, Denmark

<sup>4</sup>Antoni van Leeuwenhoek Hospital, Dept. Radiation Oncology, Amsterdam, The Netherlands

<sup>5</sup>The Institute of Cancer Research and The Royal Marsden, Clinical Oncology, Sutton, United Kingdom

<sup>6</sup>Cambridge University NHS Foundation Trust, Clinical Oncology, Cambridge, United Kingdom

**Introduction**

Traditionally, radiotherapy (RT) for breast cancer has been largely delivered after surgery. Pre-operative (pre-op RT) with or without chemotherapy has usually been limited to patients with inoperable locally advanced breast cancer. More recently, pre-op RT is being investigated in early stage breast cancer for both whole and partial breast irradiation.

**Clinical data on pre-operative radiotherapy**

The clinical data on pre-operative RT are sparse. There are some older series of pre-op RT in locally advanced disease showing varying response rates. The older studies also suggest an increased post-operative complication rate and increased acute toxicity, possibly due to older techniques. More recently, data are emerging on pre-operative partial breast irradiation with promising results both on local control (although follow-up is still short), toxicity and on post-operative complication rate. Several fractionation schedules are being used, which mirrors partial breast irradiation in the post-operative setting.

**Pros and cons of post-operative radiotherapy**

The advantage of post-operative RT (post-op RT) is the availability of post-operative pathology characteristics, in combination with a huge amount of follow-up data, supporting the indication for RT. However, since patients are increasingly treated with primary systemic treatment, the value of post-operative pathology to decide on post-op RT has become less clear. Another problem with post-op RT in breast conserving treatment is that the target volume of the tumor bed is extremely difficult to determine, as is clear from the inter-observer-variation when delineating the tumor bed. In addition, when the RT indication is clear prior to mastectomy, some oncoplastic surgeons prefer to delay breast reconstruction until after the post-mastectomy RT.

**Potential pros and cons of pre-operative radiotherapy**

The obvious disadvantages of pre-op RT are loss of post-operative pathologic characteristics to guide treatment and the lack of strong and long term clinical follow-up data, similar to our experiences with primary systemic treatment. However, the advantages of pre-op RT are also likely to be similar to primary systemic treatment: it allows evaluation of the effect of RT with or without additional agents, directly on the tumor. In addition, it may downstage the tumor and thereby facilitate surgery: in case of inoperable locally advanced disease, the tumor may become resectable; patients with large tumors likely to require mastectomy, may become eligible for breast conserving treatment after pre-op RT, especially those patients who have luminal A type tumors not responding to primary chemotherapy. Another advantage is the possibility of using tumor response as a surrogate endpoint for local control, although, as with primary systemic

therapy, pathological response may be highly dependent on tumor type. Time for regression following RT may also be an important factor determining pathological response rates, especially for strongly estrogen receptor positive tumors. If pathological response following RT proves to be a valid surrogate endpoint, then this is very attractive for future trial designs; for example, fewer patients will be needed, the primary outcome will be sooner and there is huge potential for developing translational radiobiology research. Due to the better visibility of the target volume, a reduction in inter observer variation has been shown when delineating the tumor for breast conserving therapy, resulting in smaller irradiated (boost) volumes. Finally, it may facilitate routine immediate breast reconstruction, sparing the patient not only a second operation, but also sparing the patient an awkward time without a breast.

**Future developments**

As is clear from the above mentioned pros and cons, pre-op RT potentially has several advantages above post-op RT. To investigate whether these potential advantages can be exploited in clinical practice, several trials are currently ongoing. In the presentation an overview of ongoing trials will be given.

**SP-0478 Radiation therapy after complete response after primary systemic therapy. Is it needed?**

P. Poortmans<sup>1</sup>

<sup>1</sup>UMC St Radboud Nijmegen, Department of Radiation Oncology, Nijmegen, The Netherlands

Radiation therapy (RT) improves disease-free and overall survival in the framework of breast conserving therapy (BCT) and when regional lymph nodes are involved. Outcomes improved a lot following progress in diagnosis and in loco-regional and systemic therapies. This has led, among others, to the introduction of primary systemic therapy (PST) to reduce the delay in initiation of systemic therapy in high-risk patients as well as to improve an unfavourable tumour/breast size ratio for BCT purposes. The outcome in terms of disease-free and overall survival is, however, similar irrespective of the timing of systemic therapy.

Current guidelines recommend that RT should be prescribed based on risk factors at diagnosis, irrespective of the administration of adjuvant or PST. Nevertheless, a wide variation in the indication and extent for both RT and surgery following PST is seen. Whilst a pathologically complete response following PST may lead to a better prognosis on an individual patient basis, the question remains whether this allows for de-escalation of loco-regional treatment. One of the cases of controversy is nodal treatment when patients with node-positive disease at diagnosis have a pathologically node-negative axilla after PST. A progressively more popular approach after PST is to remove only the sentinel and/or initially marked lymph node(s), followed by completion axillary surgery in case where there is residual macroscopical involvement and RT in all other cases.

Research should further elaborate on the complex interaction between risk factors of the primary tumour, the effectiveness of adjuvant systemic therapy and the influence of loco-regional treatments on outcome. The results of recent trials rather suggest that those patients treated with effective systemic therapy may benefit even more from loco-regional treatments compared to patients who respond poorly, as the latter are more likely to bear unsuccessfully treated subclinical metastatic disease. Several studies are exploring the contribution of loco-regional treatments after PST, especially in the case of a good tumour response.

## Symposium with Proffered Papers: Novel approaches in thoracic tumour treatment

### SP-0479 Primary human Lung (stem) cell models to study adverse effects of cancer treatments

M. Vooijs<sup>1</sup>

<sup>1</sup>MAASTRO GROW Research Institute, Radiation Oncology, Maastricht, The Netherlands

Lung cancer represents the leading cause of cancer death worldwide. The current standard of care includes combinations of surgery, chemotherapy and radiotherapy. New treatments based on molecular insight of driver mutations in cancers are urgently needed to obtain more durable responses and longer survival. We and others have previously reported that deregulation of the NOTCH signaling pathway is associated with poor outcome and treatment resistance in non-small cell lung cancer in patients and in preclinical models. Cancer treatments are always limited by dose-limiting side-effects which negatively affects tumour control and quality of life. Reducing side effects may improve tumor control by increasing dose and treatment duration. What is currently lacking are robust primary human tissue models that enable evaluation of deleterious normal tissue effects. Here I will discuss the use of 2D and 3D primary human lung tissue models to study the effects of lung cancer treatments on normal tissue response. Such models may be useful in parallel to in vitro tumor cell models to select the most optimal personalized precision treatment.

### SP-0480 Secretome as novel target for lung cancer

M. Pruschy<sup>1</sup>

<sup>1</sup>University Hospital Zürich, Department of Radiation Oncology, Zurich, Switzerland

For lung carcinoma, the initial biopsy material, fine needle aspirates, and in case of surgery the resected tumor, are often the only biological materials available for direct molecular analysis. The gold standard for molecular analysis therefore includes histological and cytogenetic analysis and DNA-extraction followed by mutational analysis. However, it is also of high importance to have access to tumor material during and in response to radiotherapy to gain insights into the treatment response on the molecular and cellular level and to develop putative (surrogate) markers. As such biomarker analysis of tumor-derived blood serum factors in tumor patients represents an additional minimally invasive approach to eventually identify predictive and prognostic factors. The serum proteome (secretome) can be analyzed prior to therapy start (basal level), following single high dose irradiation but also consecutively during the time course of a fractionated treatment regimen in order to identify (dynamic) responses to treatment. Such serum factors also affect the radiation resistance in an auto- and/or paracrine way via the tumor microenvironment and might act as potential targets for combined treatment modalities with ionizing radiation. Here we will discuss recent preclinical and clinical approaches and achievements to analyze the treatment-induced secretome from lung carcinoma and to exploit specific secretome factors as part of a combined treatment modality with radiotherapy.

### OC-0481 Effects of nitroglycerin on perfusion and hypoxia in non-small cell lung cancer lesions.

B. Reymen<sup>1</sup>, A.J.G. Even<sup>1</sup>, C.M.L. Zegers<sup>1</sup>, W. Van Elmpt<sup>1</sup>, M. Das<sup>2</sup>, J. Wldberger<sup>2</sup>, F. Mottaghy<sup>3</sup>, E. Vegt<sup>4</sup>, D. De Ruysscher<sup>1</sup>, P. Lambin<sup>1</sup>

<sup>1</sup>MAASTRO Clinic, Radiation Oncology, Maastricht, The Netherlands

<sup>2</sup>Maastricht University Medical Centre, Radiology,

Maastricht, The Netherlands

<sup>3</sup>Maastricht University Medical Centre, Nuclear Medicine, Maastricht, The Netherlands

<sup>4</sup>Netherlands Cancer Institute-Antoni Van Leeuwenhoek Hospital, Nuclear Medicine, Amsterdam, The Netherlands

### Purpose or Objective

Nitroglycerin is a nitric oxide donor being investigated because of its potential to increase tumour oxygenation. In phase II trial NCT01210378 nitroglycerin is added to radical radiotherapy in patients with NSCLC stage IB-IV. Using hypoxia PET tracer [<sup>18</sup>F]HX4 and dynamic contrast enhanced CT-scans (DCE-CT) we investigate in a subtrial the effect of nitroglycerin on tumour hypoxia and perfusion. Here, we report the final results of all patients that entered the subtrial.

### Material and Methods

Prior to the start of radiotherapy baseline [<sup>18</sup>F]HX4 PET (4h p.i.) and DCE-CT scans were performed to measure hypoxia and perfusion in the primary gross tumour volume (GTVp) and nodes (GTVn). At least 48 hours later, DCE-CT and [<sup>18</sup>F]HX4 PET scans were repeated after application of a Transderm nitro 5 mg patch. Between scans, patients did not receive any treatment. GTVp and GTVn were defined on the planning FDG-PET-CT scan and copied onto the HX4 and DCE-CT scans after registration of the images to the planning CT. For HX4, tumour-to-blood ratio (HX4-TBR), hypoxic fraction (HX4-HF; fraction of volume with TBR >1.4) and hypoxic volume (HX4-HV; volume with TBR >1.4) were calculated for all lesions. Perfusion parameters blood volume (BV) and blood flow (BF) were calculated. Differences between paired measurements were assessed using the Wilcoxon Signed rank test. Correlation coefficients were calculated using Spearman's correlation coefficient (SPSS, IBM, Germany).

### Results

Performed scans are summarized in table 1.

Table 1: Overview of performed scans and analyses

Scans	Number of patients	Analysis
Baseline HX4 PET	32	Baseline hypoxia in GTVp and GTVn
Baseline HX4 PET + Nitroglycerin HX4 PET	25	Nitroglycerin effect on hypoxia in GTVp and GTVn
Baseline DCE-CT	22	Baseline perfusion in GTVp
Baseline DCE-CT + Baseline HX4 PET	20	Correlation between baseline hypoxia and perfusion in GTVp
Baseline DCE-CT + Nitroglycerin DCE-CT	13	Nitroglycerin effect on perfusion in GTVp
Baseline DCE-CT + Baseline HX4 PET + Nitroglycerin DCE-CT + Nitroglycerin HX4 PET	12	Correlation between nitroglycerin effect on perfusion and effect on hypoxia in GTVp

In total 22/32 patients (69%) showed hypoxia at baseline in primary tumor and/or lymph nodes. In the 11 hypoxic tumors a significant negative correlation was found between baseline HX4-TBR and tumor blood flow ( $r = -0.618$ ,  $p = 0.043$ ) and blood volume ( $r = -0.736$ ,  $p = 0.010$ ). (Fig 1).

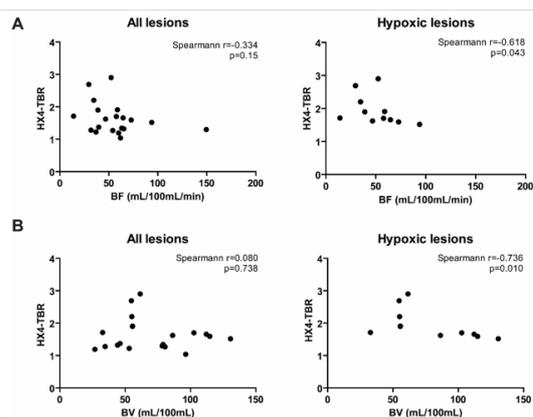

Fig. 1. Correlation between blood volume, blood flow and HX4-TBR. A. Negative correlation between tumor blood flow (BF) and HX4-TBR in hypoxic volumes. B. Negative correlation between tumor blood volume (BV) and HX4-TBR in hypoxic volumes.

After nitroglycerin administration, 4 of the 15 patients (27%) with a baseline hypoxic tumor and/ or nodes that received a second HX4-scan could not be classified as hypoxic anymore. In the group of tumors with baseline hypoxia we found a significant negative correlation between the change in blood volume and HX4-TBR ( $r = -0.829$ ,  $p = 0.042$ ) and HX4-TBR ( $r = -0.829$ ,  $p = 0.042$ ). In non-hypoxic tumors there was no correlation between the HX4-TBR and either of the perfusion parameters. **Conclusion** In this trial 27 percent of patients with baseline hypoxic tumors and nodes become normoxic after treatment with nitroglycerin. Dynamic contrast enhanced CT-scans demonstrate that this effect on hypoxic tracer uptake is negatively correlated with an effect on tumor perfusion in hypoxic tumors. These results support the hypothesis that hypoxia scans and/or DCE-CT scans could form a tool to select patients for a nitroglycerin patch adjuvant to anti-cancer treatment (radiotherapy, chemotherapy, targeted agents or immunotherapy). An animation summarizing our results is available at <https://youtu.be/udJSBYaRv9w>.

#### OC-0482 Interferon stimulated genes: a common pathway in tamoxifen- and radioresistance in breast cancer

A. Post<sup>1</sup>, M. Smid<sup>2</sup>, A. Nagelkerke<sup>1</sup>, J. Martens<sup>2</sup>, J. Bussink<sup>1</sup>, C. Sweep<sup>3</sup>, P. Span<sup>1</sup>

<sup>1</sup>Radboud university medical center, Radiation Oncology, Nijmegen, The Netherlands

<sup>2</sup>Erasmus MC Cancer Institute, Department of Medical Oncology and Cancer Genomics Netherlands, Rotterdam, The Netherlands

<sup>3</sup>Radboud university medical center, Laboratory Medicine, Nijmegen, The Netherlands

#### Purpose or Objective

Treatment resistance is an important cause of adverse outcome in breast cancer. Several mechanisms involved in resistance to either radiotherapy or endocrine therapy (tamoxifen) have been elucidated. Since tamoxifen resistant breast cancer cells were found to be less sensitive to irradiation, we aimed to investigate common pathways involved in radiotherapy and tamoxifen resistance.

#### Material and Methods

The estrogen receptor positive breast cancer cell line MCF7 was grown to radioresistance by exposing them to multiple fractions of 4 Gy irradiation, adding up to a total dose of at least 50 Gy (MCF7RT). Tamoxifen resistant MCF7 cells were created by culturing with gradually increasing concentrations of 4-hydroxy-tamoxifen up to 10  $\mu$ M (MCF7TAM). Changes in expression profiles in MCF7RT and MCF7TAM cells compared to parental MCF7 cells were investigated by RNA sequencing, and common pathways identified. QPCR was used to confirm the RNA sequencing

data, and to investigate expression of genes of interest after irradiation and tamoxifen treatment.

#### Results

Genes involved in interferon signaling were significantly increased in both MCF7RT and MCF7TAM compared to parental MCF7 cells. For further experiments, five interferon stimulated genes (ISGs; representing different parts of the signaling pathway) were evaluated, namely DDX60, STAT1, OAS1, IFI6 and IFI27. Differential expression of these five ISGs in the resistant MCF7 cells, and in treatment resistant T47D cells (also an estrogen receptor positive breast cancer cell line), was confirmed by qPCR. Expression of ISGs was induced by treatment: all five genes were increased 24h and 48h after irradiation with 4 Gy. Tamoxifen treatment (1 or 10 mM for 24h) also led to increased ISG expression.

In patients treated with tamoxifen (KMplot,  $n = 849$ ), high expression of ISGs correlated with a worse outcome (figure 1). Additionally, in a cohort of advanced breast cancer patients ( $n = 344$ ), ISGs were co-expressed and correlated with a tumor infiltrating lymphocyte signature, which in turn was associated with a shorter time to progression after tamoxifen treatment in these patients.

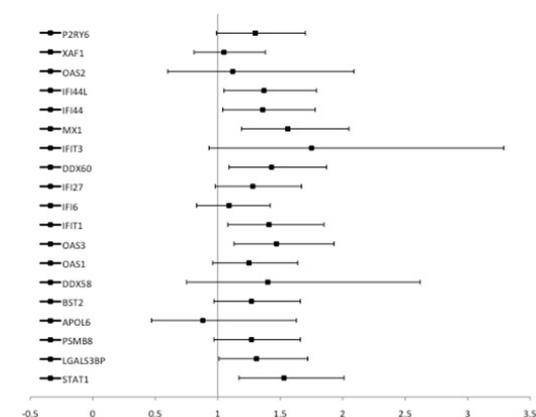

Figure 1

#### Conclusion

We show here that expression of ISGs is increased in MCF7 cells resistant to radiotherapy or tamoxifen, compared to parental MCF7 cells. Since the expression of ISGs already increased after a single dose of irradiation or tamoxifen treatment, we hypothesize that after extended treatment the interferon signaling pathway is upregulated and confers a survival advantage to the cells, ultimately leading to treatment resistance. We are currently investigating the effect of pathway inhibition on the sensitivity of resistant MCF7 cells to irradiation and tamoxifen treatment. Since high expression levels of ISGs are associated with a worse outcome in patients treated with tamoxifen, this pathway could be a valuable new target in patients, possibly also those treated with radiotherapy.

#### Proffered Papers: Inter-fraction motion management

#### OC-0483 clinical application of an adaptive

#### radiotherapy approach to baseline shifts in lung cancer

H. De Boer<sup>1</sup>, C.A. Van Es<sup>1</sup>, J.G. Bijzet-Marsman<sup>1</sup>, M.E. Kamphorst<sup>1</sup>, M.E. Bosman<sup>1</sup>, G.J. Meijer<sup>1</sup>

<sup>1</sup>UMC Utrecht, Department of Radiation Oncology, Utrecht, The Netherlands

#### Purpose or Objective

In lung cancer radiotherapy, substantial baseline shifts (shifts in the mid-ventilation position relative to surrounding anatomy) occur. When lymph nodes (LN) are

involved, baseline shifts of such nodes relative to the primary tumor can range up to cm's. Therefore, setup is often based on bony anatomy using generous planning margins for the primary tumor and LN. We present an adaptive strategy to reduce these margins for the primary tumor.

#### Material and Methods

In a previous retrospective study in 20 stage III NSCLC patients we found that a separation into 'movers' and 'non-movers' is useful. Patients with an average baseline shift < 3 mm in the first 3 fractions were deemed 'non-movers'. Dosimetric analysis of tumor coverage over the entire treatment (evaluated on 8 CBCTs per patient) showed that a 6 mm ITV-PTV margin for the primary tumor was adequate for these non-movers (in contrast to the 1 cm margin applied clinically). In the present study, we prospectively applied this selective margin reduction method. Two plans were prepared with 6 respectively 10 mm ITV-PTV margin. All patients started with the 10 mm plan. Baseline shifts of the primary tumor were determined with CBCT dual registration (XVI, Elekta) using a clipbox match on nearby bony anatomy (often vertebrae) and a simultaneous mask match on the tumor region. This registration was performed by RTTs in routine clinical practice. The results of the clipbox matches were used in an eNAL offline setup correction protocol. If, after 3 fractions, a patient was classified as a non-mover, the 6 mm plan was applied in subsequent fractions. Next, each 3<sup>rd</sup> or 5<sup>th</sup> fraction (for 25 respectively 33 fractions) was imaged to monitor the average baseline shift over the last 3 imaged fractions. If the latter average baseline shift exceeded 3 mm, a switch back to the 1 cm plan would be made.

#### Results

21 stage III NSCLC patients, treated with curative intent, were included to date. 14 patients (67%, consistent with a prediction of 70%) were found to be non-movers and switched to a plan with 6 mm margin for the remainder of the treatment. Follow-up imaging showed that all these patients remained non-movers: their average baseline shift over the entire treatment remained < 3 mm (3D vectorlength) in all cases. Although highly patient dependent, the margin reduction decreased OAR dose significantly. For instance, the average V20Gy was reduced from 15.0 to 13.4 Gy and the mean heart dose from 12.2 to 10.0 Gy.

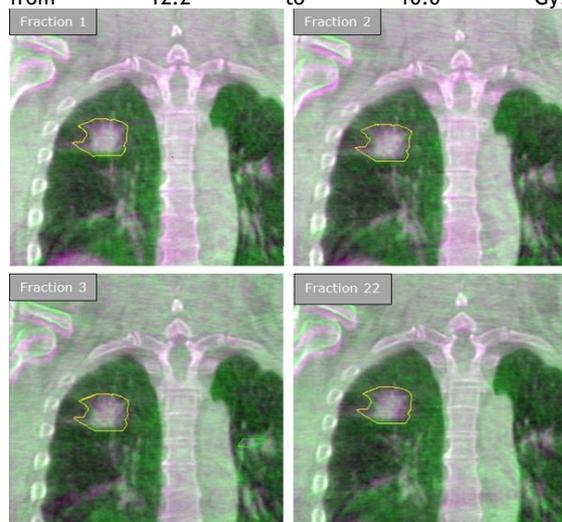

Figure: Result of registration of bony anatomy of CBCT (green) onto planning CT (magenta) for a typical non-mover. Obviously, bony anatomy registration already puts the tumor near to its intended position (yellow contour indicates the planning CT ITV) both at the beginning and near the end of treatment.

#### Conclusion

We have developed and clinically applied a practical adaptive method for planning margin reduction in non-stereotactic treatment of lung cancer. This method allows

for smaller margins in approximately 70% of patients.

#### OC-0484 Variability of breathing-induced tumour motion: 4DCT - a source of misleading information?

J. Dhont<sup>1</sup>, D. Verellen<sup>2</sup>, M. Burghelae<sup>1</sup>, R. Van Den Begin<sup>1</sup>, K. Tournel<sup>1</sup>, T. Gevaert<sup>1</sup>, B. Engels<sup>1</sup>, C. Collen<sup>1</sup>, C. Jaudet<sup>1</sup>, M. Boussaer<sup>1</sup>, T. Reynders<sup>1</sup>, G. Storme<sup>1</sup>, M. De Ridder<sup>1</sup>

<sup>1</sup>Universitair Ziekenhuis Brussel, Radiotherapy Medical Physics, Brussels, Belgium

<sup>2</sup>GZA Ziekenhuizen- Sint Augustinus - Iridium Kankernetwerk Antwerpen, Radiotherapy Medical Physics, Antwerpen, Belgium

#### Purpose or Objective

The purpose of this study was to evaluate both the short and long-term variability of breathing-induced tumour motion. In addition, it was investigated whether 4DCT is a reliable source to represent the tumour motion during the entire course of treatment.

#### Material and Methods

3D tumour motion was evaluated for 22 patients treated with SBRT for either primary NSCLC (6/22, 4x12Gy, 2 weeks), metastatic lung lesions (9/22, 10x5Gy, 2 weeks) or metastatic liver lesions (7/22, 10x5Gy, 2 weeks). Treatment was delivered with dynamic tracking (DT) on the Vero SBRT system, requiring a gold fiducial implanted near the target.

With DT, a 20 s orthogonal fast fluoroscopy (FF) sequence is acquired before each fraction. Additional sequences are taken if the breathing motion changes. As such, for each patient at least one set of X-ray images is available per fraction from which the 3D tumour motion can be extracted using the implanted marker. If multiple FF sequences were available per fraction, the tumour motion was obtained for each sequence independently. To evaluate the short-term intra-fractional variability, the amplitude, tumour position at maximum exhale (r0) and hysteresis (ie. 3D distance between the tumour position at mid-inhale and -exhale) were compared between different FF sequences from the same fraction. To assess long-term variability, amplitude and hysteresis were compared between fractions and with the 3D tumour motion registered by the pre-treatment 4D planning CT (free-breathing, using RPM (Varian) and amplitude-based binning in 10 phases, Siemens Somatom Definition AS, 2 mm slices).

#### Results

Based on r0, 10 patients showed an intra-fractional baseline drift of more than 5 mm, in one or more directions, in 50% or more fractions. For all patients, intra-fractional differences in amplitude were not statistically significant ( $p > 0,05$ ). An example of intra-fractional variability is shown in Fig 1.

In terms of long-term variability, for 11 patients the difference in mean amplitude between at least 2 fractions or a fraction and 4DCT is statistically significant ( $p < 0,05$ ). Fig 2 shows the mean amplitude per fraction per patient, together with the amplitude based on 4DCT. Both intra- and inter-fractional changes in hysteresis were smaller than 5 mm for all patients. No correlation could be found between long or short-term variability and tumour size or location.

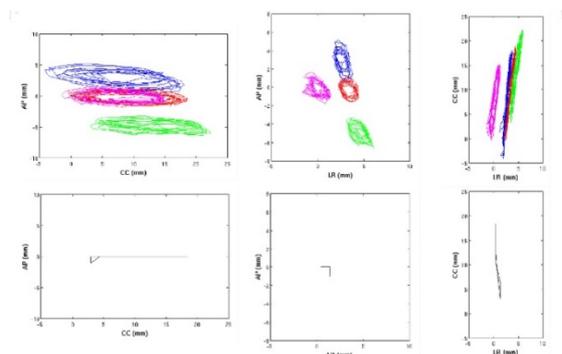

Fig. 1 The 3D tumor motion of patient 1 during 4 orthogonal fluoroscopy sequences acquired over the course of the first treatment (above), and registered by the pre-treatment 4D planning CT (below), from different views. Note the presence of a significant inter-fractional baseline drift, as well as the lack of hysteresis captured by the 4DCT.

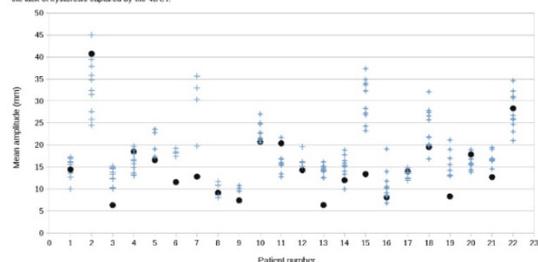

Fig. 2 Mean 3D tumor motion amplitude per patient for each fraction (+) and based on the pre-treatment 4D planning CT (\*).

### Conclusion

Based on this select group of patients, it can be concluded that breathing-induced tumour motion can vary significantly over the entire course of treatment, not rarely exceeding common safety margins of 5 mm. A previous study indicates that a single 4DCT is sufficient to evaluate breathing motion, however, long-term variability was never investigated. The results in this study indicate that a single 4DCT, a snapshot in time, can not accurately predict the motion amplitude during all fractions, which is especially cumbersome when used for ITV treatment planning.

### OC-0485 How many plans are needed for an optimal plan library in ART for locally advanced cervical cancer?

E. Novakova<sup>1</sup>, S.T. Heijkoop<sup>1</sup>, S. Quint<sup>1</sup>, A.G. Zolnay<sup>1</sup>, J.W.M. Mens<sup>1</sup>, J. Godart<sup>1</sup>, B.J.M. Heijmen<sup>1</sup>, M.S. Hoogeman<sup>1</sup>

<sup>1</sup>Erasmus MC Cancer Institute, Physics, Rotterdam, The Netherlands

### Purpose or Objective

In our institute, locally advanced cervical cancer patients are treated with online, Plan-of-the-Day ART. For patients with a tip-of-uterus displacement >2.5 cm, as measured in pretreatment full and empty bladder CTs, the plan library contains 2 plans to cope with daily anatomy variations. Increasing the number of plans for larger motion could be beneficial for tissue sparing, but is burdensome and the dosimetric benefit is yet to be proven at an individual patient level. We investigated an easy-to-use metric to individualize the number of plans in the library, balancing gain in organs-at-risk (OAR) sparing and clinical feasibility.

### Material and Methods

Data of 14 previously treated patients were analyzed. For each patient, plan libraries were created containing either 1 plan, based on the full-motion-range ITV as derived from the pre-treatment full and empty bladder CT-scans, or 2, 3 or 4 plans based on sub-motion-range ITVs. To create PTVs, the nodal CTV was expanded by 7-mm and the ITVs by 10-mm. For all PTVs, VMAT plans were created to deliver 46 Gy in 23 fractions. Daily CBCT scans were used for plan selection by calculating the bladder volume.

For the dosimetric evaluations, the cervix-uterus and the OAR (bladder, rectum, and bowel) were contoured on

daily CBCT scans. For each plan library, the OAR  $V_{40Gy}$  were recorded for all CBCT scans. As the gain in sparing varied over the OAR during the fractionated treatment, a composite volume was calculated by summing up the DVH parameters. Pearson correlation was estimated between DVH parameters and a maximum pretreatment extent of uterus motion defined as the Hausdorff distance (HD) (99%-ile) (MaxUtHD). A Wilcoxon signed-rank test was used to assess statistical differences among strategies.

### Results

Strong correlations were found between MaxUtHD and the total volume of spared normal tissue (composite gain of DVH parameters for bowel, bladder and rectum, see Fig.1). 3 patients were identified as outliers having more than 30% of the fractions an emptier or a fuller bladder than on the planning CT. They should be re-planned during treatment and were excluded from further analysis. For 2 plan ( $R=0.8$ ), 3 plan ( $R=0.9$ ) and 4 plan libraries ( $R=0.6$ ),  $p<0.01$ . For patients with MaxUtHD >35 mm, adding a 3<sup>rd</sup> plan would significantly reduce composite  $V_{40Gy}$  by  $18 \pm 6$  cc on average (from that bowel  $10 \pm 6$  cc, bladder  $6 \pm 2$  cc and rectum  $2 \pm 1$  cc). For patient >50 mm MaxUtHD, additional 12 cc would be spared by adding a 4<sup>th</sup> plan to the library.

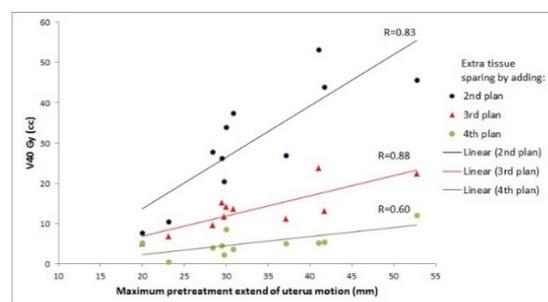

Fig. 1: Composite gain of  $V_{40Gy}$  for bowel, bladder and rectum by adding 2<sup>nd</sup>, 3<sup>rd</sup> and 4<sup>th</sup> plan to the plan library, correlated with the maximum pretreatment extent of uterus motion (MaxUtHD). R = Pearson correlation coefficient.

### Conclusion

Our results indicate that an extension of the plan library would have the most impact on sparing of bowel cavity. Patients with large MaxUtHD (>35 mm) would benefit from adding a 3<sup>rd</sup> plan to the library and patients with the extremely large MaxUtHD (>50 mm) would benefit from adding a 4<sup>th</sup> plan to the library. This study provides an easy-to-implement criteria to select patients who would benefit the most from additional plans in a plan library approach.

### OC-0486 Multi-criterial patient positioning based on dose recalculation on scatter-corrected CBCT images

J. Hofmaier<sup>1,2</sup>, J. Haehnle<sup>3</sup>, C. Kurz<sup>1,2</sup>, G. Landry<sup>2</sup>, C. Maihöfer<sup>1</sup>, P. Süß<sup>3</sup>, K. Teichert<sup>3</sup>, N. Traulsen<sup>4</sup>, C. Brachmann<sup>5</sup>, F. Weiler<sup>5</sup>, C. Thieke<sup>1</sup>, K.H. Küfer<sup>3</sup>, C. Belka<sup>1</sup>, K. Parodi<sup>2</sup>, F. Kamp<sup>1</sup>

<sup>1</sup>University Hospital of LMU Munich, Radiation Oncology, München, Germany

<sup>2</sup>Ludwig-Maximilians-Universität München, Department of Medical Physics- Faculty of Physics, München, Germany

<sup>3</sup>Fraunhofer Institute, Industrial Mathematics ITWM, Kaiserslautern, Germany

<sup>4</sup>Fraunhofer Institute, Medical Image Computing MEVIS, Lübeck, Germany

<sup>5</sup>Fraunhofer Institute, Medical Image Computing MEVIS, Bremen, Germany

### Purpose or Objective

In order to exploit the dose conformality of intensity-modulated photon therapy, an accurate patient positioning prior to treatment is required. Typically, this is achieved using in-room image data [e.g. cone beam CT

(CBCT)], which is registered to the planning CT (pCT) using a rigid body alignment. In the presence of non-rigid anatomical changes, it is not obvious which isocenter shift is the best with respect to target coverage and normal tissue sparing. We evaluate an alternative approach, where the dose is recalculated on daily scatter-corrected CBCT (scCBCT) images and the isocenter shift is determined using an interactive multicriterial optimization of DVH objectives.

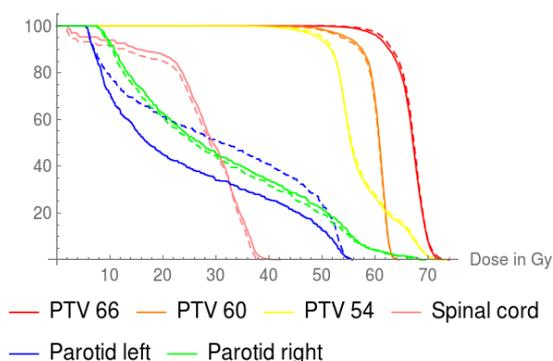

#### Material and Methods

To enable dose calculations, the CBCT projections were scatter corrected using forward projections of the virtual CT (deformable image registration of pCT on CBCT) as a prior (Park et al. 2015, Med Phys). PTV and OAR structures were transferred from the pCT to the scCBCTs and corrected by an experienced clinician. In MIRA, a research planning system interpolation between pre-calculated sample dose distributions for a set of 13 isocenter positions allows navigating continuously on the set of Pareto-optimal isocenters. DVH parameters can be manipulated interactively. The resulting isodose lines and integral DVHs of this trade-off are displayed in real time, allowing the user to repeatedly manipulate the parameters until the clinically optimal solution is found. For the resulting isocenter shift, a final dose calculation is performed. The approach is evaluated for an exemplary head and neck (H&N) patient case. The prescribed dose was 54Gy in 30 fractions with 2 integrated boosts of 60Gy and 66Gy, respectively. For 5 scCBCTs the optimized dose distribution was compared to the ones of the clinically applied shifts. To evaluate the accuracy of the underlying dose interpolation, 100 random isocenter shifts for each of the scCBCTs were interpolated and compared to an MC calculation using a 2%/2mm gamma criterion.

#### Results

Dose interpolation accuracy was high [median gamma pass rate: 99.0% (range 96.6-100.0%)]. The spinal cord  $D_{2\%}$  was comparable for both approaches (mean change -0.2Gy, range -1.7 to 0.2Gy). The mean dose of the parotid glands could be improved for 2 out of 5 fractions (one of them is displayed in Fig. 1), for the other 3 it could be preserved (mean change -1.0Gy, range -2.2Gy to +0.4Gy). Target coverage was preserved. The mean Euclidean distance between the clinical and the optimized isocenter was 1.8mm (range 0.8-3.2mm).

rel. Volume in %

**Figure 1:** Comparison between a clinical (dashed) and an optimized shift (solid). The mean dose to the left parotid gland improved from 30.6 to 26.1Gy.

#### Conclusion

Compared to a rigid bony alignment, the novel, interactive, DVH based positioning offers increased control over OAR dose and PTV coverage. For a first H&N case, in some fractions the dose to the parotid gland was improved.

#### OC-0487 Pre-treatment characteristics can predict anatomical changes occurring during RT in lung cancer.

L. Hoffmann<sup>1</sup>, A. Khalil<sup>2</sup>, M. Knap<sup>2</sup>, M. Alber<sup>3</sup>, D. Møller<sup>1</sup>

<sup>1</sup>Aarhus University Hospital, Department of Medical physics, Aarhus, Denmark

<sup>2</sup>Aarhus University Hospital, Department of Oncology, Aarhus, Denmark

<sup>3</sup>Heidelberg University Hospital, Department of Oncology, Heidelberg, Germany

#### Purpose or Objective

Anatomical changes such as the resolving atelectasis seen in Fig 1. prompt adaptive radiotherapy (ART) for a large number of lung cancer patients in order to avoid target under dosage. ART may re-establish the original dose distribution on the cost of additional work load. We investigated the correlation between patient characteristics before RT and anatomical changes during RT in order to identify the patients eligible for ART.

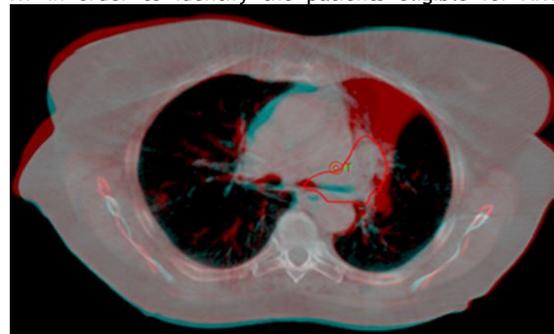

Fig 1. Atelectasis is resolving. PlanningCT is red and CBCT is turquoise.

#### Material and Methods

A decision support protocol for ART was used for treatment of 165 lung cancer patients. The patient setup on the primary tumour (T) was based on daily pre-treatment cone-beam CTs. Deviations in T >2mm, lymph nodes (N) >5mm or changes in atelectasis (A) or pleural effusion (PE) triggered replanning. The daily CBCTs were retrospectively reviewed to score changes above trigger limit in T or N position/shape, changes in A or PE, as well as T or N shrinkage >1cm. The findings were correlated to pre-treatment patient characteristics as histology, T and N volume, location and number, A or PE, and T or N adjacent to or surrounding the bronchi. Fisher's exact test was used for comparison.  $p < 0.05$  was considered significant.

#### Results

Fifty three patients (32%) were adapted due to changes in A (8%), T (6%), N (15%) or T+N (3%), and 7% had more than one replan. Atelectasis was seen at planningCT in 50 patients (30%) while in 12 patients (7%), it appeared during RT. Presence of A before or during RT was not significantly correlated with replanning. However, the changes in A during RT significantly increased the probability of replanning. ( $p=0.03$ ), see Fig.2. Additionally, A within 5mm of T or N was significant ( $p=0.01$ ). Only 11 patients (6%) had changes in PE, but only in one patient was replanning indicated. Patients with T0 or N0 had a significant low risk of replanning ( $p=0.01$ ,  $p=0.03$ ) while patients with two or more N had a high rate of replanning (ns). Nodes in stations 1,2,3 or 4,7 or 10,11,12 had significantly higher rate of replanning as compared to patients with nodes in station 5,6 and 8,9. Node-volume >30cm<sup>3</sup> had a significantly higher rate of replanning ( $p=0.02$ ). No correlation was found for T location, T size, T or N adjacent to bronchi or for T or N shrinkage. Histology was not significant for replanning. The imaging rate may be decreased for patients with T0 and no A, as none of these were adapted. For patients with N0 and no A, only 11%, were replanned. On the contrary, 60% of the patients with A and N volume >30cm<sup>3</sup> were replanned.

## Conclusion

Prognostic factors for replanning of lung cancer patients are changes in A during RT, A in the vicinity of T or N, large N volume, and the N stations involved. No correlation between risk of replanning and T size or T location was found. The imaging frequency may be adjusted based on these pre-treatment characteristics. Patients without A and TO or NO had little risk of replanning. The imaging frequency may be reduced for these patients, while patients with A and large N volumes should be monitored closely.

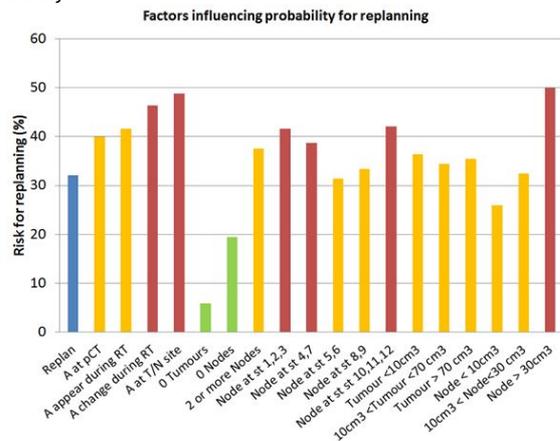

Fig. 2. Risk of replanning for selected pre-treatment patient characteristics. The blue column is the overall risk of replanning. Yellow bars represent non-significant probability for replanning. Red bars represent a significant probability ( $p < 0.05$ ) for replanning and green bars represent a significant probability for no replanning.

## OC-0488 Thoracic tumor treatment course assessment based on 4D dose accumulation for scanned proton therapy

A. Meijers<sup>1</sup>, C. Richter<sup>2</sup>, F. Dessy<sup>3</sup>, J. Widder<sup>1</sup>, E. Korevaar<sup>1</sup>, A. Jakobi<sup>2</sup>, C. Ribeiro<sup>1</sup>, J. Langendijk<sup>1</sup>, A. Knopf<sup>1</sup>

<sup>1</sup>University of Groningen - University Medical Center Groningen, Department of Radiation Oncology, Groningen, The Netherlands

<sup>2</sup>OncoRay - National Center for Radiation Research in Oncology, Faculty of Medicine and University Hospital Carl Gustav Carus- Technische Universität Dresden-Helmholtz-Zentrum Dresden - Rossendorf, Dresden, Germany

<sup>3</sup>Ion Beam Applications IBA, Clinical Solutions, Louvain-la-Neuve, Belgium

### Purpose or Objective

With the increase of proton therapy facilities worldwide featuring Pencil Beam Scanning (PBS) as their only treatment modality, PBS is on the way of becoming the standard for proton therapy. However, for some indications in the thoracic region PBS is not widely used due to uncertainties in the planned dose, which can be caused by combined effects of setup errors, range uncertainty, interplay effect, breathing irregularity, anatomical variations, delivery machine uncertainties, etc. By performing pre-treatment plan robustness evaluation that includes these effects, it is evident that actual delivered fractional dose at any instance is highly uncertain to predict. 4D dose accumulation is able to control some of the uncertainties that are affecting pre-treatment evaluation of the plan quality. Therefore, the purpose of this proof-of-concept study is to investigate the feasibility of monitoring and assessing the quality of delivered treatment fractions throughout the treatment course.

### Material and Methods

4D dose accumulation is performed by utilizing (1) delivery machine log files (IBA, Belgium), (2) breathing pattern records (ANZAI, Japan) and (3) planning 4DCT scans or

repeated 4D control CT scans (Siemens, Germany). Dose computation is performed in the RayStation (RaySearch, Sweden) treatment planning system (TPS).

For every spot that is delivered during a particular fraction, the spot energy, position, dose (as charge) and absolute time of delivery is retrieved from the machine log file using a dedicated script. Patient's breathing pattern is analyzed and inhale peaks are determined. Subsequently, all breathing cycles are divided in 10 phases and each phase is associated with absolute time. PBS spots are split in 10 groups according to their corresponding phase and written to 10 treatment sub-plans (DICOM), where every sub-plan corresponds to a particular phase of the 4DCT. Using scripting capabilities of the TPS, sub-plans are imported for dose computation. Eventually dose warping to the reference phase is performed to estimate the delivered fractional dose.

Data sets used for the proof-of-concept were not collected during the same treatment fraction.

### Results

By using the described method the timeline of a PBS delivery can be correlated with patient's breathing pattern as shown in Figure 1. Computation of log based sub-plans on 4DCT results in an accumulated fractional 4D dose distribution as shown in Figure 2. Based on the exemplary case, the method allows to assess the conformity between planned and delivered doses (i.e., CTV V95 has dropped to 96.7% from nominal 100%).

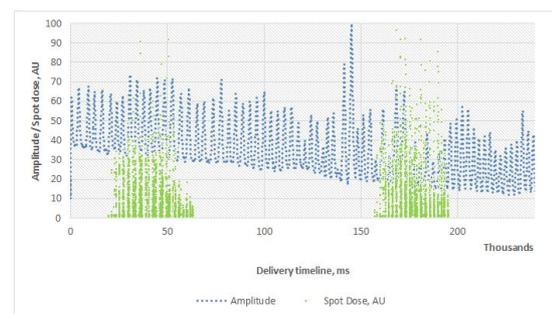

Figure 1. PBS plan delivery timeline overlaid on patient's breathing pattern. PBS delivery timeline is reconstructed based on machine log file. Spots (green dots) are represented by their dose (MU) in relative units. The plan contains two treatment fields. Breathing pattern (blue dots) is reconstructed based on ANZAI export file. The pattern is represented by the relative breathing amplitude.

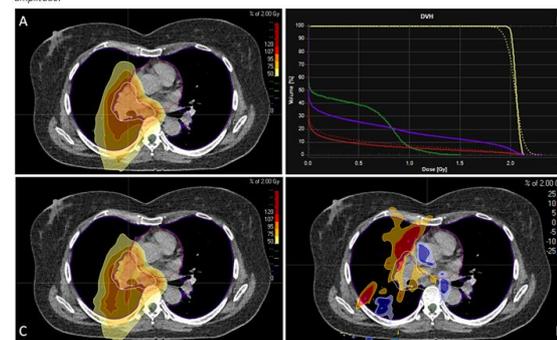

Figure 2. Comparison of nominal and accumulated fractional 4D doses. A. Nominal dose distribution for a planned 2 Gy fraction. B. DVH plots for the nominal (solid) and accumulated (dotted) dose distributions. The target structure is visualized in yellow. The heart, lung and spinal cord structures are presented in red, purple and green respectively. C. Accumulated 4D dose distribution for a delivered 2 Gy fraction (based on exemplary data sets). D. Dose difference between nominal and accumulated dose distributions.

### Conclusion

The availability of a real-time 4D dose accumulation based treatment assessment tool allows to assess the quality of the delivered dose during progress of the treatment course and to take appropriate actions, as for example, plan adaptation, in cases of significant deviations. It is foreseen to extend this study for a full treatment course of a broader population of patients.

### OC-0489 Variation in bladder volume and associated spatial dose metrics in prostate and pelvic radiotherapy

O. Casares-Magaz<sup>1</sup>, V. Moiseenko<sup>2</sup>, A. Hopper<sup>2</sup>, N.J. Pettersson<sup>2</sup>, M. Thor<sup>3</sup>, R. Knopp<sup>2</sup>, J.O. Deasy<sup>3</sup>, L.P. Muren<sup>1</sup>, J. Einck<sup>2</sup>

<sup>1</sup>Aarhus University Hospital - Aarhus University, Medical Physics, Aarhus, Denmark

<sup>2</sup>University of California San Diego, Radiation Medicine and Applied Sciences, San Diego, USA

<sup>3</sup>Memorial Sloan Kettering Cancer Center, Medical Physics, New York, USA

#### Purpose or Objective

The bladder displays considerable inter-fractional changes during a course of radiotherapy (RT) which leads to differences between delivered and planned dose/volume metrics. The aim of this study was to compare planned with actually delivered spatial bladder dose distributions for patients receiving RT for prostate cancer with a full bladder/empty rectum protocol, by using daily on-board cone-beam CT (CBCT) and to assess impact of concomitantly treating the pelvic lymph nodes.

#### Material and Methods

Twenty-five prostate cancer patients (fifteen cases receiving local prostate irradiation and ten cases also receiving pelvic node irradiation) received daily CBCT-based image-guidance RT (81 Gy in 45 fractions) adhering to full bladder and empty rectum protocol. For each patient, 8-9 CBCTs were registered to the planning CT using the clinically applied patient set-up (translations). Bladder was segmented on each CBCT and approved by a radiation oncologist. Bladder shells were extracted using a 3mm inner margin, and bladder shell quadrants were created using axial and coronal planes drawn through the center of mass of the bladder. Dose/volume histograms (DVHs) were extracted for bladder, bladder shell (BS), as well as anterior (A), posterior (P), superior (S), inferior (I), A/I, A/S, P/I, P/S sectors of the BS in each planning CT and CBCT. Differences in DVH metric between the planned and the delivered were calculated, and the association between DVH metrics and bladder volume was evaluated using the Spearman rank correlation coefficient ( $r_s$ ). DVH metrics per fraction ( $D_x$ , absolute  $V_x$  and relative  $V_x$ ; x:5-100% in 5% steps) were calculated for all bladder sectors and compared between the two groups of patients.

#### Results

Bladder volumes varied considerably during RT, with a coefficient of variation ranged between 14% to 54% across treatment. Lower bladder volumes were found for patients receiving pelvic RT compared to patients treated locally (population mean±SD: 173±94cm<sup>3</sup> vs. 217±119 cm<sup>3</sup>; p<0.01). At the anterior and superior part of the bladder, positive associations were found between DVH metrics and bladder volume for pelvic node irradiation fractions, while negative associations were found for prostate alone fractions, 25% and 75%  $r_s$  percentiles: (0.74, 0.93) and (0.78, 0.96) of S and A/S sectors for pelvic RT vs. (-0.79, -0.43) and (-0.80, -0.40) of S and A/S sectors for prostate RT across all  $V_x$  metrics (Fig. 2). Similar trend was found for the BS 25% and 75%  $r_s$  percentiles: 0.91-1.00 vs. 0.09-0.61; however, for the whole bladder, differences were smaller between 25% and 75%  $r_s$  percentiles: (0.93, 1.00) vs. (0.23, 0.71) for pelvic and prostate RT, respectively.

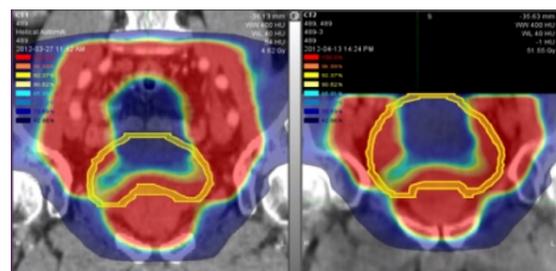

Figure 1. Upper Left Panel: characteristic patient with a smaller bladder volume in the plan CT (left figure) compared to one of the CBCT (right figure) acquired before a treatment session.

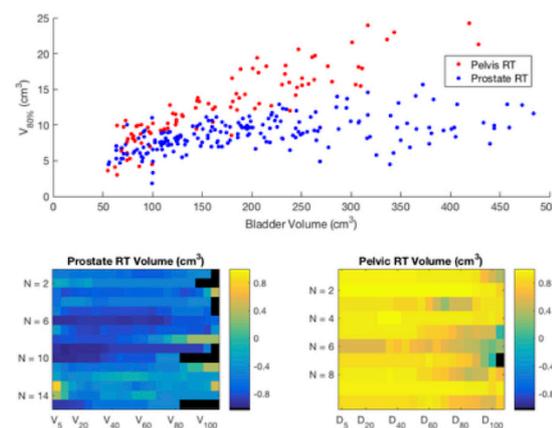

Figure 2. Upper Panel: Lower Left Panel: Scatter plot for the absolute volume at the superior part of the bladder shell receiving 80% of the dose ( $V_{80\%}$ ) plotted against the total bladder volume, for all the CBCTs of the pelvic node RT fractions (red) and prostate RT (blue). Lower Panel: Spearman rank correlation coefficients matrices between DVH metrics for the two groups of patients delivered at the superior sector of the bladder shell.

#### Conclusion

CBCT-based bladder analysis exhibits significant volume changes along RT course even under full bladder daily image-guided RT protocol. Larger bladder volumes meant higher delivered doses to the superior and anterior bladder subsectors in pelvic node irradiation, but reduced overall delivered doses for prostate treatment.

### OC-0490 A robust and fast planning approach for adaptive MR-guided treatment of pancreatic cancer

O. Bohoudi<sup>1</sup>, A. Bruynzeel<sup>1</sup>, B. Slotman<sup>1</sup>, S. Senan<sup>1</sup>, F. Lagerwaard<sup>1</sup>, M.A. Palacios<sup>1</sup>

<sup>1</sup>VUMC, Radiotherapy, Amsterdam, The Netherlands

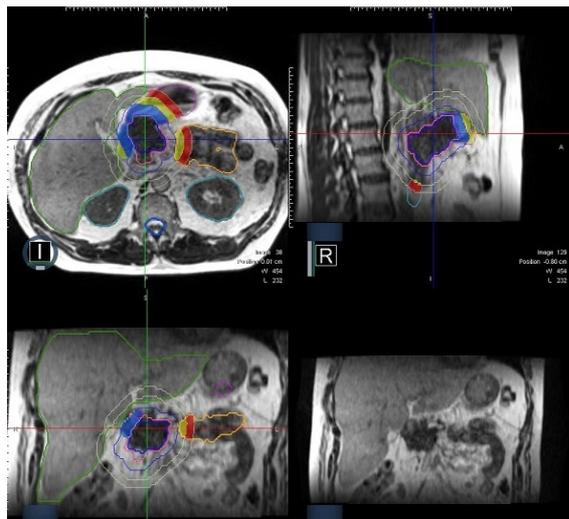

#### Purpose or Objective

In May 2016, we implemented stereotactic MR-guided adaptive radiation therapy (SMART) using the MRIdian system (Viewray) for locally advanced pancreatic cancer. Interfractional changes in the anatomy of adjacent organs-at-risk (OARs) make daily online plan adaptation desirable. The main challenge of online plan adaptation is the requirement that it must be performed fast while the patient remains in treatment position. We evaluated an in-house developed re-planning strategy, which is currently in clinical use.

#### Material and Methods

Before use of SMART, robust baseline IMRT plans for online re-optimization are first produced with the MRIdian planning system (ViewRay). The same planning software is available at the treatment console for plan adaption. The target structure used for optimization is defined as  $PTV_{OPT}$  (GTV+3mm minus OARs). OAR contours are then spatially partitioned in separate OAR portions located within 1, 2 and 3cm from the  $PTV_{OPT}$  surface, thereby allowing direct control over the spatial dose distribution (Fig. 1). The optimization process relies on a model which predicts OAR dose as a function of distance from  $PTV_{OPT}$ , and generates optimization objectives to achieve a robust baseline plan for daily adaption. For daily SMART, physicians only re-

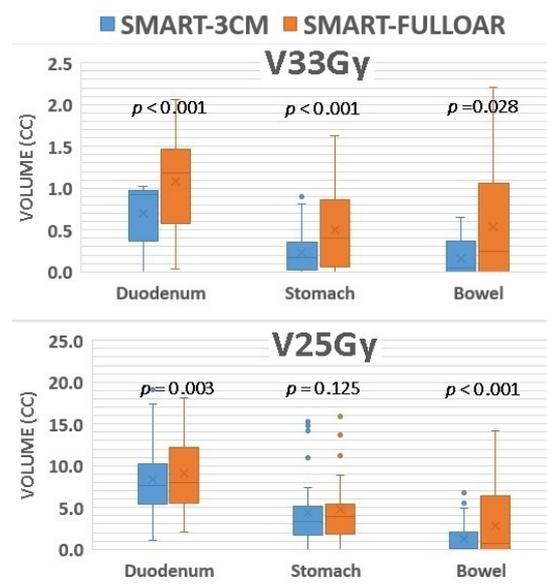

contour OAR located within 3cm from PTV<sub>opt</sub>, based on the daily MR imaging (SMART<sub>3CM</sub>). Optimization structures are automatically adapted to the new anatomy, and re-optimization is performed using exactly the same plan parameters. This limited re-contouring strategy was evaluated by comparing 45 previously delivered fractions against a simulated standard (re-)planning method using full-scale OAR (re-)contouring, where optimization objectives were used for the whole organs (SMART<sub>FULLOAR</sub>). Baseline plans for OAR were created that had identical plan quality as were achieved for SMART<sub>3CM</sub>. Efficiency of both strategies was scored according to the number of optimizations needed to generate a high quality plan. Plan quality was assessed using PTV coverage (V95%) and institutional OAR constraints (V33Gy and V25Gy).

**Fig. 1:** Optimization contours spatially partitioned within 3 cm outside of PTV<sub>OPT</sub> (purple) in separate OAR portions (blue, yellow and red).

### Results

The SMART<sub>3CM</sub> baseline plans required a lower number of optimizations than SMART<sub>FULLOAR</sub> (4 vs 17 on average). PTV<sub>OPT</sub> coverage with both strategies was identical in all fractions (median V95%=93±6.8%). SMART<sub>3CM</sub> uniformly resulted in plans which complied with the V33Gy dose constraint for OARs, whereas SMART<sub>FULLOAR</sub> failed in 35% of the cases to adhere to the V33Gy dose constraint according to the clinical protocol. Both strategies achieved V25Gy values lower than 20 cc for all OARs in every fraction. However, on average, SMART<sub>3CM</sub> resulted in a lower V25Gy than SMART<sub>FULLOAR</sub> (Fig.2).

**Fig. 2:** The V33Gy (cc) and V25Gy (cc) for duodenum, stomach and bowel compared for SMART<sub>3CM</sub> and SMART<sub>FULLOAR</sub>.

### Conclusion

This fast and robust (re-)planning approach for SBRT to pancreatic tumors requires clinicians to only re-contour OARs located within 3cm of the PTV<sub>OPT</sub>. Spatially partitioned optimization structures within this 3 cm region allowed for optimal OAR sparing, and adequate target coverage, using exactly the same plan parameters.

### OC-0491 Quality assurance of a novel table mounted imaging device integrated in a patient positioning system

A. Utz<sup>1</sup>, A. Ableitinger<sup>1</sup>, A. Zechner<sup>1</sup>, M. Mumot<sup>1</sup>, M. Teichmeister<sup>1</sup>, P. Steininger<sup>2</sup>, H. Deutschmann<sup>2</sup>, M. Stock<sup>1</sup>

<sup>1</sup>EBG MedAustron GmbH, Medical Physics, Wiener Neustadt, Austria

<sup>2</sup>medPhoton GmbH, Medical Physics, Salzburg, Austria

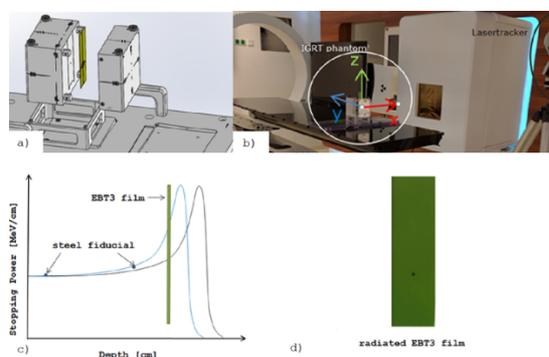

### Purpose or Objective

Image guided radiation therapy (IGRT) aims to reduce margins and subsequently increase dose sparing for OAR. The majority of image guidance procedures are based on ceiling/floor- or gantry mounted imaging devices. In our particle therapy center a novel approach for patient alignment was introduced. The imaging system (imaging ring) is mounted on the treatment table and as such, allows high imaging flexibility e.g. CBCT or planar imaging at different table positions. The goal was to establish a phantom and a concept for a quality assurance procedure for the whole IGRT workflow.

### Material and Methods

The IGRT Phantom consists of a PMMA cube with steel fiducials, which can be placed in predefined offset positions on a baseplate to simulate clinical patient shifts. An additional support structure is used to lift the cube. Holes on the upper corners of the cube allow to independently determine the absolute position with a lasertracker (see figure 1a). A CT imageset of the cube in a reference position serves as planning CT. The baseplate is indexed on the patient couch. The cube can be moved to a predefined translational and rotational offset position on the couch. Two planar images were acquired and registered to the CT. The calculated correction vector was applied by the patient positioning system. This workflow was repeated at three index positions (equal distributed along the treatment volume), payloads (0kg, 100kg, 150kg), cube offsets (long.: 10mm, lat.: 15mm, vert.: -

3mm with/without rot 3°) and couch positions. After the alignment into the isocenter the absolute position was measured with a lasertracker (u: 0.1mm)(see figure 1b). To determine the total accuracy including the treatment beam and patient alignment system, an EBT3 film was inserted into the cube. Two fiducials in a row are used to shift the Bragg peak into the layer of the film (see figure 1c). For the combined workflow with an EBT3 film, a rotation error of 1° results in a fading of the fiducials.

## Results

The mean 3D accuracy for all workflows was 0,34mm (n=24). Most of the residual rotational errors were below 0.15°. The mean deviation in x and y changes significantly in relation to the couch rotation (xmean for 0°: -0.74mm; xmean for 180°: +0.27mm)(see table 1). In figure 1d) an EBT3 film after image guided alignment and radiation with a proton beam is shown. For the combined workflow with treatment beam the translation in y and z axes was below 1mm and the rotation for rot Y and rot Z is lower than 1°.

Couch rotation : workflows :	0° n = 8	30° n = 5	90° n = 5	180° n = 6	all rotations n = 24
	mean ± std	mean ± std	mean ± std	mean ± std	mean ± std
X [mm]	-0.74 ± 0.47	-0.59 ± 0.13	-0.15 ± 0.19	0.27 ± 0.41	-0.34 ± 0.5
Y [mm]	-0.18 ± 0.17	0.11 ± 0.2	0.26 ± 0.1	-0.08 ± 0.31	0 ± 0.27
Z [mm]	-0.16 ± 0.48	0.17 ± 0.11	0.2 ± 0.13	0.13 ± 0.09	0.06 ± 0.38
rot Z [°]	0.16 ± 0.19	0.07 ± 0.15	0.09 ± 0.14	0 ± 0.04	0.09 ± 0.15
rot X [°]	0.03 ± 0.19	0 ± 0.14	-0.07 ± 0.09	-0.07 ± 0.21	-0.02 ± 0.17
rot Y [°]	-0.09 ± 0.11	-0.17 ± 0.29	0.03 ± 0.15	0.07 ± 0.23	-0.04 ± 0.2
3D vector [mm]	0.78 ± 0.7	0.63 ± 0.26	0.36 ± 0.24	0.31 ± 0.47	0.34 ± 0.68

## Conclusion

The dependencies for couch rotations might arise from a lateral offset of the imaging ring. A flexmap calibration with exactly known phantom position may reduce the lateral offset. The largest deviation (mean 3D vector = 0.78mm) was found for couch rotation 0°. The inserted EBT3 film allows determining the overall accuracy of the whole treatment workflow. The IGRT Phantom is an appropriate equipment for daily QA and for more detailed workflow tests.

## Symposium: Focus on prostate cancer: what is the best of radiotherapy we need to treat our patients with

### SP-0492 What are the best ingredients to deliver the optimal radiotherapy for prostate cancer

V. Khoo<sup>1</sup>

<sup>1</sup>Royal Marsden Hospital Trust & Institute of Cancer Research, Department of Clinical Oncology, London, United Kingdom

Optimisation for prostate radiotherapy involves understanding the natural history of prostate cancer, its prognosticators, the underlying radiobiology and strategies for radiotherapy treatment as well as how best to deliver the therapy regimes devised. Prostate cancer presents with a large spectrum of risk factors that drives its natural history as such the presenting prostate specific antigen (PSA) levels, the summed Gleason score and the

local tumour nodal and metastasis (TNM) staging. Taken together this combination of prognostic factors still provides the most reliable disease stratification compared to new tests or potential biomarkers that still require validation. It is well recognised that more reliable and sensitive predictive and prognostic factors are needed to distinguish risk groups within each risk stratification due to the large heterogeneity that exists within them. Using this approximately set of factors, prostate cancer can be divided into low, intermediate and high to very high risk groups for localised to regional disease that may receive radiotherapy curatively. This further guides the treatment volumes needed to achieve the best curative rate as well as the treatment strategies ie external beam photon therapy alone or in combination with high dose rate (HDR) brachytherapy or HDR monotherapy or proton therapy. In addition, over the past one to two decades, the understanding of prostate radiobiology has changed from accepting the standard alpha-beta ratio of 10 assigned for the majority of cancer diseases to a much lower alpha-beta ratio much more akin to that of late reacting tissues. This lower alpha-beta ratio of around 1.2 to 2.5 has driven the radiotherapy rationale for using larger dose per fraction or hypofractionation. Earlier trials have suggested that this may provide a therapeutic benefit. Recently in the past year, 2 very large randomised trials have provided outcome equivalence for the use of moderate hypofractionation compared to conventional fractionation. The first randomised trial of over 800 cases from USA in early stage disease compared 2.75Gy to 1.8Gy dose fractions in a non-inferiority study can reported equivalence for the schedules. The second non-inferiority UK/International trial recruited nearly 3300 cases and reported equivalence of 3Gy to 2Gy dose fractions for early to intermediate stage prostate cancer. These outcomes have now established a new standard for the radiotherapeutic management of early to intermediate stage localised prostate cancer. These results should not be confused with the Dutch study looking for superiority of 3.3Gy over 2Gy dose fractions where the primary endpoint was not achieved. It remains to be determined if larger dose fractions (≥ 5Gy) delivered over 1 week such as that used in stereotactic radiotherapy may provide further benefit. Trials are currently on going and their results are eagerly awaited. As important as the dose fractionation are the therapy regimes and the potentially combinations listed above. It is recognised that local failure often occurs at the site of dominant clonogenic numbers thus the utilisation of simultaneous integrated boosts with hypofractionation has potential. This is being assessed in several studies such as the FLAME study where toxicity was demonstrated to be similar to standard and conventional regimes. Important questions that need to be addressed include identification of appropriate treatment volumes and potential regions of dose escalation or even dose de-escalation. Just as important will be methods of ensure that these shorter treatment regimes are delivered both accurately and reliably. These aspects will be reviewed by the co-lecturers within this symposium.

### SP-0493 The role of spacers in the era of highly conformal, hypo-fractionated, image guided, adaptive radiotherapy of the prostate

P. Scherer<sup>1</sup>, F. Wolf<sup>1</sup>, C. Gaisberger<sup>1</sup>, F. Sedlmayer<sup>1</sup>  
<sup>1</sup>Gemeinn. Sbg. Landeskliniken Betriebs. GmbH, University Clinic for Radiotherapy and RadioOncology, Salzburg, Austria

The latest data from large prospective phase III hypo-fractionation studies, such as the CHHiP trial, support the notion that the  $\alpha/\beta$  ratio for prostate cancer might be as low as 1.5Gy, and therefore offer the opportunity to utilise hypo-fractionation to broaden the therapeutic ratio. Additionally, highly conformal treatment plans and reduced margins due to advanced image guidance as well as the use of adaptive approaches further decrease the

doses administered to the organs at risk. The broadened therapeutic ratio and the highly conformal planned and accurately administered treatment plans allow for further dose escalation to the prostate while maintaining low toxicity. However, with the rectum and the bladder being - more or less - directly adjacent to the prostate there is still a need for an approach to further reduce the dose delivered to the organs at risk.

Reviewing the current literature reveals that spacers offer an invasive, but safe and effective way to partly overcome the spatial proximity by introducing additional material between the prostate and the rectum. The increased distance - which is mostly reported to be in the range of approximately 1 cm - is clearly correlated to a significant reduction of administered doses and the volumes of the rectum receiving high doses respectively; including the anterior rectal wall which can otherwise hardly be spared. Especially the clinically important volumes receiving a high percentage of the prescribed dose or an EQD<sub>2</sub> of more than 60 or 70 Gy, which could lead to severe acute and late side effects can be significantly reduced. Several studies clearly demonstrate these dosimetric benefits of the different materials currently available. Nevertheless, there is a certain learning curve that has to be absolved to fully exploit the potential of such spacers. Another property that all of them share is that the materials are resorbed after a certain time. While all the different materials/approaches such as hyaluronic acid, hydrogels or balloons are fundamentally based on the same principle - to create a space between the prostate and the anterior rectum wall - each has slightly different characteristic. The spacer balloon (Bioprotect™) for example, has been shown to result in an advantageous dose distribution compared to spacer gels; however, it also has been shown to shrink substantially during the course of a treatment, thus losing some of its initial advantage.

Factors such as the detailed course of the resorption, together with the handling during injection/placement, the achievable increase of the distance, the actual shape and its stability, the possible influence on prostate movements, as well as the possible toxicity/side effects inflicted by the spacer itself are the factors that need to be considered when comparing the different materials/approaches.

According to the available literature, there is no evidence yet that one material is generally superior to the others, showing only slightly different properties that need to be weighted to choose the one fitting the respective requirements. However, several of the properties still need to be further evaluated and compared offering interesting research opportunities.

#### **SP-0494 Using a MRI-guided radiation therapy system for prostate cancer patients**

O. Bohoudi<sup>1</sup>, A. Bruynzeel<sup>1</sup>, S. Senan<sup>1</sup>, B. Slotman<sup>1</sup>, M.A. Palacios<sup>1</sup>, F. Lagerwaard<sup>1</sup>  
<sup>1</sup>VUMC, Radiotherapy, Amsterdam, The Netherlands

Recently, stereotactic MR-guided adaptive radiation therapy (SMART) for prostate cancer has been clinically implemented at our center, using the MRIdian system (Viewray, Inc, Cleveland OH). This dedicated device combines a split-bore 0.35T MRI which has real-time imaging possibilities, and a radiotherapy delivery system consisting of a ring gantry with three multileaf collimator-equipped 60Co heads. An integrated Monte Carlo-based treatment planning system in combination with an independent adaptive QA system, allows for online adaptive (re-)planning based on the actual daily anatomy for optimal dose delivery. We report on the first year of clinical experience with SMART for prostate patients. Here we describe the clinical implementation and workflow, provide details on daily plan adaptation and gated radiation delivery under real-time MRI-guidance.

#### **SP-0495 Introduction of FALCON (Fellowship in Anatomic delineation and CONtouring) online contouring system as a tool for e-learning**

J.G. Eriksen<sup>1</sup>

<sup>1</sup>Odense University Hospital, Department of Oncology, Odense, Denmark

Heterogeneity in contouring of target volumes and organs at risk is one of the major uncertainties for modern radiotherapy planning. Competencies in delineation requires both knowledge and skills obtained under supervised practice in the clinic. Several online possibilities for training contouring exists and can be a valid supplement in training and maintaining of skills in delineation. The ESTRO teaching programs called FALCON (Fellowship in Anatomic delineation and CONtouring) - using the EduCase platform - is presented.

#### **SP-0496 Role of radiotherapy in the treatment of stage IIIA/pN2 non-small cell lung cancer**

L. Käsmann<sup>1</sup>

<sup>1</sup>University of Lübeck, Department of Radiation Oncology, Lubeck, Germany

Lung cancer is the leading cause of cancer mortality, surgery and radiotherapy play key roles in curative treatment of this disease. Stage III comprises a heterogeneous group of tumours and an optimal multimodal treatment is warranted. However, the role of postoperative radiotherapy in the treatment of stage IIIA/pN2 non-small cell lung cancer (NSCLC) remains controversial. Pre-operative staging based on endoscopy and the use of FDG-PET has improved in the last decade. Radiotherapy technology is also emerging with 4D-CT simulation and cone beam CT for image-guidance resulting in improved survival. Meta-analysis of the PORT phase III studies using several radiotherapy technique (Cobalt, 2D-planned, 3D-conformal) show conflicting data. In the first part of this presentation we will outline the controversy of radiotherapy in the treatment of stage IIIA/pN2 non-small cell lung cancer according to the latest literature and international guidelines. Besides we will present an interesting case with focus on treatment planning, target definition as well as delineation guidelines using the e-learning programmes "Falcon" and "Dove" for a practical overview.

#### **SP-0497 Role of radiotherapy in the treatment of stage IIIA/pN2 non-small cell lung cancer**

B. Jeremic<sup>1</sup>

<sup>1</sup>Belgrade, Serbia,

Stage III non-small cell lung cancer (NSCLC) is a heterogeneous disease presentation based on the range of patient and tumor characteristics. Concurrent radiochemotherapy (RT-CHT) is the standard treatment approach for inoperable stage III NSCLC. However, in certain favorable subsets of patients with Stage III, namely those with low burden stage disease (i.e. IIIA/pN2), there seems to be greater potential for cure. In this setting, treatment regimens consisting of surgery alone or in combination with adjuvant CHT- and/or RT have been historically among the most common approaches used, with recent decades showing a trend for induction regimens followed by surgery. The latter have included induction CHT followed by surgery, and, in more recent years, induction RT-CHT followed by surgery. When tested in prospective randomized phase III studies, preoperative RT-CHT (with or without preceding CHT) followed by surgery brought no improvement in overall survival or local control compared to definitive concurrent RT-CHT, and

was associated also with an increase in treatment-related mortality. In the second part of this presentation we will discuss and clarify the role of radiotherapy according to the latest literature and international guidelines. We invite all to join the final discussion.

**SP-0498 Cervical cancer: literature overview and discussion of clinical case**

L. Bolm<sup>1</sup>

<sup>1</sup>Lübeck, Germany,

Cervical cancer is the leading cause of death from gynecological cancer worldwide and the majority of patients are diagnosed with locally advanced tumours. Therapeutic concepts are based on clinical FIGO staging. Standard treatment in FIGO IB1 to IVA cervical cancer remains a multi-modality therapy involving external-beam radiotherapy, platinum-based chemotherapy and a local brachytherapy boost. Regarding the literature to date several aspects in the treatment of cervical cancer are an issue of debate. We will discuss internationally varying treatment guidelines as to outline current controversies. Pre-therapeutic staging accuracy and the role of imaging techniques such as MRI are emerging in the treatment of locally advanced cervical cancer (LACC). Image-guided therapy may not only serve to optimize treatment planning of external beam radiotherapy, but to constantly check motions of target volume and organs at risk also in brachytherapy. We will present the process of treatment planning, target definition as well as delineation guidelines involving the e-learning programmes "Falcon" and "Dove". A case of LACC with nodal involvement will be presented at the symposium to demonstrate therapeutic challenges, side effects and the process of follow-up. We invite everyone to join the final discussion.

**SP-0499 "Cervical cancer: literature overview and discussion of clinical case"**

L. Motisi<sup>1</sup>

<sup>1</sup>University of Lübeck, Radiation Oncology, Lübeck, Germany

For the treatment of cervical cancer a multi-modality approach plays a crucial role from the point of diagnosis to treatment until follow up. The gynecological examination is still the most important investigation for the staging of cervical cancer, but on the other hand the introduction of new imaging techniques such as MRI are emerging, not only as a support for the planning treatment of external beam radiotherapy (EBRT,) but also for brachytherapy. Furthermore these new techniques are helping to detect the "target" and also the organs at risk as to spare them from high doses. Moreover the use of new techniques of EBRT, such as Cone Beam CT, are helpful to constantly check the motions of organs at risk especially rectum and bladder in daily routine, and to adapt the treatment plan. We will focus our attention also on the contouring of lymph nodes according to the new criteria of classification in low-, intermediate- and high-risk patients. Even if the lymphadenectomy and images like PET-CT are important for the staging of lymph nodes, we have to take into account many other factors predictive of local recurrence and that will guide the radiotherapist to define the best treatment plan for the patient.

**SP-0500 Rectal cancer: literature overview and discussion of clinical case**

I.S. Barua<sup>1,2</sup>

<sup>1</sup>Akershus University Hospital - Norway, Department of Oncology, Oslo, Norway

<sup>2</sup>University of Oslo, Faculty of Medicine, Oslo, Norway

The first part of the talk will cover epidemiology, staging and management of rectal cancer in Europe. This includes

last decades' development and differences in prevalence and treatment in Europe. TNM classification will be presented and radiology images shown to illustrate different stages. The management of rectal cancer, including the most common treatment modalities, will be covered and followed by a presentation of the European guidelines for radiotherapy of rectal cancer. In the second part a rectal cancer case from Akershus University Hospital in Norway will be presented. The focus will be on the views from biology, physics and RTT perspectives as well as the clinical aspect. At the end there will be a discussion with the senior expert regarding typical challenges related to choice of treatment, before the senior expert will end the session with summarizing the clinical case and the preferred treatment option at her clinic.

**SP-0501 Rectal cancer: literature overview**

K. Haustermans<sup>1</sup>

<sup>1</sup>UZ KU Leuven, Department of Radiation Oncology, Leuven, Belgium

The treatment of rectal cancer is risk-adapted and depends on the initial staging. If a patient has a low risk of local recurrence, no preoperative treatment is needed and the patient can go straight to surgery. For superficial lesions a Transanal Endoscopic Microsurgery (TEM) procedure can be considered. For more advanced cases Total Mesorectal Excision (TME) is preferred. The addition of preoperative radiotherapy has further reduced the risk of local recurrence. Patients with an intermediate risk of relapse are currently treated by a short course of radiotherapy (5 times 5 Gy) followed by immediate surgery. Patients with a high risk of local recurrence e.g. threatened mesorectal fascia by the primary tumor, are treated with a long course of chemoradiation followed by TME surgery 8 to 12 weeks after the end of the chemoradiation. In case of threatened sphincter, a long course of chemoradiation followed by a long interval is currently the treatment of choice. Currently, many studies are ongoing looking into the possibility of organ preservation or in intensifying the preoperative chemotherapy with the aim of reducing the risk of distant metastasis. Omitting radiotherapy in patients responding well to preoperative chemotherapy aims at reducing radiation induced toxicity. Lengthening the interval after short course radiotherapy is being compared with preoperative chemoradiotherapy followed after 8 to 12 weeks by TME. Until the results of these studies become available none of these approaches can be regarded as standard.

**PV-0502 Post-operative radiation therapy in atypical meningiomas: analysis of prognostic factors**

S. Shakir<sup>1</sup>, L. Souhami<sup>2</sup>, K. Petrecca<sup>3</sup>, J. Mansure<sup>4</sup>, V. Panet-Raymond<sup>1</sup>, G. Shenouda<sup>1</sup>, K. Singh<sup>5</sup>, A. Alodaini<sup>6</sup>, B. Abdulkarim<sup>1</sup>, M. Guiot<sup>6</sup>

<sup>1</sup>McGill University Health Center, Radiation Oncology, Montreal, Canada

<sup>2</sup>McGill University Health Centre, Radiation Oncology, Montreal, Canada

<sup>3</sup>McGill University Health Centre, Neurosurgery, Montreal, Canada

<sup>4</sup>McGill University Health Center, Clinical Statistics, Montreal, Canada

<sup>5</sup>McGill University Health Center, Medical physics, Montreal, Canada

<sup>6</sup>McGill University Health Center, Pathology, Montreal, Canada

### Purpose or Objective

The role of adjuvant radiotherapy (RT) in the post-operative management of atypical meningiomas remains controversial, particularly after a gross total resection (GTR). In this study, we reviewed long-term results in such patients aiming to identify patient-, tumor- or treatment-related variables potentially associated with prognostic significance that might influence outcomes.

### Material and Methods

Between 1992 and 2013, we retrospectively identified 72 patients with atypical meningioma treated at our institution. All of them underwent a maximal safe surgical resection. Patients with multiple tumors, neurofibromatosis type 2, previous cranial RT, multiple lesions, previously resected grade I lesion that had transformed to a grade II at time of recurrence or inadequate follow-up imaging were not eligible. Pathology was reviewed in each case to confirm grading. We performed pre- and post-operative serial planimetric and volumetric measurements of tumor size changes from magnetic resonance imaging. Age, tumor location, bone involvement, extent of resection, tumor growth rate, use of post-operative radiotherapy (PORT), and residual tumor volume at time of radiotherapy (RT) were assessed by uni- and multivariate analysis to determine their influence on local tumor progression. We measured, before and after RT, absolute and relative tumor growth rates and tumor doubling time in all patients.

### Results

Median age was 62 years and the median follow-up was 69 months. Forty-two patients (58%) underwent GTR and 30 (42%) underwent a subtotal resection (STR). PORT was delivered to 12 patients (28.5%) with GTR and only 4 (13%) with subtotal resection (STR). Control rates at 5 years for GTR patients with or without PORT were 100% vs. 53% (median time for failure = 30 months), respectively ( $p=0.0034$ ). Similarly, local control for STR patients +/- PORT were 75% vs 4% (median time for failure = 10 months), respectively ( $p=0.0038$ ). On multivariate analysis, no-PORT ( $p=0.01$ ) and STR ( $p=0.0002$ ) were the only independent significant prognostic factors for local recurrence. Based on Youden-Index-J, a cut-off residual volume of less than 8.76 cm<sup>3</sup> was associated with lower failure rate (7% vs 77%,  $p<0.001$ ). In patients not receiving RT, the median relative and absolute growth rates, and tumor doubling time were 115.75%/year, 4.27 cm<sup>3</sup>/year and 0.78 year, respectively. These indices improved after the addition of RT (74.5%/year, 2.48 cm<sup>3</sup>/year and 1.73 year, respectively). Volumetric measurement detected tumor progression earlier than planimetric by a median time lag of 18 months.

### Conclusion

In patients with atypical meningioma, regardless of whether a GTR or STR is performed, the use of PORT appears to be associated with significant improvement in local disease control. Patients with a residual tumor larger than 8.76 cm<sup>3</sup> have an increased failure rate and should be considered for early RT.

### PV-0503 Novel RPA classification combining MGMT promoter methylation status in newly diagnosed glioblastoma

C.W. Wee<sup>1</sup>, E. Kim<sup>1</sup>, I.A. Kim<sup>1</sup>, T.M. Kim<sup>2</sup>, Y.J. Kim<sup>2</sup>, C.K. Park<sup>3</sup>, J.W. Kim<sup>3</sup>, C.Y. Kim<sup>3</sup>, S.H. Choi<sup>4</sup>, J.H. Kim<sup>4</sup>, S.H. Park<sup>5</sup>, G. Choe<sup>6</sup>, S.T. Lee<sup>6</sup>, I.H. Kim<sup>7</sup>

<sup>1</sup>Seoul National University College of Medicine, Department of Radiation Oncology, Seoul, Korea Republic of

<sup>2</sup>Seoul National University College of Medicine, Department of Internal Medicine, Seoul, Korea Republic of

<sup>3</sup>Seoul National University College of Medicine, Department of Neurosurgery, Seoul, Korea Republic of  
<sup>4</sup>Seoul National University College of Medicine, Department of Radiology, Seoul, Korea Republic of

<sup>5</sup>Seoul National University College of Medicine, Department of Pathology, Seoul, Korea Republic of  
<sup>6</sup>Seoul National University College of Medicine, Department of Neurology, Seoul, Korea Republic of

### Purpose or Objective

Since the prognostic and predictive value of MGMT promoter methylation is widely understood, a refinement of the recursive partitioning analysis (RPA) classification for glioblastoma (GBM) integrating the MGMT methylation status is warranted.

### Material and Methods

A total of 256 patients since 2006 were prospectively intended to be treated with radiotherapy (RT) plus concurrent and adjuvant temozolomide (TMZ) according to the standard regimen and the MGMT methylation status was available in all patients. In 45.3% of the patients, the MGMT promoter was methylated.

### Results

The median follow-up and survival (MS) were 17.7 and 19.6 months, respectively. RPA was performed based on the results of multivariate analysis, and in contrast to the RTOG RPA classification, Karnofsky performance status (KPS) score made the initial split ( $\geq 70$  vs.  $< 70$ ). Four RPA classes were identified ( $p < .001$ ); class I,  $KPS \geq 70$ /GTR/methylated MGMT (MS 69.2 months); class II,  $KPS \geq 70$ /GTR/non-methylated MGMT or  $KPS \geq 70$ /residual disease/methylated MGMT (MS 23.7 months); class III,  $KPS \geq 70$ /residual disease/non-methylated MGMT (MS 15.4 months); class IV,  $KPS < 70$  (MS 11.0 months).

### Conclusion

A novel RPA classification for GBM was formulated highlighting the significance of MGMT promoter methylation in the TMZ era. This model integrating pertinent molecular information can be used effectively for the prediction of individual patient's prognosis.

### PV-0504 Observed survival in 3270 patients treated with Whole Brain Radiotherapy compared to the QUARTZ data

P. Jeene<sup>1</sup>, R. Kwakman<sup>1</sup>, J. Van Nes<sup>2</sup>, K. De Vries<sup>3</sup>, G. Wester<sup>4</sup>, E. Dieleman<sup>1</sup>, T. Rozema<sup>5</sup>, J. Zindler<sup>6</sup>, J. Verhoeff<sup>7</sup>, L. Stalpers<sup>1</sup>

<sup>1</sup>Academic Medical Center, Radiotherapy, Amsterdam, The Netherlands

<sup>2</sup>Radiotherapeutisch Instituut Friesland, Radiotherapy, Leeuwarden, The Netherlands

<sup>3</sup>Antoni van Leeuwenhoek, Radiotherapy, Amsterdam, The Netherlands

<sup>4</sup>Radiotherapiegroep, Radiotherapy, Arnhem, The Netherlands

<sup>5</sup>Instituut Verbeeten, Radiotherapy, Tilburg, The Netherlands

<sup>6</sup>MAASTRO Clinic, Radiotherapy, Maastricht, The Netherlands

<sup>7</sup>Academic Medical Center Utrecht, Radiotherapy, Utrecht, The Netherlands

### Purpose or Objective

Since Horton et al (1971), Whole Brain Radiotherapy (WBRT) is considered the standard of care for patients with more than 3 brain metastases or patients otherwise unfit for radical local treatment and with at least a reasonable performance score. In the 2016 QUARTZ trial, patients with brain metastases from a primary non-small cell lung cancer (NSCLC) were randomized between best supportive care (BSC) and WBRT with BSC. There was no difference in overall survival (OS), Quality of Life or use of dexamethasone. These unexpected results were criticized because OS was poorer (2 months) than the alleged survival in common radiotherapy practice, suggesting selection bias. Indeed, only 6% of included patients had a favorable RPA class 1. Furthermore, patients with a more favorable primary tumor such as breast cancer, could perhaps benefit more from WBRT. Therefore, we

compared the QUARTZ data with survival after WBRT in 'common radiotherapy practice' from a large multicenter retrospective cohort in the Netherlands.

#### Material and Methods

Survival data from all patients with brain metastases from NSCLC or any type of breast cancer treated with WBRT between 2000 and 2014 were analyzed. Patients were treated in seven different institutes (both academic and non-academic covering 33% of Dutch radiotherapy practices). All patients were treated with 5 fractions of 4 Gy. Survival was calculated from the first day of radiotherapy until the day of death or last follow-up. Date of death was retrieved from the Dutch Municipal Personal Records Database.

#### Results

Between 2000 and 2014, 3270 patients were identified, 2384 with brain metastases from NSCLC (73%) and 886 from primary breast cancer (27%). The median OS was 2.7 months for the NSCLC group and 3.8 months for the breast cancer group ( $p < 0.001$ ). At time of analysis, 97% of all patients was deceased. There was no difference between academic and non-academic centres. No correlation between the year of treatment and OS was found.

#### Conclusion

The survival of patients after WBRT for brain metastases from NSCLC treated in Dutch 'common radiotherapy practice' is practically the same as in patients treated in the British QUARTZ study. Survival for patients with brain metastases from breast cancer is only marginally better. Our analysis supports the conclusion from the QUARTZ study that there is insufficient evidence to consider WBRT the standard of care for patients with multiple brain metastases. We advocate more studies in this patient population and recommend a more restrictive use of WBRT in daily radiotherapy practice.

**PV-0505 Association between the diagnosis-to-treatment interval and overall survival in Taiwan OSCC**  
C.T. Liao<sup>1</sup>, Y.W. Wen<sup>2</sup>, S.H. Ng<sup>3</sup>, L.Y. Lee<sup>4</sup>, C.Y. Lin<sup>5</sup>, H.M. Wang<sup>6</sup>, C.H. Lin<sup>7</sup>, T.C. Yen<sup>8</sup>

<sup>1</sup>Chang Gung Memorial Hospital, Otorhinolaryngology-Head and Neck Surgery, Taoyuan, Taiwan

<sup>2</sup>Chang Gung University, Clinical Informatics and Medical Statistics Research Center, Taoyuan, Taiwan

<sup>3</sup>Chang Gung Memorial Hospital, Diagnostic Radiology, Taoyuan, Taiwan

<sup>4</sup>Chang Gung Memorial Hospital, Pathology, Taoyuan, Taiwan

<sup>5</sup>Chang Gung Memorial Hospital, Radiation Oncology, Taoyuan, Taiwan

<sup>6</sup>Chang Gung Memorial Hospital, Medical Oncology, Taoyuan, Taiwan

<sup>7</sup>Chang Gung Memorial Hospital, Plastic and Reconstructive Surgery, Taoyuan, Taiwan

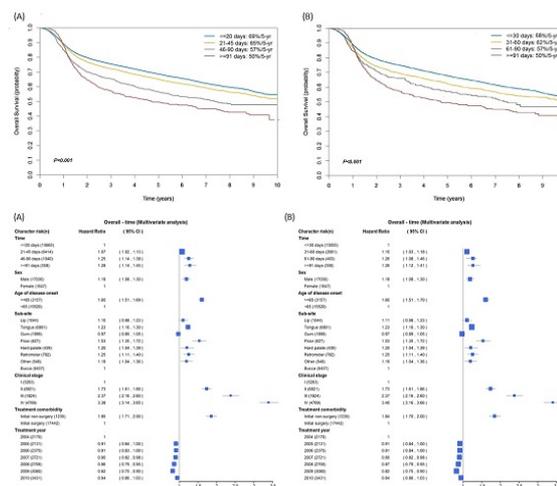

<sup>8</sup>Chang Gung Memorial Hospital, Nuclear Medicine, Taoyuan, Taiwan

#### Purpose or Objective

To investigate the association between the diagnosis-to-treatment interval (DTI) and overall survival (OS) in patients with oral cavity squamous cell carcinoma (OSCC).

#### Material and Methods

A total of 18,677 patients with first primary OSCC identified in the Taiwanese Cancer Registry Database between 2004 and 2010 were examined. The effect of DTI on 5-year OS rates was investigated with multivariate Cox regression analysis. After the identification of the optimal cutoff for DTI based on the 5-year OS rates, DTI was classified in the following 20-day groups:  $\leq 20$  days (57% of the study patients), 21–45 days (34%), 46–90 days (6%), and  $\geq 91$  days (3%). In additional exploratory analyses, DTI was reclassified in the following 30-day interval groups:  $\leq 30$  days (81% of the study patients), 31–60 days (14%), 61–90 days (2%), and  $\geq 91$  days (3%).

#### Results

Multivariate analyses identified DTI ( $\leq 20$  days vs. other subgroups), sex (female vs. male), age ( $< 65$  vs.  $\geq 65$  years), clinical stage (p-Stage I vs. p-Stage II, III, IV), and treatment modality (initial surgery vs. initial non-surgery) as independent prognostic factors for 5-year OS. Compared with a DTI  $\leq 20$  days, the DTI categories  $\geq 91$  days (hazard ratio [HR]: 1.28,  $P < 0.001$ ), 46–90 days (HR: 1.25,  $P < 0.001$ ), and 21–45 days (HR: 1.07,  $P = 0.007$ ) were independently associated with a higher risk of 5-year mortality. Similar results were obtained for DTI  $\leq 30$  days groups.

#### Conclusion

DTI is independently associated with 5-year OS in OSCC patients. A DTI longer than 30 days or even 20 days may potentially decrease survival.

**PV-0506 Comparison of Clinical Behavior of Viral Related Oropharyngeal and Nasopharyngeal Carcinoma**

Xu<sup>2</sup>, B. O'Sullivan<sup>2</sup>

<sup>1</sup>Princess Margaret Cancer Centre University Health Network, 2B-Radiation Therapy, Toronto, Canada

<sup>2</sup>Princess Margaret Cancer Centre / University of Toronto, Radiation Oncology, Toronto, Canada

<sup>3</sup>Princess Margaret Cancer Centre / University of Toronto, Biostatistics, Toronto, Canada

<sup>4</sup>Princess Margaret Cancer Centre / University of Toronto, Division of Medical Oncology, Toronto, Canada

<sup>5</sup>Princess Margaret Cancer Centre / University of Toronto, Otolaryngology - Head & Neck Surgery, Toronto, Canada

<sup>6</sup>Princess Margaret Cancer Centre / University of Toronto, Pathology, Toronto, Canada

#### Purpose or Objective

To compare clinical behavior between viral related oropharyngeal (OPC) and nasopharyngeal carcinoma (NPC) at a western institution.

#### Material and Methods

We reviewed all newly diagnosed viral related OPC and NPC treated with IMRT from 2005-2014. Viral etiology was confirmed by p16 immunohistochemistry staining for HPV and EBER in situ hybridization for EBV. Demographics, the new HPV+ OPC specific UICC/AJCC TNM (ICON-5) and current TNM for NPC, failure patterns, and outcomes were compared between OPC and NPC.

#### Results

A total of 802 HPV+ OPC and 369 NPC (360 EBER+ and 9 HPV-) were eligible. Compared to NPC, OPC were older (median age: 59 vs 52), and comprised more males (83% vs 67%), Caucasians (94% vs 20%; Asian 4% vs 75%), smokers (66% vs 40%), and drinkers (35% vs 9%) (all  $p < 0.01$ ). OPC

presented more often as T1-T2 (58% vs 43%), and/or unilateral neck diseases (57% vs 24%) (all  $p < 0.01$ ). Median follow up was 4.5 years for OPC and 6.1 years for NPC. Distant metastasis (DM) was the main form of failure for both diseases and occurred in 92 (11%) OPC and 51 (14%) NPC patients. Most DM (85% OPC and 76% NPC) did not have local or regional failures ( $p = 0.22$ ). DM to multiple sites was common for both (51% OPC DM and 35% NPC DM) and most commonly to lung, liver, and bone for both. However, DM to brain was more often in OPC vs NPC (13% vs 2%,  $p = 0.03$ ). Compared to NPC, OPC had slightly higher 5-year recurrence-free survival (RFS) (84% vs 79%,  $p = 0.01$ ) but became non-significant after adjusting for TNM (HR 0.89,  $p = 0.40$ ). RFS for OPC was higher in T1 (93% vs 88%,  $p = 0.045$ ) or N0 (91% vs 78%,  $p = 0.047$ ), but similar for T2 (88% vs 80%,  $p = 0.13$ ), T3 (80% vs 81%,  $p = 0.76$ ), T4 (68% vs 62%,  $p = 0.61$ ), N1 (88% vs 82%,  $p = 0.09$ ), N2 (77% vs 81%,  $p = 0.66$ ), and N3 (67% vs 60%,  $p = 0.75$ ) diseases. Similar RFS was found for the HPV+ OPC specific TNM (ICON-S) stage I and current NPC I-II [both T1-2N0-1] (91% vs 90%,  $p = 0.26$ ), OPC ICON-S II vs NPC III [both T1-2N2 or T3N0-2] (84% vs 87%,  $p = 0.95$ ), and OPC ICON-S III vs NPC IVA-B [both T4 or N3] (69% vs 63%,  $p = 0.56$ ). Long-term survivors (survived >2 years after DM) were found in 24/92 (26%) OPC and 15/51 (29%) NPC with DM. Overall survival after DM for OPC and NPC were also similar (5-year: 17% vs 22%,  $p = 0.20$ ).

#### Conclusion

This large western cohort study depicted remarkable similarity with few differences in clinical presentation and outcomes between viral related OPC and NPC in the IMRT era. Patterns of relapse and oncologic outcomes are very similar by TNM classification. DM is the main form of failure and long-term survivors after DM are seen for both diseases. Such similarities in clinical behavior could reflect common mechanisms of oncogenesis, metastasis, and radio-/chemo- sensitivity and/or resistance induced by HPV and EBV. Uncovering these pathways could present new therapeutic opportunities for both diseases in the future.

#### PV-0507 NGS for prognostic stratification in oral cancer harboring lymph node without extracapsular spread

H.M. Wang<sup>1</sup>, C.T. Liao<sup>2</sup>, T.C. Yen<sup>3</sup>, S.J. Chen<sup>4</sup>, L.Y. Lee<sup>5</sup>, C.H. Hsieh<sup>1</sup>, C.Y. Lin<sup>6</sup>, S.H. Ng<sup>7</sup>

<sup>2</sup>Chang Gung Memorial Hospital, Section of Head and Neck Surgery- Department of Otorhinolaryngology, Taoyuan, Taiwan

<sup>3</sup>Chang Gung Memorial Hospital, Department of Nuclear Medicine and Molecular Imaging Center, Taoyuan, Taiwan

<sup>4</sup>ACT Genomics, Taipei, Taiwan

<sup>5</sup>Chang Gung Memorial Hospital, Department of Pathology, Taoyuan, Taiwan

<sup>6</sup>Chang Gung Memorial Hospital, Department of Radiation Oncology, Taoyuan, Taiwan

<sup>7</sup>Chang Gung Memorial Hospital, Department of Diagnostic Radiology, Taoyuan, Taiwan

#### Purpose or Objective

Patients with resected oral squamous cell carcinoma (OSCC) harboring metastatic lymph node without extracapsular spread (ECS) show heterogeneous outcomes. We aim to improve their prognostic stratification by combining the traditional clinicopathological prognosticators with the genetic information obtained from next-generation sequencing (NGS).

#### Material and Methods

The hotspot mutation regions of 45 cancer-related genes were investigated using NGS with an ultra-deep (>1000x) sequencing approach in formalin-fixed paraffin-embedded

samples obtained from 144 patients who had resected OSCC harboring neck lymph node without ECS.

#### Results

Pathologic T4 was the most important traditional prognosticators for disease-specific survival (DSS). The 5-year DSS for patients with pT4 versus pT1-3 was 48.8% versus 80.2% ( $P < 0.001$ ). Multivariate analysis in patients with pT1-3 ( $n = 101$ ) identified the following adverse prognostic factors: 1) HRAS/BRAF mutation ( $n = 7$ ) for distant metastasis (DM) (27% versus 7%,  $P = 0.006$ ) and DSS (57% versus 82%,  $P = 0.005$ ); and 2) TP53 DNA-binding domain missense mutations ( $n = 38$ ) for DM (13% versus 3%,  $P = 0.053$ ) and DSS (68% versus 90%,  $P = 0.004$ ). The prognosticators in patients with pT4 ( $n = 43$ ) were: 1) Lymph node number  $\geq 3$  ( $n = 10$ ) for locoregional failure (70% versus 33%,  $P = 0.032$ ) and DSS (30% versus 55%,  $P = 0.050$ ); 2) HRAS/BRAF mutation ( $n = 6$ ) for DM (67% versus 14%,  $P = 0.008$ ) and DSS (0% versus 57%,  $P = 0.001$ ); and 3) no adjuvant radiotherapy ( $n = 2$ ) for DSS (0 versus 51%,  $P = 0.013$ ).

#### Conclusion

Genetic information from NGS may improve the prognostic stratification offered by traditional prognosticators in resected OSCC patients harboring metastatic lymph node without ECS. Our findings will contribute to implementation of precision medicine in OSCC patients.

#### PV-0508 Prognostic significance of PD-L1 expression in patients with head and neck squamous cell carcinoma

C. Peng<sup>1</sup>, X. Gu<sup>1</sup>, X.S. Gao<sup>1</sup>, X. Li<sup>1</sup>, S. Qin<sup>1</sup>, M. Ma<sup>1</sup>, M. Cui<sup>1</sup>, M. Xie<sup>1</sup>, Y. Bai<sup>1</sup>

<sup>1</sup>Peking University First Hospital, Department of Radiation Oncology, Beijing, China

#### Purpose or Objective

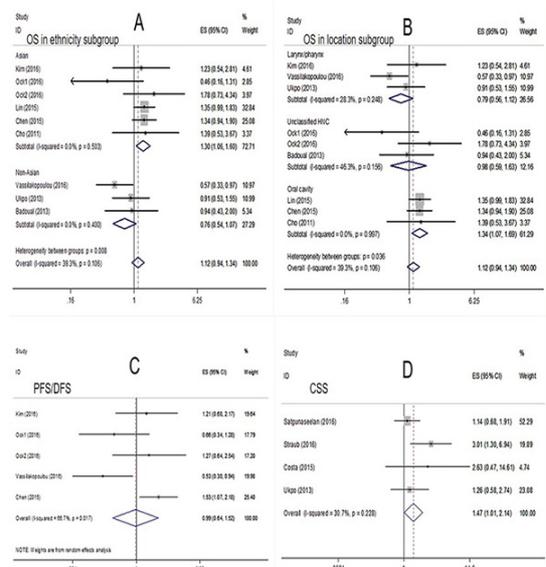

Previous studies have investigated the association between programmed death ligand-1 (PD-L1) expression and survival of patients with head and neck squamous cell carcinoma (HNSCC). However, the results were controversial and inconclusive. We therefore conducted a meta-analysis of published studies to evaluate the prognostic significance of PD-L1 expression in HNSCC.

#### Material and Methods

Relevant studies were retrieved through PubMed, Web of Science, Embase, Cochrane Library, China National Knowledge Infrastructure (CNKI). Combined hazard ratio (HR) and 95% confidence interval (CI) were calculated to assess the association between PD-L1 and overall survival (OS), progression-free survival (PFS)/ disease-free survival (DFS), cancer-specific survival (CSS). ORs with 95% CIs were calculated to evaluate the relationship between PD-L1 status and clinicopathological factors. Subgroup analyses and publication bias were also conducted.

#### Results

A total of 12 studies (13 cohorts) with 1777 patients were ultimately included in the meta-analysis. Results showed that high PD-L1 expression predicted poor CSS in HNSCC (HR 1.472, 95%CI: 1.013-2.138). Stratification analyses revealed that high PD-L1 expression was associated with poor OS in Asians (HR= 1.301; 95% CI:1.056-1.602) and oral SCC (HR=1.343; 95% CI:1.071-1.685) patients. In addition, we observed that high PD-L1 expression was correlated with female patients (OR=0.638, 95% CI: 0.478-0.853), lymph node metastasis (OR=1.415, 95% CI: 1.082-1.85), nonsmokers (OR=0.753, 95% CI: 0.569-0.995), HPV positive patients (OR=1.523, 95% CI: 1.032-2.247) in HNSCC.

Table 1. Association between PD-L1 expression and clinical characteristics of HNSCC. HPV: human papillomavirus; OR: odds ratio; CI: confidence interval.

**Conclusion**

Our findings suggest that PD-L1 may serve as a promising biomarker for poor prognosis as well as risk stratification and even therapeutic targets in HNSCC. Further well-designed studies and long-term follow up are warranted to verify these results.

**PV-0509 Failure type specific prognostic model for selection of HNSCC patients for experimental treatments**

<sup>4</sup>University of Maryland Greenebaum Cancer Center, Division of Biostatistics and Bioinformatics, Baltimore, USA

<sup>5</sup>University of Maryland School of Medicine, Department of Epidemiology and Public Health, Baltimore, USA

**Purpose or Objective**

Most clinical trials involve simple inclusion/exclusion criteria without support by prognostic models. Here, we present a multivariate model on multiple endpoints to generate an individual risk profile. We then examine the risk profile of patients actually referred to a dose escalation trial and patients that would be candidates for the RTOG 1016 de-intensification trial.

**Material and Methods**

Data from 600 HNSCC patients receiving intensity-modulated radiotherapy at our institution from 2005-2012 were retrospectively analyzed. Outcome was time from start of radiotherapy to the first occurrence of loco-regional failure (LRF), distant metastasis (DM) or death

with no evidence of disease (death NED), and was censored in case of event-free at last follow-up. Three cause-specific Cox models were built using clinical, functional and morphological imaging input as candidate predictors, and using a cross validation technique to reduce the model to the prediction variables included in Table 1.

Individualized estimates of 3-yr LRF, DM and death NED were obtained combining the three Cox regression models<sup>1</sup>, thus taking competing risks into consideration. The performance of the risk predictions was quantified by cause-specific concordance (C)-indices<sup>2</sup> (ideal C-index=1, coin flip C-index=0.5). The risk profiles of patients referred to an in-house dose escalation study were examined, as were the risk profiles of those of the 600 patients from model building which fulfilled the published inclusion criteria for the RTOG 1016 de-intensification trial.

**Results**

In the final analysis, 547 patients with complete data were included. The observed 3-year incidences were: LRF 25%, DM 10% and death NED 14%. Figure 1a presents a visualization of the individual risk of all patients (note that all probabilities add to 100%). The C-indices for the risk predictions were: LRF: 0.72, DM: 0.67, Death NED: 0.65. Of the 547 patients, 131 would have met the inclusion criteria of the RTOG 1016 de-escalation trial. The risk profiles of these patients (Figure 1b) show that 27 (21%) of them had an estimated risk of failure (LRF and DM) exceeding 20%. Of the 15 patients included in our local dose escalation study, 11 had a risk of loco-regional failure of less than 20% (Figure 1c).

Table 1. Cause specific Cox models for the hazard rate of loco-regional failure, distant metastasis and death with no evidence of disease. All three models were stratified for prescription of cisplatin. \*\* p < 0.05.

Loco-regional failure				
Variable	Unit	Hazard ratio	Confidence interval (95%)	p-value

Tumor size	per 10 cm <sup>3</sup>	1.04	[1.02;1.06]	< 0.001*

Distant metastasis				
Variable	Unit	Hazard ratio	Confidence interval (95%)	p-value
Tobacco	Never/previous smoker	1.00	(reference)	
	Current smoker	1.28	[0.73;2.24]	0.381
OPSCC	Oropharynx, p16+	1.00	(reference)	
	Oropharynx, p16-/other tumor	1.69	[0.89;3.20]	0.110
T stage		1.18	[0.86;1.62]	0.296
N stage		1.19	[0.96;1.48]	0.103
Tumor size	per 10 cm <sup>3</sup>	1.06	[1.03;1.09]	< 0.001*

Death NED				
Variable	Unit	Hazard ratio	Confidence interval (95%)	p-value
Performance status	0	1.00	(reference)	
	1-3	1.94	[1.23;3.05]	0.004*
Age		1.03	[1.01;1.06]	0.014*
Tobacco	Never/previous smoker	1.00	(reference)	
	Current smoker	2.13	[1.33;3.41]	0.002*

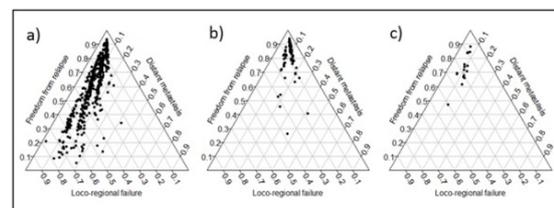

Figure 1. Individual risk predictions of 3-yr outcome (loco-regional failure, distant metastasis and chance of freedom from relapse), for a) all 547 patients, b) all candidates to RTOG 1016 de-escalation trial (131 of 547 patients) and c) the 15 patients included in the CONTRAST phase I dose-escalation trial.

**Conclusion**

The prediction model performed well for LRF, but death NED and DM risk were only moderately well predicted. Using the model to examine the profile of patients that are candidates for a de-intensification schedule, we document that several patients at a relatively high risk of failure could be included. Conversely, our own dose escalation study included several low risk patients, despite focusing on p16 negative patients or heavy

smokers. We believe the presented failure-type specific models are a highly relevant decision support aid to supplement the inclusion criteria of clinical trials.

#### Purpose or Objective

Tumor hypoxia in squamous cell carcinoma of the head and neck (HNSCC) is associated with poor prognosis. In the following study, the dynamics of hypoxia during chemoradiation (RCTx) is detected with FMISO PET/CT and correlated to perfusion MRI parameters.

Perfusion-weight MRI parameters can be correlated with tumor hypoxia and thereby have the potential to serve as predictors of treatment failure. In particular, the volume transfer constant between plasma and interstitial space  $K^{trans}$  is an indirect measure of the capillary permeability and blood flow. High skewness of  $K^{trans}$  is associated with good treatment response, whereas primary tumors with lower  $K^{trans}$  values have a poor prognosis (Shukla-Dave et al., 2012). A subsequent rise of  $K^{trans}$ ,  $v_e$  (fractional volume of the extracellular, extravascular space) during RCTx is associated with a good response to treatment.

#### Material and Methods

A prospective serial imaging study was conducted in patients undergoing definitive RCTx (70 Gy, concomitant cisplatin) for HNSCC: in weeks 0, 2 and 5 3T-MRI and FMISO PET were acquired. Tumor hypoxia was assessed in FMISO PET 2.5 h p.i. Gross tumor volume in MRI ( $GTV_{MRI}$ ) was defined as the area of high signal on T2-weighted images using the T1-weighted images for anatomic cross reference. Perfusion parameters  $K^{trans}$  and  $v_e$  were calculated from a dynamic T1-weighted study after contrast agent injection. Hypoxic subvolume (HSV) of  $GTV_{MRI}$  was defined after normalization to the FMISO background in the contralateral sternocleidomastoid muscle, thresholded with 1.4. Volumetric parameters between weeks 0, 2 and 5 were compared and related to treatment response in terms of local recurrence (LR) and stable disease (SD). Statistical analysis was done with Spearman correlation. Before t-test analysis, normal sample distribution was confirmed with Shapiro-Wilk test.

#### Results

Between 2014 and 2015 10 male patients, treated for HNSCC with RCTx, were included. All patients received a total dose of 70 Gy. In total, 30 FMISO-PET/CT data sets and 27 MRI data sets were obtained. Mean follow up (FU) was 14.6 months (4 - 28 months). In weeks 0-5, patients with LR showed a mean  $K^{trans}$ -decrease of 19%, whereas in weeks 0-2 an increase of  $SUV_{max}$  (57 %) was shown. Patients with SD showed  $K^{trans}$ -increase (36 %) and  $SUV_{max}$ -decrease (-61 %). HSV diminished in all patients. The correlation analysis was significant between  $\Delta GTV_{MRI}$  and  $\Delta K^{trans}$  in week 0-2 ( $p=0.037$ ) and between  $\Delta SUV_{max}$  (week 0-5) and  $\Delta K^{trans}$  (week 0-2),  $p=0.045$ .

#### Conclusion

As was previously shown we conclude that changes in  $SUV_{max}$  are crucial in week 2. In our limited patient cohort and the short FU, we found that a decrease in  $K^{trans}$  might

indicate a poorer outcome. Finding markers in bioimaging may allow individualization of treatment by dose painting and adaptive radiotherapy.

#### PV-0511 Fitting NTCP models to patient reported xerostomia and dysphagia after H&N radiotherapy to 60Gy

P. Mavroidis<sup>1</sup>, A. Price<sup>1</sup>, D. Fried<sup>1</sup>, M. Kostich<sup>1</sup>, R. Amdur<sup>2</sup>, W. Mendenhall<sup>2</sup>, C. Lu<sup>2</sup>, S. Das<sup>1</sup>, L.B. Marks<sup>3</sup>, B. Chera<sup>3</sup>

<sup>1</sup>University of North Carolina, Radiation Oncology, Chapel Hill, USA

<sup>2</sup>University of Florida Hospitals, Radiation Oncology, Gainesville- FL, USA

<sup>3</sup>University of North Carolina & Lineberger Comprehensive Cancer Center- University of North Carolina Hospitals, Radiation Oncology, Chapel Hill, USA

#### Purpose or Objective

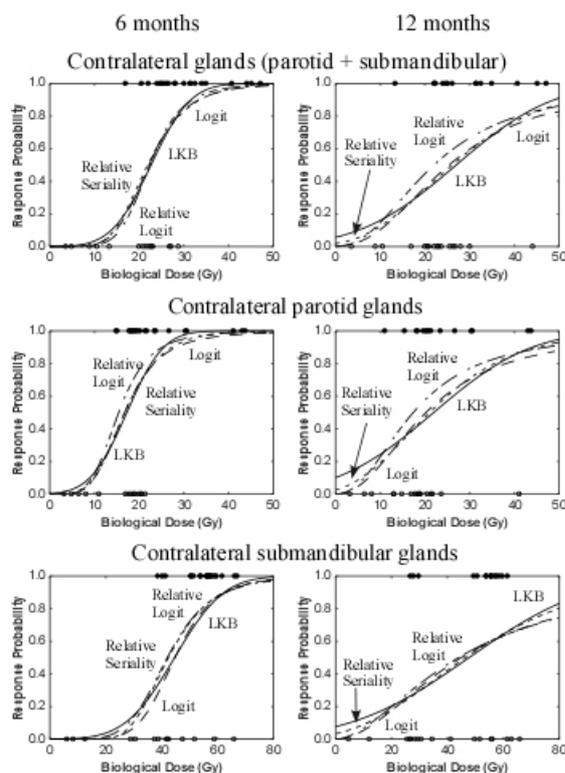

To determine the correlation between different dosimetric indices of salivary glands and pharyngeal constrictors with patient reported xerostomia and dysphagia 6- and 12- months after de-intensified chemoradiotherapy. To estimate the respective radiobiological parameters of four NTCP models regarding xerostomia and dysphagia, respectively.

#### Material and Methods

Forty-three patients were treated on a prospective multi-institutional phase II study involving patients with favorable risk, HPV-associated oropharyngeal squamous cell carcinoma. All patients were treated with IMRT to 60 Gy with concurrent weekly intravenous cisplatin (30 mg/m<sup>2</sup>). The patient reported outcome version of the CTCAE was used to record the severity of patients' xerostomia and dysphagia (pre- and post-treatment). A change in severity (from baseline) of  $\geq 2$  was used as response threshold. Individual patient dosimetric data of salivary glands (as combined and separate structures) and pharyngeal constrictors (as combined and separate sections) were correlated with xerostomia and dysphagia (at 6 and 12 months post-treatment). The Lyman-Kutcher-Burman (LKB), Relative Seriality (RS), Logit and Relative Logit (RL) NTCP models were used to fit the patients' data. The ability of different dosimetric indices to discriminate and classify patient outcomes was assessed through the area under the Receiver Operating Characteristic (ROC) curve (AUC) and linear regression analysis. The goodness-of-fit of the different models was assessed through the maximum of the log-likelihood function, normal error distribution and Akaike information criterion (AIC).

#### Results

The V15-V55 of the combined contralateral glands correlated well with xerostomia (AUC = 0.83-0.86). Similarly, at 12 months, the metrics V10-V17 were the best predictors of xerostomia (AUC = 0.82-0.87). The patient with dysphagia had V55 = 88.7 $\pm$ 12.8 (%) to the superior pharyngeal constrictor compared to a V55 = 76.2 $\pm$ 12.7 (%) for the patients without the symptom. The points V55-V60 had the highest correlation with dysphagia (AUC = 0.70-0.75). The AIC values of the different NTCP models ranged between 43.7-44.9 in the case of the combined contralateral glands and 38.1-38.9 in the case of the superior pharyngeal constrictors. For the combined contralateral glands, the NTCP threshold ranges between 70-74% for statistical Odd ratios (OR) ranging between 7.3-8.0.

### Conclusion

Following de-intensified chemoradiotherapy, the rate of patient reported xerostomia was best correlated with V15-V55 of the combined contralateral glands at 6 months and V15 of the combined contralateral glands and contralateral parotid at 12 months. Dysphagia at 6 months was best correlated with V55-V60 of the superior pharyngeal constrictors. It was shown that all the examined NTCP models could fit the clinical data well with very similar accuracy. Statistically significant NTCP thresholds could be identified for each model for the respective organs and clinical endpoint cases.

### Purpose or Objective

The aim of this study was to investigate the correlation between preoperative, postoperative imaging characteristics and survival after radiotherapy in pediatric ependymoma patients.

### Material and Methods

A retrospective review of 121 patients who underwent primary resection of ependymoma followed by radiation therapy was undertaken utilizing quantitative volumetric analysis of pre- and postoperative MR images. Preoperative tumor volume (PRTV) on Post contrast (PC) T1 imaging, preoperative tumor volume ((PRTVF) on T2/FLAIR imaging, postoperative tumor volume on T2/FLAIR (POTVF) and Contrast Enhancement volume (CEPTV) on PC-T1 imaging were delineated by an experienced radiation oncologist and double-checked by a neuroradiologist, after coregistration of T2/FLAIR imaging to the PC-T1WI. A survival analysis was done including clinical data (Gender, tumor location, tumor grade, the extent of resection, radiation dose) and extracted imaging volumes. All survival times were calculated from the date of beginning of RT. Overall survival (OS) and disease free survival (DFS) were estimated by the Kaplan-Meier method and using the following first-event definitions: local and distant relapse or death for disease free survival (DFS) and death for overall survival (OS). Univariate analyses were performed using Cox proportional hazards model for quantitative variables and the log-rank test for qualitative variables. The hazard ratio (HR) (respectively, the survival rate at 3 years) is presented for each quantitative covariate (qualitative respectively) with 95% confidence interval. PRTV variable was dichotomized with the median value ( $\leq 43.8$  cc, vs  $> 43.8$  cc) and POTVF variable with (0 (no) vs  $> 0$  (presence)).

### Results

At the end of analysis, 80.2% of patients were alive, 39.7% presented with one events (local relapse, distant relapse or death). The median overall survival was 38.5 months (9% IC [30.5; 47.7]). The Median age at diagnosis was 4 years (1.0-22.0), 58.7% were male, tumor location was

70.2% infratentorial, the tumor grade was anaplastic in 62.0%, the extent of resection was complete in 85.1% and 64.5% of patients received a dose >54 Gy. The median PRTV was 43.8 cc (1.1-287.9), and the median CEPTV was 13.3 cc (0-71.4). The median PRTVF was 49.4 cc (0-336.7) and the median POTVF was 4.6 cc (0-118.7). A statistically significant benefit in survival was seen with a POTVF equal to 0 cc in univariate analysis for the DFS and the OS (71.9% versus 40.3%  $p=0.006$ ) and (93.7% versus 72.37%  $p=0.023$ ) respectively. In multivariate analysis, POTVF was also statistically significant for OS ( $p=0.05$ ) and almost significant for DFS ( $p=0.06$ ).

#### Conclusion

In this retrospective study, POTVF was found to be significant predictor of overall survival after ependymoma radiotherapy. POTVF was the more significant predictor of survival compared with PRTV, suggesting that this volume and residual contrast-enhancing tumor may be a more accurate and meaningful reflection of the pathobiology of ependymoma.

#### OC-0513 Radiation necrosis following stereotactic RT and immunotherapy for melanoma brain metastases

O. Kaidar-Person<sup>1</sup>, T. Zagar<sup>1</sup>, A. Deal<sup>2</sup>, S. Moschos<sup>3</sup>, M. Ewend<sup>4</sup>, D. Sasaki-Adams<sup>4</sup>, C. Lee<sup>3</sup>, F. Collichio<sup>3</sup>, D. Fried<sup>1</sup>, L. Marks<sup>1</sup>, B. Chera<sup>1</sup>

<sup>2</sup>UNC Lineberger Comprehensive Cancer Center- Chapel Hill- North Carolina- USA, Statistics, Chapel Hill, USA

<sup>3</sup>University of North Carolina- Chapel Hill, Medicine, Chapel Hill, USA

<sup>4</sup>University of North Carolina- Chapel Hill, Neurosurgery, Chapel Hill, USA

#### Purpose or Objective

Stereotactic radiotherapy (SRT) is the standard treatment for patients with limited number of brain metastases. In the past few years, newer immunotherapies (immune checkpoint inhibitors) have been proven to prolong survival in patients with metastatic melanoma. The safety of the combination of SRT and immunotherapy for brain metastases is unknown.

#### Material and Methods

We retrospectively identified patients with melanoma brain metastases treated with SRT between 2007 and 2015. Patients who did not have at least 3 months of follow-up with imaging after SRT were excluded from the analysis. Outcomes were compared between patients who were treated with or without immunotherapy.

#### Results

A total of 58 patients were included, of these 29 were treated with SRT and immunotherapy. MAPK inhibitors (BRAF, MEK inhibitors) were used more often in the immunotherapy group (9 vs. 2 patients). There was a higher incidence of intracranial complications in patients treated with immunotherapy and SRT. Eight patients had radiation necrosis, all occurred in patients who were treated with immunotherapy. Nine patients had hemorrhage, of which 7 occurred in patients who were treated with immunotherapy ( $p=0.08$ ). However, patients treated with immunotherapy and SRT had a significant overall survival advantage compared to SRT without immunotherapy (15 vs. 6 months,  $p = 0.0013$ ).

#### Conclusion

Patients treated with SRT and immunotherapy, have a higher incidence/risk of intracranial complications but a longer overall survival.

#### OC-0514 radiation necrosis after proton beam therapy - when and where does it happen?

S. Harrabi<sup>1,2,3</sup>, C. Gudden<sup>1</sup>, S. Adebeg<sup>1,2,3</sup>, N. Bougatf<sup>2,3</sup>, T. Haberer<sup>3</sup>, S. Rieken<sup>1,2</sup>, J. Debus<sup>1,2,3</sup>, K. Herfarth<sup>1,2,3</sup>

<sup>1</sup>University Hospital Heidelberg, Radiation Oncology,

Heidelberg, Germany

<sup>2</sup>Heidelberg Institute of Radiation Oncology, HIRO, Heidelberg, Germany

<sup>3</sup>Heidelberg Ion-Beam Therapy Center, HIT, Heidelberg, Germany

#### Purpose or Objective

Radiation necrosis after irradiation of central nervous system tumors is a rare but severe side effect. The differentiation on magnetic resonance imaging between postoperative changes, gliosis and therapy associated changes remains a challenge and is not always possible with absolute certainty. Available data almost exclusively refer to conventional radiotherapy with photons (XRT). Since the use of proton beam therapy (PRT) is constantly increasing - especially for the treatment of neurooncologic diseases - we set out to determine the safety of proton irradiation by evaluating the incidence of radiation necrosis.

#### Material and Methods

We reviewed 430 patients with a median age of 37 years (4 - 85 years) who received radiotherapy between 2009 and 2015 for meningioma or low grade glioma with either protons ( $n=276$ ) or photons ( $n=154$ ). Median applied dose was 54 Gy (50 - 60 Gy). Clinical and radiological information of regular follow-up examinations were analyzed resulting in nearly 3.000 available magnetic resonance imaging (MRI) examinations with a minimum follow up of 12 months (median 30 months, range 12 - 82 months). Findings on MRI were delineated in the treatment plan system and correlated with parameters of the treatment plan. Complementary calculations for dose distribution, linear energy transfer (LET) and relative biological effectiveness (RBE) for the original treatment plan using different models (Monte Carlo, Wedenberg, Carabe) were made.

#### Results

The cumulative incidence of radiation necrosis after PRT in our cohort was 3.3 % with a median time to occurrence of 12 months (6 - 32 months). No risk factor could be identified with regard to treatment specific parameters such as optimization algorithm (single beam optimization vs intensity modulated proton therapy), number of used beams (one vs multiple), concomitant chemotherapy or applied dose ( $\leq 54$  GyE vs  $> 54$  GyE). However, the observed radiation necrosis affected significantly often the periventricular border and were almost exclusively at the distal edge of the spread-out Bragg peak (SOBP).

#### Conclusion

Radiation necrosis after PRT can be a severe side effect but is as rare as after XRT. The accumulation of incidence at the distal edge of the SOBP and at the periventricular border warrants further radiobiological investigation.

#### OC-0515 Radiation necrosis in children with brain tumours treated with pencil beam scanning proton therapy

B. Bojaxhiu<sup>1</sup>, F. Ahlhelm<sup>2</sup>, M. Walser<sup>1</sup>, L. Placidi<sup>1</sup>, U. Kliebsch<sup>1</sup>, L. Mikroutsikos<sup>1</sup>, P. Morach<sup>1</sup>, A. Bolsi<sup>1</sup>, T. Lomax<sup>1</sup>, R. Schneider<sup>1</sup>, D.C. Weber<sup>1</sup>

<sup>1</sup>Paul Scherrer Institute, Center for Proton Therapy, Villigen, Switzerland

<sup>2</sup>Cantonal Hospital Baden, Department of Radiology, Baden, Switzerland

#### Purpose or Objective

To assess the rate of radiation-induced brain necrosis (RN) and related neurologic symptoms in paediatric patients with primary brain tumours treated with Pencil Beam Scanning (PBS) proton therapy (PT) with or without concomitant chemotherapy at the Paul Scherrer Institute, Switzerland.

#### Material and Methods

One hundred and seventy-one children and adolescent young adults (AYA) (<18 years) with brain tumours were

treated with PBS PT between 1999 and 2015. Median age at diagnosis was 3.3 years (range, 0.3-17) and the male/female ratio was 1.44. The median delivered dose was 54 Gy(RBE) (range, 40-74.1). Post PT brain alterations (white matter lesions [WML] and RN) were defined as a new area of abnormal signal intensity on T2-weighted images or increased signal intensity on T2-weighted images and contrast enhancement on T1 occurring in the brain parenchyma included in the radiation treatment field, which did not demonstrate any abnormality before PT. RN was graded according to the National Cancer Institute Common Terminology Criteria for Adverse Events v4.03 and EORTC grading systems. The median follow-up period for the surviving patients was 49.8 months (range, 5.9-194.7).

**Table 1. Patients' and disease characteristics (n = 171)**

\*Re-surgery during treatment in one patient

## Results

Twenty-nine (17%) patients developed RN with a median time of 5 months (range, 1-26), the majority of them (n=17; 59%) being asymptomatic (grade 1). Grade 2, 4 and 5 toxicities were observed in 8, 2 and 2 patients, respectively. The observed toxicity reversed in a majority of cases (n=18; 62%). The observed WML rate was 11%

(n=18 patients). The 5-year RN-free survival was 71%. In univariate analysis, neo-adjuvant chemotherapy (p=0.025) and hydrocephalus before PT (p=0.035) were significant predictors of RN.

## Conclusion

Children treated with PT demonstrated a low prevalence (7%) of symptomatic RN. Exposure to chemotherapy before PT and hydrocephalus as an initial symptom were significant risk factors associated with RN in these children/AYAs.

## OC-0516 Brainstem linear energy transfer in intensity-modulated proton therapy of paediatric brain tumours

L.F. Fjaera<sup>1</sup>, Z. Li<sup>2</sup>, K.S. Ytre-Hauge<sup>1</sup>, L.P. Muren<sup>3</sup>, D. Indelicato<sup>2</sup>, Y. Lassen-Ramshad<sup>4</sup>, G.M. Engeseth<sup>5</sup>, M. Brydøy<sup>5</sup>, S. Flampouri<sup>2</sup>, O. Dahl<sup>3</sup>, C.H. Stokkevåg<sup>2</sup>

<sup>1</sup>University of Bergen, Department of Physics and Technology, Bergen, Norway

<sup>2</sup>University of Florida, Department of Radiation Oncology, Jacksonville, USA

<sup>3</sup>Aarhus University Hospital, Department of Medical Physics, Aarhus, Denmark

<sup>4</sup>Aarhus University Hospital, Department of Oncology, Aarhus, Denmark

<sup>5</sup>Haukeland University Hospital, Department of Oncology and Medical Physics, Bergen, Norway

## Purpose or Objective

The enhanced linear energy transfer (LET) and relative biological effectiveness (RBE) at the end of a proton track is usually only accounted for qualitatively during treatment planning. Intensity-modulated proton therapy (IMPT) plans are currently optimised using dose/volume constraints for the brainstem, but there is growing concern about the clinical consequences of the elevated LET surrounding a tumour volume and potentially within nearby organs at risk. For posterior fossa tumours invading or in close proximity to the brainstem, the brainstem may receive an unintended increased biological dose. The aim of this study was to investigate how various posterior fossa tumour locations impact the LET and biological dose distributions in the brainstem.

## Material and Methods

The brainstem was contoured on CT/MRI images on a five year old male patient with a posterior fossa tumour treated with protons. Multiple IMPT treatment plans were generated (in Eclipse, Varian) for different simulated tumour locations relative to the brainstem: full overlap between tumour and brainstem (A), half overlap (B), juxtaposed posteriorly (C) and 1 cm posterior of the brainstem (D). Two lateral and one posterior non-coplanar fields were applied for all plans. The dose prescription was 54 Gy(RBE) and brainstem constraints were applied based on published metrics to keep the risk of brainstem necrosis <5%. All plans were optimized using a fixed RBE value of 1.1. The dose-averaged LET (LET<sub>d</sub>) as well as the dose-weighted LET<sub>d</sub> (LET<sub>d</sub> x dose) were subsequently calculated using the FLUKA Monte Carlo code. The dose-weighted

$LET_d$  was also scaled by a parameter  $c=0.04 \mu\text{m}/\text{keV}$  (IJROBP 2016), such that the resulting product quantifies the additional biological dose stemming from the LET effect.

### Results

High  $LET_d$  values surrounded part of the PTV and encompassed portions of the brainstem (Fig 1). The mean  $LET_d$  values to the brainstem were 4.0, 5.6, 5.9 and 8.6  $\text{keV}/\mu\text{m}$  for cases A, B, C and D, while the mean  $LET_d$  values for the PTVs were between 3.0-3.5  $\text{keV}/\mu\text{m}$  for cases A-D. In cases where the target volume overlapped the brainstem, the  $c \times LET_d \times$  dose resulted in 'hot-spots' within the brainstem. The highest absolute  $LET_d$  values were seen in the cases with the PTV located most distant from the brainstem, whereas lower and more homogeneous  $LET_d$  values were seen for the full overlap case (Fig 2). When examining dose-weighted  $LET_d$ , however, the opposite trend was seen: An increase in dose-weighted  $LET_d$  was observed in tumours closer to the brainstem.

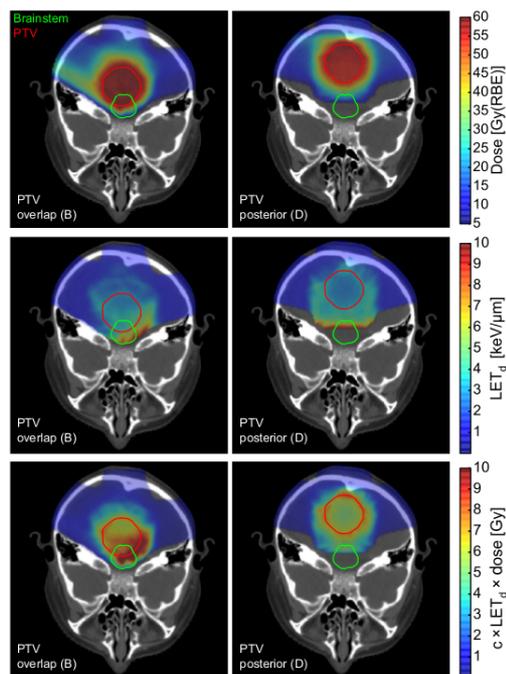

Figure 1: Top: Dose distributions (RBE = 1.1). Middle:  $LET_d$  distributions. Bottom:  $c \times LET_d \times$  dose distributions. Areas with doses below 10 % of the prescription dose (54 Gy(RBE)) have been set transparent.

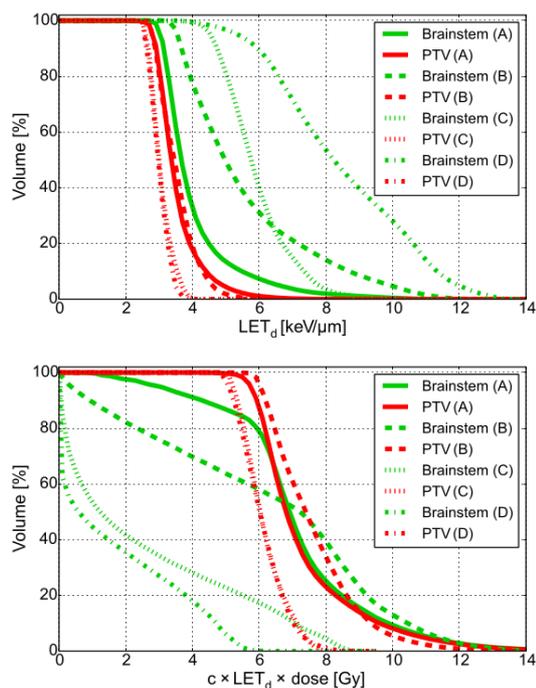

Figure 2: Volume histograms of  $LET_d$  (top) and  $c \times LET_d \times$  dose (bottom) for the PTVs and brainstem.

### Conclusion

When treating children with posterior fossa tumours with IMPT, our modelling study demonstrated that elevated  $LET_d$  values are located in the brainstem, in particular if the tumour volume was distant from the brainstem. However, the impact of  $LET_d$  on overall biological dose was greater for tumours that approached or invaded the brainstem.

### OC-0517 Investigation of the RBE variation of protons in the rat spinal cord within a spread-out Bragg peak

M. Saager<sup>1</sup>, P. Peschke<sup>2</sup>, S. Brons<sup>3</sup>, M. Scholz<sup>4</sup>, P.E. Huber<sup>2</sup>, J. Debus<sup>5</sup>, C.P. Karger<sup>1</sup>  
<sup>1</sup>DKFZ, Medical Physics in Radiation Oncology, Heidelberg, Germany

<sup>2</sup>DKFZ, Clinical Cooperation Unit Molecular Radiooncology, Heidelberg, Germany

<sup>3</sup>Heidelberg Ion Beam Therapy Center, HIT, Heidelberg, Germany

<sup>4</sup>Center for Heavy Ion Research GSI, Dept. of Biophysics, Darmstadt, Germany

<sup>5</sup>University Hospital of Heidelberg, Dept. of Radiation Oncology, Heidelberg, Germany

#### Purpose or Objective

Proton therapy allows highly conformal treatments of head and neck cancer due to its inverted depth-dose profile and advanced beam delivery systems. This allows escalating the dose while still sparing the surrounding healthy tissue. For treatment planning in patients, a fixed relative biological effectiveness (RBE) of 1.1 is currently used. However, experimental *in vitro* studies indicate that the RBE increases at the distal edge of the spread-out Bragg peak (SOBP). This increased biological effectiveness may either lead to detrimental side effects, especially in the late responding normal central nervous system, or it may compromise dose escalation in the tumor. In this study, the potential increase of the proton RBE along the SOBP is investigated for late reactions of rat spinal cord.

#### Material and Methods

The cervical spinal cord of female Sprague Dawley rats was positioned at four different depths of a 6 cm spread-out Bragg peak (entrance region, center and two positions at the distal edge of the SOBP, linear energy transfer (LET): 1.45-5.60 keV/μm). Single proton doses of increasing dose levels were applied to the segments C1-C6 of the cervical spinal cord using a field size of 10 x 15 mm<sup>2</sup>. At each position, complete dose-response curves were established and the tolerance doses TD<sub>50</sub> (dose at 50% complication probability) were determined for the clinically relevant endpoint "development of forelimb paresis grade II within 300 days". Based on the TD<sub>50</sub>-values, RBEs were calculated using the tolerance doses for photons of our previous study. Rats reaching this endpoint were sacrificed and the spinal cord was removed and processed for histological examinations.

#### Results

Preliminary evaluations of the single dose experiments showed that the minimum and mean latency time decrease with increasing LET. Preliminary data of the dose-response curves confirm an RBE of 1.1 in the entrance region (LET 1.45 keV/μm) while a further increase of the RBE was found towards the distal edge of the SOBP (LET 5.40 keV/μm).

#### Conclusion

The preliminary data of this study suggests an increased proton RBE at the distal edge of the SOBP. Further experiments with fractionated treatments are ongoing. If the finding of this study is confirmed quantitatively, it might be necessary to include the variability of the RBE in clinical treatment planning to optimize safety and effectiveness of proton therapy in patients.

reports on symptoms and side effects, as well as multi-dimensional health-related quality of life, evaluation of the perceived health and psychological status, reports about adherence to treatment, satisfaction with treatment, according to the US Food and Drug Administration (FDA) and the European Medical Agency (EMA). In contrary to the physician assessed morbidity grading, the evaluation of PROs is performed without any interpretation by a clinician, relative or anyone else and reflects the patients' subjective experience [1].

With the development of validated questionnaires with robust psychometric properties over the last decades, PROs have been established as valuable and reliable complementary information in clinical studies [2].

Moreover, PRO assessment is recently regarded as quality indicator in routine cancer care [3].

The reporting of PROs regarding symptoms and side effects particularly in conjunction with the physician assessed morbidity following standard grading systems has been thoroughly investigated. A recently published literature review analyzed 28 high quality studies and concluded only fair to moderate associations between both assessment methods; furthermore the majority of studies demonstrated the tendency of underreporting morbidity in the physician assessed grading systems [4].

Therefore, an initiative has been started in the United States to combine both methods in a collaborative approach to enable a comprehensive and in-depth understanding of morbidity. The National Cancer Institute (NCI) has recently published a patient questionnaire version of the widely used Common Toxicity Criteria of Adverse Events (CTCAE) [5,6]. The PRO-CTCAE enables patients' self-reporting of symptoms via paper questionnaire, touchscreen tablet computer or interactive voice response system [7]. To date, several translations and linguistic validations of the PRO-CTCAE are in progress and a widespread use in clinical cancer trials is expected in the near future [8,9].

In Europe, the Patient Reported Outcomes and Behavioral Evidence initiative (PROBE) within the European Organisation for Research and Treatment of Cancer (EORTC) [10] has recently reported on a meta-dataset pooled from different international randomized controlled clinical trials across different patient populations, disease stages and treatments, which included the EORTC quality of life assessment [11]. It has been shown that baseline EORTC quality of life assessment increases the prognostic accuracy for overall survival significantly (by 6-8%) on top of clinical and sociodemographic risk factors. For each cancer type, at least one specific quality of life domain provided prognostic information, even though no universal domain could be identified for all patients [12,13].

In conclusion, PROs add unique and highly valuable information to clinical cancer trials and should be actively promoted to complement physician assessed morbidity.

### SP-0519 Collecting PROs in clinical practice to assess radiotherapy toxicity and develop normal tissue complication probability models

A. Gilbert<sup>1</sup>, S. Davidson<sup>2</sup>, G. Velikova<sup>3</sup>, D. Sebag-Montefiore<sup>1</sup>

<sup>1</sup>University of Leeds, Clinical Oncology, Leeds, United Kingdom

<sup>2</sup>The Christie Hospital, Clinical Oncology, Manchester, United Kingdom

<sup>3</sup>University of Leeds, Medical Oncology, Leeds, United Kingdom

The initial part of this presentation will focus on an overview of the literature and theory around the collection and use of patient reported outcomes (PROs) in oncological clinical practice. The second part will focus on the use of PROs to collect symptomatic radiotherapy toxicity data and develop normal tissue complication probability (NTCP) models using examples from RCTs and clinical practice.

Improvements in cancer survival have led to an increasing number of patients with significant long-term adverse events/toxicity. The multiple modalities used to treat cancer make monitoring toxicity challenging and a systematic method of documenting acute and late adverse events has yet to be used in routine care. Increasingly PROs have been included in clinical trials as a standard data source for subjective patient experience. Research shows good concordance between patient and clinician evaluated toxicity with patients providing data on a wider range and milder toxicities.

The integration of PRO results for use in routine practice has been found in multiple RCTs to improve patient-clinician communication and symptom management without lengthening the duration of the consultation. Increasingly, electronic systems have been used to collect and integrate PRO results within existing electronic health records systems. Electronic methods are acceptable to patients and provide better quality data. They also provide the opportunity for remote monitoring of

symptoms. However, there are a number of technical and procedural barriers that must be considered when implementing a complex intervention. International examples will be presented alongside experiences from our research group.

The international committee QUANTEC (Quantitative Analysis of Normal Tissue Effects in the Clinic) aimed to establish best practice guidelines to help clinicians and treatment planners to determine acceptable dose/volume constraints to minimise toxicity to normal tissue. One of the key recommendations was the inclusion of PROs in toxicity assessment alongside clinician-reporting in routine clinical practice to define clinically relevant endpoints and aim to standardise outcome measures. Development of predictive models for normal tissue complications requires a detailed evaluation of the relationship between dosimetric, patient and clinical factors, as well as accurate measures of toxicity. Illustrative examples where PRO data has been incorporated within NTCP models from RCTs and observational study experience from our research group will be presented.

### SP-0520 PROs instruments used in clinical trials S. Faithfull<sup>1</sup>

<sup>1</sup>University of Surrey, Faculty of Health and Medical Sciences, Guildford, United Kingdom

The utilization of Patient Reported Outcomes (PROs) in clinical trials have become widespread but data collection from such studies is not always consistent or fully reported leaving gaps in our knowledge of treatment consequences and quality of life. PROs focus on physical symptoms, treatment toxicities, psychosocial problems or global health related quality of life and the impacts of the disease and treatment from the patient's perspective. PROs are therefore critical to understanding the consequences of radiotherapy from a 'whole-person' perspective and the impact of treatment on people's lives [1]. To this end PROs have become an important tool for clinical trials to reflect not only the differences between therapies from the personal perspective but also predictors of health and treatment factors that may influence cancer outcomes. In view of their importance there is a need to ensure rigorous PRO data collection and analysis within clinical trials.

Despite their importance PROs have not always been able to demonstrate significant long-term changes in QOL when evaluating new radiotherapy techniques. In reviewing radiotherapy clinical trials PRO generic quality of life tools tend to be more widely used [2]. These generic tools provide population based data that are useful for comparison in large studies but can be strongly influenced by environmental factors. Improving diversity of PROs by combining a range of instruments to demonstrate granularity can improve sensitivity of PROs to change. It is important to target measures and review the sensitivity of current measures to detect PRO changes as emerging radiotherapy treatments evolve. Furthermore, PROs can be influenced by non-radiotherapy factors such as comorbidities, other cancer treatments, age, health status as well as health care provided. Over time there is a so called 'response shift' as patients become used to chronic symptoms and adapt their lives improving QOL scores despite symptom occurrence. These effects should be mitigated within randomization.

Improving the rigor of how PROs are used in clinical trials is essential for good data capture and the credibility of future radiotherapy evidence. A survey of PRO research staff found that the timing of PRO measures within UK clinical trials varies substantially i.e. prior to the participant's clinical consultation or after, by post or via help from a research nurse. These small differences can impact on participant's responses and subsequent data quality [3]. Use of reminders and digital capture

techniques does improve data collection but for some patient populations and studies this approach is not as effective or financially possible. Furthermore, missing PRO data may influence the ability to detect difference within long term data. Missing data is rarely random with participants from the poorest outcomes or highest vulnerability not returning questionnaires so most likely to create conclusions biased to complete cases [4]. Longer term monitoring of radiotherapy effects requires innovative ways of collecting data from patients. PROs produce large data sets which need to be summarized and or transformed. Multiple tools can provide an overlap in items and domains scores. Clustering of symptoms across tools and looking at change in symptoms over time rather than cross sectional analysis approaches can be of benefit [5]. Using data sharing and linkage approaches to access and link PROs to wider data sets such as primary health care records and resources used by patients may help in addressing some of the knowledge gaps. Lack of consistency in analysis techniques, volume of data and missing values are challenges for researchers. Failure to address these challenges and standardize PROs assessment during clinical trials risks the introduction of bias and devalues the importance of patient reported outcomes within studies.

#### Purpose or Objective

SBRT is a safe and effective treatment which could postpone androgen deprivation therapy (ADT) in oligorecurrent PC. Despite that, in literature there is a lack of data about the role of SBRT in patients (pts) with oligoprogressive castrate resistant PC (oligo-CRPC). Our aim is to assess the feasibility and efficacy of SBRT in the treatment of oligorecurrent PC in terms of biochemical progression-free survival (BPFS) and ADT-free survival (ADT-FS) and also in pts with oligo-CRPC, in terms of distant progression free survival (DPFS) and second line systemic-treatment-free survival (STFS).

#### Material and Methods

100 pts with oligorecurrent disease detected with Choline-PET or CT+Scintigraphy following biochemical recurrence were treated with SBRT. BPFS and ADT-FS were the primary endpoint. Secondary endpoints were local control and toxicity. On the other hand, oligo-CRPC pts detected with choline-PET or CT+scintigraphy after PSA rise during ADT were enrolled in the analysis. Primary endpoint were DPFS and STFS. Univariate analysis was performed in order to assess factors influencing outcome in both categories.

#### Results

100 pts with oligorecurrent PC (139 lesions; lymph nodes 84.2%, bones 15.8%) were treated from 03/2010 to 02/2016. After a median follow up of 20.4 months, 1yr- and 2yrs-BPFS were 58.1% and 38.3%. 15 pts underwent a second course of SBRT for a further oligoprogression: this result in a median ADT-FS of 20.9 months with 1-, 2-, 3- yrs ADT-FS of 67.4%, 47.3% and 31%. At univariate analysis, low PSA-DT is related with a worse ADT-FS. LC rate was 88,2% at two years. No G3 toxicity was reported. 41 pts with oligo-CRPC (70 lesions) were treated from 01/2010 to 04/2016. After a median follow up of 23.43 months, 1yr- and 2yrs-DPFS were 43.2% and 21.6% with a median DPFS of 11 months. 10 pts underwent a second course of SBRT. At the time of analysis, 20 patients had started systemic treatment (10 pts with Abiraterone or Enzalutamide and 10 pts with Docetaxel): median STFS was 22 months with 1-, 2-, 3-yrs STFS of 74.8%, 41.3% and 29.5%. No significant correlations were found at univariate analysis. No toxicity was registered.

#### Conclusion

SBRT for oligorecurrent PC is an effective treatment and postpones palliative ADT for almost 2 yrs without toxicity. SBRT has proven effective even in oligoprogressive CRPC with a capacity to delay the start of systemic second line therapies for almost 2 yrs.

##### OC-0522 Extracranial stereotactic Radiotherapy for lymph nodal recurrences: a dose escalation trial

F. Deodato<sup>1</sup>, G. Macchia<sup>1</sup>, M. Ferro<sup>1</sup>, M. Ferro<sup>1</sup>, G. Torre<sup>1</sup>, v. Picardi<sup>1</sup>, M. Nuzzo<sup>1</sup>, S. Cilla<sup>2</sup>, A. <sup>8</sup>Policlinico Universitario "A. Gemelli"- Università Cattolica del Sacro Cuore, Department of Radiotherapy, Rome, Italy

**Purpose or Objective**

To determine the maximum tolerated dose (MTD) of fractionated extracranial stereotactic radiotherapy (ESRT) to lymph nodal recurrences in different clinical settings.

**Material and Methods**

Patients enrolled in a phase I clinical trial entered the analysis. Each enrolled subject was included in a different study arm, according to nodal site and previous treatment. Dose has been prescribed according to ICRU 62. A four no-coplanar beams class solution or a volumetric technique (VMAT) have been applied in all patients. The planning target volume (PTV) has been defined as gross tumour volume (GTV) plus 5-15 mm. According to different arms, patients received an ESRT dose ranging from 20 Gy up to the maximum planned dose of 50 Gy in 5 fractions. Dose-limiting toxicity (DLT) was any grade > 3 acute toxicity or any grade > 2 late toxicity. The MTD was exceeded if 2 of 6 or 4 of 12 patients in a cohort experienced DLT.

**Results**

101 patients (M/F: 47/54; median age 67 years, range 43-87years) with 128 nodal lesions were treated. Of these, 48 (37.5%) were nodal recurrences in neck or chest, 34 (26.5%) were in abdomen and 46 (35.9%) were in pelvis. The primary tumour was most frequently gynaecologic cancer (44%), followed by genito-urinary cancer (22%), gastro-intestinal (13%), lung (13%) and other (9%). The median ESRT delivered dose was 35 Gy (20-50) in five fractions. With a median follow up of 19 months (4-104), the overall response rate was 88% (CI95: 80-93.6; Complete Response: 68%; Partial Response: 20%), with only 5% of patients developing disease progression. No DLT was recorded in this group of patients. Two- and 4-year local control were 81% and 70.2%, respectively. Two- and 4-year metastases free survival were 43.5% and 30.9%, respectively.

**Conclusion**

In quite varied setting of lymph nodal recurrences an ESRT treatment in five fractions up to a dose of 50 Gy is safe and well tolerated.

**Purpose or Objective**

Stereotactic body radiation therapy (SBRT) is applied in the oligometastatic setting to treat liver metastases. However, factors influencing tumor control probability (TCP) other than radiation dose have not been thoroughly investigated. Here we set out to investigate such factors with a focus on the influence of histology and chemotherapy prior to SBRT using a large multi-center database from the German Society of Radiation Oncology.

**Material and Methods**

From 17 German and Swiss radiotherapy centers, data on all patients treated for liver metastases with SBRT since its introduction in 1997 has been collected and entered into a centralised database as an effort of the SBRT task group of the DEGRO.

452 SBRT treatments in 363 patients were analysed after retrieval of patient, tumor and treatment data from the aforementioned multi-center database.

Histology was considered through random effects in semi-parametric and parametric frailty models. Dose prescriptions were parametrized by conversion to the biologically effective dose at the isocenter (BED<sub>max</sub>) using the LQ formalism.

**Results**

After adjusting for histology, BED<sub>max</sub> was the strongest predictor of TCP. Larger PTV volumes, chemotherapy prior to SBRT and non-advanced motion management techniques predicted significantly lower TCP. For an average metastasis, the model predicted a BED of 208±76 Gy<sub>10</sub> necessary for 90% TCP at 2 years with no prior chemotherapy, but 292±109 Gy<sub>10</sub> when chemotherapy had been given. Breast cancer metastases were significantly more responsive to SBRT with 90% TCP at 2 years achieved with BED<sub>max</sub> of 178±65 Gy<sub>10</sub> or 94±55 Gy<sub>10</sub> with and without prior chemotherapy, respectively. There was a tendency that colorectal metastases had an inferior TCP.

**Conclusion**

Besides dose, histology and pretreatment chemotherapy were important factors influencing local TCP in this large cohort of liver metastases. After adjusting for prior chemotherapy, our data adds to the emerging evidence that breast cancer metastases do respond better to hypofractionated SBRT compared to other histologies.

**OC-0524 Phase II trial on SBRT for Liver Metastases: Long-term outcomes and prognostic factors of survival.**

T. Comito<sup>1</sup>, C. Franzese<sup>1</sup>, E. Clerici<sup>1</sup>, A. Tozzi<sup>1</sup>, C. Iftode<sup>1</sup>, P. Navarra<sup>1</sup>, G.R. D'Agostino<sup>1</sup>, D. Franceschini<sup>1</sup>, F. De Rose<sup>1</sup>, A. Ascolese<sup>1</sup>, L. Di Brina<sup>1</sup>, S. Tomatis<sup>1</sup>, M. Scorsetti<sup>1</sup>  
<sup>1</sup>Istituto Clinico Humanitas, Radiotherapy and Radiosurgery, Rozzano Milan, Italy

**Purpose or Objective**

Liver is a common site of metastases for several cancers. In selected patients with oligometastatic disease confined to liver, surgical resection improves overall survival (OS). Approximately 70-90% of liver metastases, however, are unresectable and a safe and effective alternative therapeutic option is necessary for these patients. The aim of this study was to evaluate long-term

outcomes of SBRT for unresectable liver metastases and to analyze prognostic factors affecting OS of these selected oligometastatic patients.

#### Material and Methods

Patients with 1 to 3 unresectable liver metastases, with maximum individual tumor diameters less than 6 cm and a Karnofsky Performance Status of at least 70, were enrolled and treated by SBRT on a phase 2 clinical trial. Dose prescription was 75 Gy on 3 consecutive fractions. SBRT was delivered using the volumetric modulated arc therapy by RapidArc (Varian, Palo Alto, CA) technique. Primary end point was in field local control (LC), secondary end points were overall survival (OS), progression free survival (PFS) and toxicity.

#### Results

Between February 2010 and September 2011, a total of 61 patients with 76 lesions were enrolled in this phase II trial, with a median follow-up time of 1.9 years. One-, three- and five- years LC rates were 94%, 78% and 78 %, respectively, with a median LC of 1.7 years. Median OS was 2.3 years and the survival rates were 83%, 30% and 21% at 1, 3 and 5 years, respectively. Univariate analysis showed two independent positive prognostic factors affecting survival: female sex ( $p = 0.012$ ) and primary tumour ( $p = 0.001$ ). Toxicity was moderate. One patient experienced G3 late chest wall pain, which resolved within 1 year from SBRT. No cases of RILD were detected.

#### Conclusion

Long-term results of this Phase II study suggest the efficacy and safety of SBRT for unresectable liver metastases at 5 years of follow-up. Selection of cases with positive prognostic factors may improve long-term survival of these oligometastatic patients and may confirm the role of SBRT as an effective alternative local therapy for liver metastases.

#### OC-0525 Factors affecting local control for pulmonary oligometastasis treated with SBRT

A. Sharma<sup>1</sup>, M. Duijm<sup>1</sup>, E. Oomen-de Hoop<sup>2</sup>, J. Aerts<sup>3</sup>, C. Verhoef<sup>4</sup>, M. Hoogeman<sup>1</sup>, J. Nuytens<sup>1</sup>

<sup>1</sup>Erasmus MC-Daniel den Hoed Cancer Center- Rotterdam- The Netherlands, Department of Radiation Oncology, Rotterdam, The Netherlands

<sup>2</sup>Erasmus MC-Daniel den Hoed Cancer Center- Rotterdam- The Netherlands, Department of Medical Oncology, Rotterdam, The Netherlands

<sup>3</sup>Erasmus MC-Daniel den Hoed Cancer Center- Rotterdam- The Netherlands, Department of Pulmonology, Rotterdam, The Netherlands

<sup>4</sup>Erasmus MC-Daniel den Hoed Cancer Center- Rotterdam- The Netherlands, Department of Surgical Oncology, Rotterdam, The Netherlands

#### Purpose or Objective

To evaluate local control (LC) and identify factors associated with LC for inoperable pulmonary oligometastases treated with stereotactic body radiotherapy (SBRT).

#### Material and Methods

In 206 patients, 326 pulmonary oligometastases were treated with SBRT. Oligometastatic tumors were defined as  $\leq 5$  metastases in no more than two organs at time of treatment. Metastases were categorized as synchronous if metastases developed within 5 months of diagnosis of primary tumor, else were assigned to metachronous group. SBRT schedule depended on location of metastasis, its size and dose calculation algorithm. Dose to PTV was prescribed at 70-90% isodose line (median 78%), covering at least 95% of the PTV. LC was calculated from first session of SBRT to date of local recurrence. Patients without any local recurrence at date of last follow up were censored. Variables assessed as prognostic factors for LC included: metachronous versus synchronous metastasis, pre SBRT chemotherapy, primary

site, location in lower lobes versus other, central and peripheral lung metastasis, tumor size, single versus fractionated SBRT, BED, algorithm used, delay in SBRT. Toxicity was recorded as per NCI CTCAE, version 3.0. Ninety per cent of pulmonary oligometastases were treated with BED>100 and with fractionated SBRT. Two hundred and thirty nine oligometastases were peripheral in location and majority (258) were <3 cm in diameter. Primary tumor site included 117 colorectal tumors, 36 lung cancers, 11 melanoma, 10 sarcoma, 7 breast carcinoma, and 25 metastases were from other sites. Median follow up was 22 months (range 1-100).

#### Results

LC at 2 and 5 years was 83% and 73%, respectively. On univariate analysis BED <100 (HR=3.08), single fraction radiotherapy (HR=2.81), synchronous metastasis (HR=2.13), pre SBRT chemotherapy (HR=2.83), and SBRT delay > 4 months (HR=2.49) were significantly associated with inferior LC. At BED >100 synchronous metastasis (2 year LC 76% vs 88%), pre SBRT chemotherapy (2 year LC 78% vs 91%), and SBRT delay >4months (2 year LC 79% vs 90%) were significantly associated with lower LC rate. On multivariate analysis BED <100 (HR 4.36), single fraction radiotherapy (HR 4.02), pre SBRT chemotherapy (HR 2.32), synchronous metastasis (HR 2.16), and SBRT delay >4 months (HR 2.17) remained independently associated with lower LC. Median OS in entire cohort was 32 months. The 2, 3, and 5 year OS rates were 63%, 47% and 30%, respectively. Less than 2% of patients experienced grade 3 acute or late toxicities. There were no grade 4 and 5 events.

#### Conclusion

The study identified 5 factors independently associated with inferior LC. Despite BED >100 synchronous metastasis, pre SBRT chemotherapy and SBRT delays were significantly associated with inferior LC rate. These findings will help to refine SBRT practice for pulmonary oligometastasis.

Multivariate analysis of factors affecting local control for pulmonary oligo metastasis

	Covariate	HR 95%CI	p-value
1	Biological equivalent dose o <100 (34) o $\geq 100$ (292)	4.36(2.11-9.00)	<0.001
2	Fractionation of SBRT o Single (33) o Fractionated (293)	4.02(2.04-7.89)	<0.001
3	Pre SBRT Chemotherapy o Yes (164) o No (160)	2.32(1.22-4.43)	0.010
4	Timing of metastasis o Synchronous (91) o Metachronous (235)	2.16(1.20-3.89)	0.010
5	Delay in initiation of SBRT o $\geq 4$ months (139) o < 4 months (187)	2.17(1.18-4.01)	0.013

#### OC-0526 Quality of life after SBRT in bone metastases: analysis from the prospective PRESENT cohort

G. Fanetti<sup>1</sup>, A.S. Gerlich<sup>2</sup>, E. Seravalli<sup>2</sup>, H.M. Verkooijen<sup>3</sup>, M. Van Vulpen<sup>2</sup>, R. Orecchia<sup>4</sup>, B.A. Jereczek-Fossa<sup>1</sup>, J. Van der Velden<sup>2</sup>

<sup>1</sup>European Institute of Oncology - University of Milan, Department of Radiation Oncology, Milan, Italy

<sup>2</sup>University Medical Center, Department of Radiation Oncology, Utrecht, The Netherlands

<sup>3</sup>University Medical Center, Julius Center for Health Sciences and Primary Care, Utrecht, The Netherlands

<sup>4</sup>European Institute of Oncology - University of Milan, Scientific Directorate, Milan, Italy

#### Purpose or Objective

Stereotactic body radiotherapy (SBRT) is an emerging treatment in patients with bone metastases (BM). Local control is achieved in up to 95% of lesions and up to 80% of patients experience pain relief after SBRT. However, in patients with a limited life expectancy, quality of life

(QoL) becomes very important but studies evaluating QoL in these patients is lacking. This study evaluates the course of QoL in patients treated with SBRT for BM with validated pain and QoL questionnaires.

#### Material and Methods

At the University Medical Center of Utrecht, the PRESENT cohort is ongoing: a prospective cohort enrolling all patients with bone metastases candidate to radiotherapy. From this cohort, patients treated with SBRT were selected to evaluate QoL and pain. EORTC C15-PAL and BM22 questionnaires were administered at baseline, after 4, 8 weeks, 3, 6, and 12 months. BPI questionnaires were administered together with QoL questionnaires, and additionally after 2 and 6 weeks. Performance status and comorbidity index were scored at baseline. Pain flare was measured during treatment. Questionnaires were scored according to the scoring manuals and analyzed with descriptive statistics. QoL changes in time of  $\geq 10$  points were considered clinically relevant.

#### Results

Forty-nine patients with 35 spinal and 27 non-spinal lesions were included. Thirty-nine patients had oligometastatic disease. Median follow up was 6 months (range 1-31 months). Questionnaire return rates were 93% at baseline and 71-88% during follow up. At baseline, 25 patients had painful lesions with a mean BPI pain score of 5. During follow up, pain decreased to a score of 3 at 3 months, 2 at 6 months and 1 at 12 months (figure 1). In general, QoL based on EORTC C15-PAL and BM22 improved during follow up. No major deteriorations in functional and symptom scales were observed. At 12 months, further improvement of all functional and symptom scales was observed, except for dyspnea. Patients rated their global health status (GHS) in questionnaire EORTC C15-PAL. Overall GHS improved at 4 weeks, showed a decrease at 8 weeks and improved steady during follow up. GHS at baseline was lower in patients with pain than in patients without pain (58 vs 80 on a scale of 100). The difference in GHS between patients with and without pain reduced during follow up (difference of 22 points at baseline vs 2 points after 6 months) (Figure 2). Pain flare was reported in six patients, but no relevant differences in QoL in patients with and without pain flare were observed.

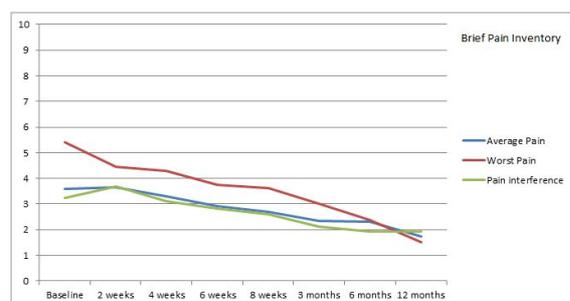

Fig 1. Worst pain, average pain and pain interference during follow up after SBRT scored with Brief Pain Inventory questionnaire in the subgroup of patients with pain at baseline.

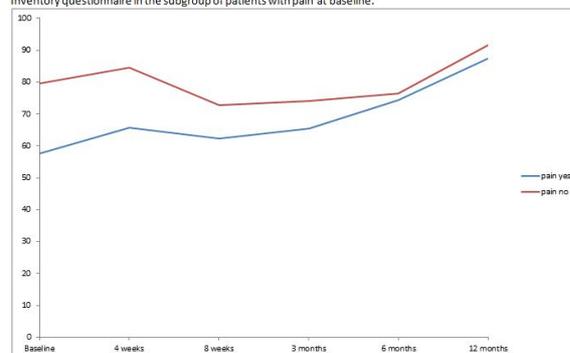

Fig 2 Global health status/Quality of life scale (from QLQ-C15-PAL) during follow up in patients with and without pain at baseline.

#### Conclusion

After SBRT for BM, our patients showed a clinically relevant improvement in QoL. At baseline, patients with pain report worse QoL and higher pain related scores compared to non-painful patients. SBRT on BM leads to a substantial reduction of pain scores contributing to a relevant QoL improvement in painful patients.

#### Symposium with Proffered Papers: Novel approaches in colorectal tumour control

##### SP-0527 State of the art in colorectal cancer radiobiology

J. Bussink<sup>1</sup>

<sup>1</sup>UMC St Radboud Nijmegen, Radiation Oncology, Nijmegen, The Netherlands

There is a limited amount of information on radiobiological data with respect to normal tissues for colorectal cancer. Experimental data that give an indication of a/b values are from studies dating back to the eighties. For acute toxicity the values are low (9-13) for late toxicity this was in the lower range (3-5). Late toxicity such as rectal bleeding is also strongly depending on irradiated volume but also on the topographical distribution of this volume, i.e. circumferential irradiation results in more toxicity than non-circumferential treatment. Tumor response is predominately hampered by the classical radiation resistance mechanisms such as intrinsic radioresistance, and hypoxia but also aberrant signaling by means of EGFR or VEGF may result in reduced radiation sensitivity. Several studies have investigated these parameters in the clinical and preclinical setting. These parameters can only be of relevance if it is possible to monitor these prior to treatment initiation. To assess the efficacy of interventions to address resistance ideally this would be monitored during treatment. Application of functional imaging by means of PET or MRI during treatment has been applied to limited extend in colorectal cancer.

##### SP-0528 Immunobiology of gastro-intestinal tumours

P. Huber<sup>1</sup>

<sup>1</sup>German Cancer Research Center DKFZ, Clinical Cooperation Unit Molecular Radiooncology, Heidelberg, Germany

GI cancers are among the most frequent cancer in the western world. Many patients have high numbers of tumor specific T cells (cytotoxic T cells and T helper cells) in their blood and bone marrow. The molecular identification of tumor-associated antigens has led to the development of antigen-specific immunotherapy targeting these antigens which have so far failed to show efficacy in the clinic. Potential reasons for this lack of efficacy include the inefficiency of T cell activation in vivo, insufficient migration of cytotoxic T cells into the tumor, the choice of irrelevant antigens, induction or application of monovalent T cells. Here we will discuss the role of radiotherapy, the effective non-surgical local cancer therapeutic, in the immunobiology of GI cancer in the context of the microenvironment modifications, endothelial cells, intratumoral lymphocytes or dendritic cells, alone and in combination with checkpoint inhibitors, TLR agonists and other immune effectors. We will in particular discuss the effects of low dose radiotherapy on T cell infiltration, macrophages and associated antitumor immune response in preclinical models and patients with operable liver metastases and pancreatic carcinoma.

### OC-0529 Circulating exosomal miRNA related to chemoradiotherapy outcome in locally advanced rectal cancer

S. Meltzer<sup>1,2</sup>, L.G. Lyckander<sup>3</sup>, A.H. Ree<sup>1,2</sup>, K.R. Redalen<sup>1</sup>  
<sup>1</sup>Akershus University Hospital, Department of Oncology, Lørenskog, Norway  
<sup>2</sup>University of Oslo, Institute of Clinical Medicine, Oslo, Norway  
<sup>3</sup>Akershus University Hospital, Department of Pathology, Lørenskog, Norway

#### Purpose or Objective

Exosomes are extracellular vesicles shown to carry complex biological information (mRNAs, miRNAs, proteins, etc.) of their cells of origin, such as tumor cells. Recent studies have also shown that normoxic and hypoxic cells produce exosomes with different biological content, proposing a role of exosomes in the aggravated biology caused by tumor hypoxia. Further advances in rectal cancer care require early identification and treatment of aggressive tumors with poor chemoradiotherapy (CRT) response and high metastatic propensity. In this context, we explored associations between plasma exosomal miRNAs, CRT outcome and survival in locally advanced rectal cancer (LARC).

#### Material and Methods

Plasma samples from 20 patients were collected at baseline. Sixteen patients underwent neoadjuvant long-course CRT and four patients with synchronous liver metastasis underwent short-course radiotherapy, followed by surgery. Exosomes were isolated using the miRCURY™ isolation kit and analyzed using the miRCURY LNA™ Universal RT microRNA PCR Human panel I (Exiqon, Denmark). miRNA expression data was normalized to the global array mean before miRNA with high differential expression were determined using the SAM software with a false recovery rate of 10% and verified by t-tests using p-values < 0.05 as statistically significant. CRT response was evaluated by ypTN staging and tumor regression grade (TRG) (College of American Pathologists system) scoring, and survival differences assessed by the log-rank test and visualized using Kaplan-Meier curves. Median follow-up time was 21 months (range 1-34).

#### Results

Significant associations between several exosomal miRNAs to TNM, ypTN, TRG and PFS were detected. For TRG, the most significant findings were lower expression of miR-20b-5p and miR-301a-3p in poor responders (TRG2-3 vs TRG1). Looking at baseline characteristics, patients with synchronous liver metastasis had higher expression of several miRNAs, particularly miR-141-3p (p=0.010) (Table 1). Further, for patients without metastasis at baseline, higher expression of this miRNA was associated with both metastatic progression to the liver (p=0.020) and thus poor overall survival (p=0.032) (Figure 1).

Figure 1 hsa-miR-141-3p

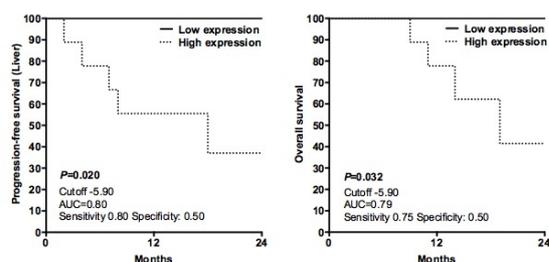

Table 1 hsa-miR-141-3p

Differential expression relative to global mean

		Median (Range)		
Age		63 (41-80)		
BMI		27 (18-36)		
		n (%)	Mean (SD)	P
Gender	Female	6 (30)	-4.065 (1.792)	
	Male	14 (70)	-5.289 (1.102)	0.076
TNM stage	T2-3	8 (40)	-4.656 (1.914)	
	T4	12 (60)	-5.099 (1.024)	0.508
	N0-1	12 (60)	-4.776 (1.704)	
	N2	8 (40)	-5.141 (0.889)	0.586
	M0	16 (80)	-5.309 (0.984)	
ypTN stage	M1	4 (20)	-3.371 (1.964)	0.010
	ypT0-2	7 (44)	-5.516 (0.952)	
	ypT3-4	9 (56)	-5.5149 (1.034)	0.478
	ypN0	6 (38)	-5.344 (1.234)	
TRG score	ypN1-2	10 (62)	-5.288 (0.875)	0.916
	Good	6 (38)	-5.700 (0.896)	
	Poor	10 (62)	-5.075 (1.002)	0.230

#### Conclusion

We identified plasma exosomal miRNAs predicting both CRT response and survival. Particularly, miR-141-3p was significantly associated with both synchronous liver metastasis at time of diagnosis and future progression of liver metastasis. miR-141-3p has shown to be overexpressed in colorectal tumour stroma compared to normal tissue, and was recently associated with radiation resistance in experimental H&N squamous cell carcinoma models. The results warrant further investigation into these miRNAs as potential biomarkers of liver metastasis and treatment resistance, and if they can be specifically targeted in LARC treatment. The results are currently being validated in an independent, larger cohort.

#### Proffered Papers: Dosimetry and detector development

### OC-0530 Equivalent uniform square field sizes of machine specific reference fields in FFF beams

W. Lechner<sup>1</sup>, P. Kuess<sup>1</sup>, D. Georg<sup>1</sup>, H. Palmans<sup>2,3</sup>

<sup>1</sup>Medizinische Universität Wien Medical University of Vienna, Department of Radiotherapy and Christian Doppler Laboratory for Medical Radiation Research for Radiation Oncology, Vienna, Austria

<sup>2</sup>EBG MedAustron GmbH, Department of Dosimetry, Wiener Neustadt, Austria

<sup>3</sup>National Physical Laboratory, Radiation Dosimetry, Teddington, United Kingdom

#### Purpose or Objective

Flattening filter free (FFF) photon beams have been available in dedicated linear accelerator (LINAC) designs such as CyberKnife and TomoTherapy for several years. More recently they were also introduced in clinical practice at conventional C-arm LINACs. However, reference dosimetry procedures vary amongst these types of FFF machines. This work aims to investigate the concept of equivalent uniform square fields (EQUFS) of FFF beams as proposed by the upcoming IAEA/AAMP code of practice on small field dosimetry.

#### Material and Methods

In-house determined experimental data as well as published data [1,2] of the ratio of doses at depths of 20 cm and 10 cm in water (D<sub>20,10</sub>) was used to characterize the depth dose in square fields ranging from 2 x 2 cm<sup>2</sup> to 40 x 40 cm<sup>2</sup>, for 6 and 10 MV flattened (WFF) and FFF beams. A scatter function (S(x)) that takes the lateral

profiles of the individual beams into account was fitted to the data. The lateral profiles of the WFF beams were assumed to be uniform while those of the FFF beams were approximated using 4th or 6th order polynomials. The scatter functions of the FFF beams were recalculated using a uniform lateral profile (the same as the physical profile of the WFF beams) and are henceforth denoted as virtual uniform FFF beams (VUFFF). The field sizes of the VUFFF beams having the same scatter contribution as the corresponding FFF beams at a given field size were defined as the EQUFS.

#### Results

In total, the data of four different LINACs and 18 different beam energies were analysed. The average values of EQUFS over all investigated LINACs of the conventional 10 x 10 cm<sup>2</sup> reference fields of 6 MV and 10 MV FFF beams for C-arm LINACs and machine specific reference fields for CyberKnife and TomoTherapy were 9.5 cm, 9 cm, 5.3 cm and 6.5 cm, respectively. The standard deviation of these averaged EQUFSs was below 0.1 cm. Figure 1 illustrates the process of finding the EQUFSs of a FFF field. The scatter functions of a 10 MV WFF, a 10 MV FFF and a 10 MV VUFFF beam are plotted as a function of field size. In this example the 10 x 10 cm<sup>2</sup> reference field of the 10 MV FFF beam has the same scatter contribution as the 9 x 9 cm<sup>2</sup> field of the 10 MV VUFFF beam which was defined as EQUFS. The scatter function of the 10 MV WFF was plotted for comparison purposes.

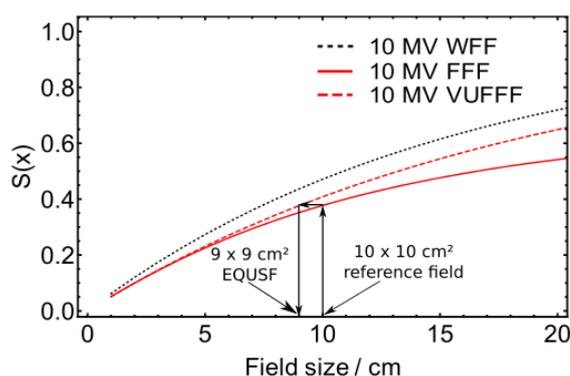

Fig 1: An example of the determination of an EQUFS of FFF beams. The field size of the 10 MV VUFFF beam with the same scatter contribution as the 10 x 10 cm<sup>2</sup> reference field of the 10 MV FFF beam is defined as the EQUFS.

#### Conclusion

It has been shown that with the introduction of a VUFFF beam, EQUFSs can be consistently defined for a variety of energies and collimations. These EQUFSs serve as basis for a unified reference dosimetry protocol for all different types of FFF machines.

<sup>3</sup>Azienda USL Toscana Centro- Sede di Firenze, Radiotherapy Unit, Florence, Italy

#### Purpose or Objective

2D detector arrays have become the standard device for verification of VMAT dose distributions. The detector pixel size is a key parameter to reproduce complex dose distributions.

Aim of this work is to compare the gamma analysis of three ionization chamber systems and to test the ability of each system to detect deliberate errors.

#### Material and Methods

Measurements performed by PTW Octavius 4D 729 (5x5x5mm<sup>3</sup> ionization chamber, 10 mm spacing), PTW Octavius 4D 1500 (4.4x4.4x3mm<sup>3</sup> ionization chambers, 7.1 mm spacing) and PTW Octavius 4D 1000 SRS (2.3x 2.3x 0.5 mm<sup>3</sup> liquid filled ionization chamber, 2.5 mm spacing) in the PTW Octavius 4D phantom were used to validate the dosimetric accuracy of the VMAT delivery. Firstly, 50 VMAT SBRT treatment plans from a variety of clinical sites were considered. Secondly, systematic variations in collimator (2° and 5° rotation) and gantry angle (shift of 2° and 5°) and lack of monitor units were applied to four clinical treatments (2 lung tumors, 1 spine and 1 abdominal lymph node) in order to establish the detection sensitivity of the three devices. Measurements were compared with TPS Elekta Monaco computed doses via local gamma analysis (2%/2 mm, 2%/1 mm and 1%/1 mm). For the 729 and 1500 detectors, the resolution was improved by merging two measurements performed with 5 mm couch shift.

The threshold for a success in error detectability was established, by using the concept of confidence limit (CL), as suggested by AAPM Task Group 119 [1]:

$$CL = (100 - D) + \sigma$$

where D and  $\sigma$  are respectively the mean dose and the standard deviation of the distribution of the gamma passing rate (35 plans for 6 MV and 15 plans for 10 MV) measured by each dosimeter; the detectability threshold (DT) has been calculated as:

$$DT = 100 - CL$$

#### Results

The average pass rate with 2%/2 mm criterion for the 6MV cases was 86.6 ± 5.2 (no shift) and 90.3 ± 4.3 (merged) for 729, 91.5 ± 3.7 (no shift) and 94.7 ± 2.9 (merged) for 1500 and 98.9 ± 1.1 for 1000 SRS. Box plot relative to 6 MV VMAT SBRT 2%/2 mm pass rate is presented in figure 1. Similar results were achieved for 10 MV plans. The results for the plans with errors, normalized to the DT for a success in error detectability, show that only the SRS system can distinguish the delivery errors, as shown in figure 2 for 6MV. Only a 2%/1 mm gamma criterion proved to be sensitive enough to detect errors.

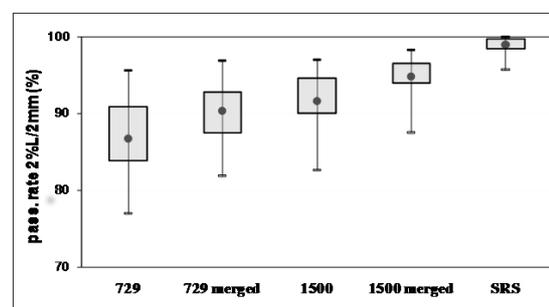

Figure 1 : Box plot for 2%/2 mm gamma passing rate of 6 MV VMAT SBRT plans for the investigated 2D arrays.

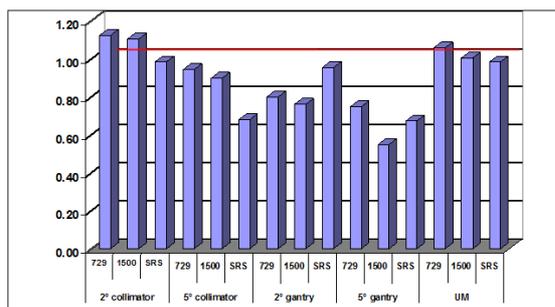

Figure 2: Gamma passing rate for the plans (6 MV) with errors, normalized to the detectability threshold, measured by SRS, 729 (merged) and 1500 (merged) dosimeters.

#### Conclusion

Improving the resolution of the planar detector used for QA increases the points with  $\gamma < 1$ .

The SRS matrix can detect delivery errors in almost all cases at 2%L/1mm.

#### OC-0532 QA of stereotactic radiotherapy combined with electromagnetic MLC tracking by a silicon detector

M. Petasecca<sup>1</sup>, M.K. Newall<sup>1</sup>, M. Duncan<sup>1</sup>, V. Caillet<sup>2</sup>, B. James<sup>1</sup>, J.T. Booth<sup>2</sup>, M.L.F. Lerch<sup>1</sup>, V. Perevertaylo<sup>3</sup>, P. Keall<sup>4</sup>, A.B. Rosenfeld<sup>1</sup>

<sup>1</sup>University of Wollongong, Centre for Medical Radiation Physics, Wollongong NSW, Australia

<sup>2</sup>Royal North Shore Hospital, Northern Sydney Cancer Centre, Sydney - NSW, Australia

<sup>3</sup>SPA-BIT, Microelectronics, Kiev, Ukraine

<sup>4</sup>University of Sydney, Radiation Physics Laboratory-School of Medicine, Sydney - NSW, Australia

#### Purpose or Objective

Optimisation of treatment delivery based on patient-specific intra-fractional changes in anatomy is compulsory in organs affected by breathing or cardiac cycle. MLC tracking by using electromagnetic transponders implanted in the tumor is one strategy to adapt the beam shape and position in real-time. MLC tracking combined with highly conformal delivery modalities such as SRT has been shown to be feasible for lung and liver cancer treatment on a standard linac. QA for such treatments requires specialised tools with high spatial resolution for accurate measurement of sharp dose fall-off and high timing resolution for verification of the interplay of effects between organ motion and modulation of the irradiation fields. A dosimetry system for fast verification of the performance of MLC tracking in SRT is proposed.

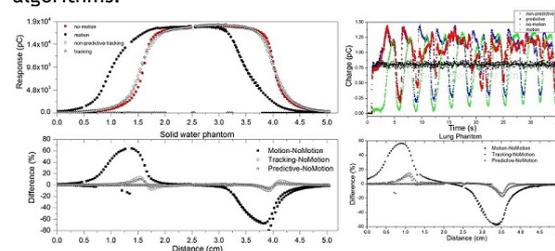

#### Material and Methods

A monolithic 2D silicon detector, known as DUO, has been developed and comprises 512 pixels each with size 40x80mm<sup>2</sup> and pitch 0.2mm arranged in two linear orthogonal arrays. The DUO is read out by a multichannel electrometer synchronised with the linac. For evaluation of the accuracy and effectiveness of MLC tracking in both soft tissue and lung, we placed DUO in a solid water phantom, homogeneous timber phantom and timber phantom with a solid water spherical hidden target of 1 cm diameter. We installed the phantoms on a moving platform supplied with a set of patient-specific motion patterns. The commercial Calypso system provides real-time position of the target to the MLC software which has been tested using a predictive and non-predictive tracking algorithm. We planned the target dose using 3DCRT (a 2 cm diameter field) and IMRT (with 5mm margins)

treatments. Measurements performed by DUO are compared to EBT3 film for cases with and without motion, as well as motion with the MLC tracking algorithms enabled.

#### Results

Fig.1 shows the comparison of the SUP-INF 3DCRT static beam profile measured by DUO in the solid water phantom and the same beam delivered using a patient specific breathing motion pattern with and without MLC tracking. The predictive tracking has a lower discrepancy with respect to the static beam showing a reduction of the beam misplacement from  $\pm 70\%$  to  $\pm 12\%$  and  $\pm 58\%$  to 20% in the solid water and timber phantom respectively. Discrepancies between DUO and EBT3 are within 2.4% overall. Temporal analysis shows the interplay effects between beam position and target motion with clear difference between predictive and non-predictive algorithms.

Solid water phantom		DUO		EBT3	
Modality	Profile direction	FWHM (cm)	RHS Penumbra (cm)	FWHM (cm)	RHS Penumbra (cm)
no motion	inf-sup	2.43 ± 0.02	0.3 ± 0.02	2.49 ± 0.02	0.4 ± 0.02
motion	inf-sup	2.5 ± 0.02	0.66 ± 0.02	2.6 ± 0.02	0.69 ± 0.02
tracking	inf-sup	2.48 ± 0.02	0.42 ± 0.02	2.5 ± 0.02	0.43 ± 0.02
predictive tracking	inf-sup	2.46 ± 0.02	0.38 ± 0.02	2.5 ± 0.02	0.41 ± 0.02

#### Conclusion

It is observed that motion distorts the planned dose profile in both solid water and lung phantom. MLC tracking reduces dose smearing significantly as demonstrated by the no-motion and motion-tracking results. The DUO detector has proven to be an effective tool for pre-treatment verification of real-time adaptive stereotactic deliveries with both high spatial resolution for dose profiling and high temporal resolution for pulse by pulse dose reconstruction.

#### OC-0533 ADAM: a breathing phantom for testing radiotherapy treatment on moving lesions

S. Pallotta<sup>1</sup>, L. Foggi<sup>1</sup>, S. Calusi<sup>1</sup>, L. Marrazzo<sup>1</sup>, C. Talamonti<sup>1</sup>, L. Livi<sup>2</sup>, G. Simontacchi<sup>2</sup>, R. Lisci<sup>3</sup>

<sup>1</sup>University of Florence, Department of Medical Physics, Firenze, Italy

<sup>2</sup>University of Florence, Department of Radiotherapy, Firenze, Italy

<sup>3</sup>University of Florence, Department of Agricultural-Food and Forestry System, Firenze, Italy

#### Purpose or Objective

Dose delivery to moving targets can be approached following different strategies. For stereotactic radiotherapy treatments motion-encompassing methods, respiratory-gating techniques and respiration-synchronized techniques permit the treatment during lesions motion using different dose planning/delivering solutions. In all cases the complexity of the proposed methods needs the development of solutions for accurate Quality Assurance tests as stated also by AAPM TG76. For this purpose we developed a new phantom: ADAM (Anthropomorphic Dynamic breathing Model), capable of simulating realistic patient movements. The phantom and some preliminary tests showing ADAM performances are here presented.

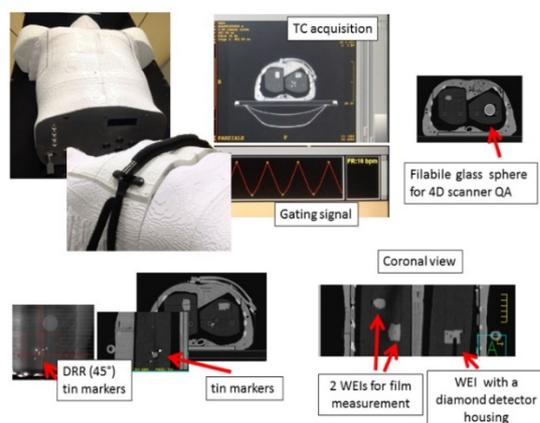

#### Material and Methods

ADAM is a 3D printed anthropomorphic phantom created using a real patient CT data. The central portion of the

torso contains lungs and ribs and is made of materials mimicking human tissue Hounsfield Unit. The lungs are shaped thus to host four water equivalent inserts (WEI) that simulate lung lesions and a fillable QA sphere (QAS) to test reconstruction performances of 4D scanners. Films can be inserted between two WEIs and a specific housing for a diamond detector has been drilled into one WEI. 6 small tin markers have also been included near the fourth WEI to test markers guided tracking procedure. The anterior part of the phantom moves up and down in sync with lungs movements driven by an Arduino programmable board hosted in the caudal phantom portion. Elliptical paths (axes up to 2cm), pre-programmed in the microcontroller, and patient specific respiratory movements, programmable by users, can be chosen on the LCD screen placed on the caudal extremity of the phantom. Preliminary tests were performed to assess Adam usability and its performances in terms of HU, WEI motion repeatability and lungs-to-surface motion correlation. Finally a VMAT plan, to deliver 18Gy to one internal WEI, was planned on an average reconstructed 4DCT data set and delivered to ADAM. Dose was prescribed to 95% of the PTV = ITV (encompassing all motion and delineated on MIP) + 5 mm margin. The delivered dose distribution, measured with a Gafchromic EBT3 film, was overlapped on the WEI to assess moving target dose coverage.

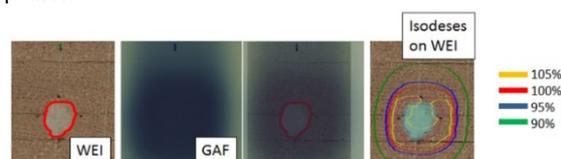

### Results

In Figure 1 ADAM and some internal details, as appear in CT images, are presented.

CT acquisitions demonstrate realistic human tissues HU values:  $-860 \pm 37$ ,  $77 \pm 30$ ,  $83 \pm 20$ ,  $1098 \pm 84$  respectively for lung, thorax soft tissue, WEI and bone. The absence of artifacts of reconstructed QAS and WEIs in all phases, demonstrate lungs-to-surface motion correlation. Movement tests show a long (20 days) and short-term (30min) amplitude repeatability  $< 1$  mm along both axes. In Figure 2 measured dose distribution delivered to a moving target is shown together with the QAS volume measured in static CT and in some 4DCT reconstructed

phases.

Known volume	4DCT volume test					
	CT static	phase 0%	phase 20%	phase 40%	phase 60%	phase 80%
[cc]	[cc]	[cc]	[cc]	[cc]	[cc]	[cc]
33,5	33,98	32,73	32,96	32,95	32,57	32,86
(measured - known) [%]						
	-1,4	2,3	1,6	1,6	2,8	1,9

### Conclusion

ADAM demonstrates suitable performances to test instruments and methods used to treat moving lesions.

### OC-0534 Establishment of patient-specific quality assurance procedure for Dynamic WaveArc delivery technique

H. Hirashima<sup>1</sup>, N. Nakamura<sup>1</sup>, Y. Miyabe<sup>1</sup>, N. Mukumoto<sup>1</sup>, M. Uto<sup>1</sup>, K. Nakamura<sup>1</sup>, T. Mizowaki<sup>1</sup>, M. Hiraoka<sup>1</sup>  
<sup>1</sup>Kyoto University Hospital, Department of Radiation Oncology and Image applied Therapy, Kyoto, Japan

### Purpose or Objective

Dynamic WaveArc (DWA) is a novel delivery technique that uses the Vero4DRT system (Mitsubishi Heavy Industries [MHI], Ltd., Tokyo, Japan, and Brainlab, Feldkirchen, Germany) for volumetric modulated arc therapy, with continuous non-coplanar delivery. DWA achieves high-dose conformity by optimizing the dose rate, gantry speed, ring speed, and positions of the dynamic multi-leaf collimator (MLC). The purpose of this study was to establish the patient-specific quality assurance (QA) procedure for the DWA.

### Material and Methods

Twenty DWA plans, 10 for brain tumors and 10 for prostate cancer, were created using RayStation version 4.7 (RaySearch Laboratories, Stockholm, Sweden). The prescribed dose for the brain tumor was set as 52.2 Gy at 1.8 Gy per fraction, and that for the prostate tumor was set as 76 Gy at 2 Gy per fraction. The patient-specific QA included the accuracy verification of the measured dose distribution, machine movement, and reconstructed dose distribution. First, absolute dose distributions measured by ArcCHECK (Sun Nuclear Inc, Melbourne, FL) were assessed by using 3%/3 mm global  $\gamma$ -tests for the area receiving more than 10% isodose, based on the AAPM TG119 report. Next, the log files were analyzed to evaluate the accuracy of the machine movement. The log files, including the actual gantry angle, ring angle, MLC position, and monitor unit (MU) were obtained at 50 ms intervals. Root mean square errors (RMSEs) between the planned and actual values in the log files were calculated. Finally, the delivered dose distributions were reconstructed based on the log files. The in-house software was used to load the original DICOM-RT plan file, and searched the actual values at each control point. Thereafter, the in-house software replaced the planned values at each control point with the actual values based on the log file, and then generated a reconstructed DICOM-RT plan file. The reconstructed plan was imported into RayStation, and then recalculated on the planning CT. The originally-planned dose-volumetric indices were compared with the reconstructed ones.

### Results

In the ArcCHECK dosimetry, the means  $\pm$  standard deviations (SDs) of the  $\gamma$ -pass rates were  $97.0\% \pm 1.2\%$  (range, 94.3%-98.7%) and  $98.4\% \pm 1.0\%$  (range, 96.6%-99.5%) for the brain and prostate tumors, respectively. In the log file analysis, the RMSEs for the gantry angle, ring

angle, MLC position, and MU were  $0.16^\circ \pm 0.01^\circ$  (range,  $0.12^\circ$ - $0.17^\circ$ ),  $0.08^\circ \pm 0.00^\circ$  (range,  $0.0.7^\circ$ - $0.08^\circ$ ),  $0.08 \pm 0.02$  mm (range,  $0.04$ - $0.11$  mm), and  $0.37 \pm 0.05$  MU (range,  $0.30$ - $0.44$  MU), respectively. In the delivered dose reconstruction, the means  $\pm$  SDs of the dose difference of the all dose-volumetric indices were  $0.5\% \pm 0.8\%$  (range,  $0.0\%$ - $4.2\%$ ) and  $0.2\% \pm 0.2\%$  (range,  $0.0\%$ - $0.7\%$ ) for the brain and prostate tumors, respectively.

Table 1. Summary of the accuracy verification of measured dose distribution, machine movement, and dose difference of dosimetric endpoint between planned and reconstructed.

Patient	ArcCHECK $\gamma 3\%/3$ mm	Log file analysis				Dose difference [%]			
		RMSEs		MLC position [mm]	MU	PTV D95%	CTV D99%	Chiasma D2%	Optic nerve D2%

## Purpose or Objective

LIAC and NOVAC (SIT, Italy) are two mobile linacs dedicated to IORT generating electron beams in the energy range of 3-12 MeV. Due to the large amount of scattered electrons from the collimator walls inside the IORT field, their energy spectra are very different from the traditional linacs on which are based the international dosimetry protocols. In addition, the methods recommended by these protocols to determine the ion-recombination correction factor ( $k_s$ ) fail under these high dose-per-pulse beams. Hence in 2003 the Italian Health Institute stated that ion chambers cannot be used for reference dosimetry of these linacs. Based on a retrospective multi-center survey, a comparison with ferrous sulphate dosimetry is now used to validate parallel-plate ion chambers for this purpose.

## Material and Methods

17 centers participating in this study had modified the IAEA TRS-398 dosimetry protocol regarding the reference irradiation setup and the determination of  $k_s$ , for which a previously published method, independent of ferrous sulphate dosimetry, was adopted. Ferrous sulphate dosimeters and ion chambers had been irradiated in water phantoms. When both were positioned at the depth of maximum dose the beam-quality correction factor  $k_{Q,Q_0}$  was renormalized based on water-air stopping power ratios. The equivalence between the dosimetry systems was checked by verifying the deviations  $\Delta_{ic-fs}$  between ion chambers and ferrous sulphate dosimetry together with the associated uncertainties.

## Results

The mean  $\Delta_{ic-fs}$  is -0.5% with an uncertainty of  $\pm 0.9\%$ , which shows no systematic deviations between systems.  $\Delta_{ic-fs}$  dispersion is 3.9% ( $2\sigma$ ). 40% of the  $\Delta_{ic-fs}$  are within  $\pm 1\%$ , 70% within  $\pm 2\%$  and 90% within  $\pm 3\%$ . No significant dependence on electron energy was found, thus confirming  $k_{Q,Q_0}$  renormalization. The influence of both chamber type and polarizing voltage on  $k_s$  was also analyzed. Ion chambers with lower electrode spacing or polarizing voltages higher than the normal operating ones allows a reduction of  $k_s$ , providing the chamber performance at these voltages has previously been checked for linearity of  $1/Q$  versus  $1/V$ .

## Conclusion

Parallel-plate ionization chambers can properly and accurately substitute ferrous sulphate detectors in reference dosimetry of LIAC and NOVAC mobile linacs. Therefore, we hope that the main dosimetry protocols for reference dosimetry in external-beam radiotherapy will provide guidance in the calibration of electron beams from linacs dedicated to IORT.

## Proffered Papers: Novel methods for auditing

### OC-0536 Causes of irradiation failures of IROC Houston's IMRT credentialing phantom

S. Kry<sup>1</sup>, J. Kerns<sup>1</sup>, M. Carson<sup>1</sup>, A. Molineu<sup>1</sup>, P. Taylor<sup>1</sup>, D. Followill<sup>1</sup>

<sup>1</sup>UT MD Anderson Cancer Center Radiation Physics, Radiation Physics, Houston- TX, USA

### Purpose or Objective

IROC Houston's head and neck phantom has been used to verify IMRT dose delivery for over a decade. While the passing rate has seen gradual improvement, at present more than 10% of institution's that irradiate this phantom still fail to meet the generous acceptability criteria. This study explores the causes of these failures.

### Material and Methods

To pass the head and neck phantom, the TPS-calculated dose must agree within 7% with TLD measurement at 6 assessed locations in two PTVs. Two film planes must show >85% of pixels passing a 7%/4mm gamma criterion. Failed irradiations over the past year were evaluated qualitatively for the cause of the failure: positioning errors, systematic dosimetric errors, and other errors. Based on the finding that most errors were systematic dosimetric errors, further quantitative exploration was done. Potential errors in institutional TPS beam models were evaluated using an independent recalculation of the phantom's treatment plan. This was done using "reference" beam models constructed from aggregated IROC Houston measurements for different classes of accelerator that were developed in Mobius 3D. 259 phantom plans were recalculated with these models.

### Results

On qualitative evaluation, only 13% of failures were attributed to localization errors, 18% were other non-systematic errors, and the vast majority, 69%, were systematic dosimetric errors: the dose distribution had the right shape and was in the right place, but it was the wrong magnitude. The independent recalculation of 259 phantom plans showed many cases where our reference model was less accurate than the institution, but a shocking number of cases where our recalculation was more accurate, both significantly (based on a 2-sided t-test with a failure detection rate correction applied), and substantially (>2% average improvement across the 6 TLD). The independent recalculation was significantly and substantial better than the institution's calculation in 18% of all cases, and in 68% of cases where the institution failed the phantom.

### Conclusion

Failures of the IROC Houston IMRT phantom overwhelmingly indicated a deficiency in the beam model. This is concerning because this beam model is applied to all patients, suggesting suboptimal treatment at nearly 1 in 5 radiotherapy facilities. It also indicates that physicists should increase attention to beam modeling.

### OC-0537 A remote EPID-based dosimetric auditing method for VMAT delivery using a digital phantom concept

P. Greer<sup>1</sup>, K. Legge<sup>2</sup>, N. Miri<sup>2</sup>, P. Vial<sup>3</sup>, T. Fuangrod<sup>1</sup>, J. Lehmann<sup>1</sup>

<sup>1</sup>Calvary Mater Newcastle Hospital, Department of Medical Physics, Newcastle, Australia

<sup>2</sup>University of Newcastle, School of Physical and Mathematical Sciences, Newcastle, Australia

<sup>3</sup>Liverpool Hospital, Radiation Oncology, Sydney, Australia

### Purpose or Objective

Current methods to perform dosimetric audits for participation in clinical trials are expensive and time-consuming with high failure rates. Currently nearly 2/3 of trial centres in Australia/New Zealand have not had an independent VMAT dosimetric audit. The aim of this work is to develop an inexpensive new method for remote dosimetric VMAT auditing.

### Material and Methods

Remote centres are provided with CT datasets and planning guidelines to produce trial VMAT plans for a head and neck and a post-prostatectomy treatment. The plans are transferred in the treatment planning system (TPS) to two digital water equivalent phantoms, one cylindrical (20

cm diameter) and one flat phantom. EPID cine images are then acquired during the VMAT delivery to the EPID panel in air. The cine images are backprojected to 3D dose in the digital cylindrical phantom using an established conversion method. This dose is then compared to TPS dose at a central site. Individual 2D arc doses (with gantry angles collapsed to zero in the TPS) are compared to EPID derived dose at 10 cm depth in the flat phantom. For Varian systems EPID images are obtained for Clinac systems using cine imaging mode and for Truebeam systems using image processing service which stores individual cumulative frames. Both of these systems store the gantry angle for the image in the header. For Elekta systems the service XIS software was used as the clinical cine mode normalises every image. This software acquires individual frames without a gantry angle. Three methods for gantry angle measurement were investigated, an inclinometer, a video-based method, and the machine iCom log files. The video-based method uses a printed green arrow attached to the gantry, with a mobile phone video recording during delivery. Colour detection and image processing were used to determine the angle in each movie frame.

### Results

To date six Varian centres have been fully analysed. The 3D gamma comparison results (3%,3mm for >10% of global maximum dose) were greater than 95% pass-rate for five centres and 93% for the one centre. For the 2D individual arcs all results were greater than 95% pass-rate for 3%,2mm criteria. Three Elekta centres have had preliminary investigations. Gantry angle comparisons show that the video method is comparable to the inclinometer and is easy to perform using only a printed piece of paper and mobile phone. Challenges for the method include synchronisation of the angle measurement and the EPID frames, and difficulty of use of the XIS software.

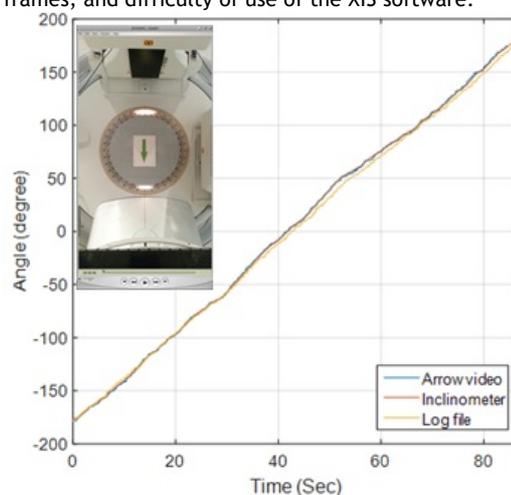

Figure 1. Comparison of gantry angles recorded for Elekta system, inclinometer (NG360), iCom log file and mobile phone method (insert)

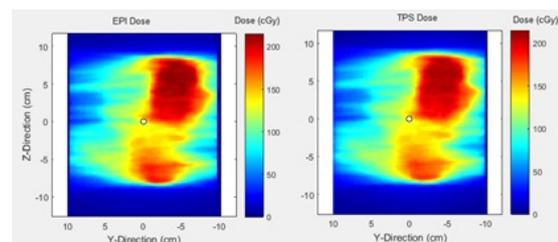

Figure 2. Comparison of EPID derived dose and TPS dose calculation for a Varian Truebeam system (sagittal dose plane)

## Conclusion

The remote EPID based digital phantom method is feasible for centres equipped with Varian linear accelerators either Clinac or Truebeam. The methods to date for Elekta systems require improvement before widespread use in the remote audit.

### OC-0538 A virtual dosimetry audit - towards transferability between global QA groups in clinical trials

M. Hussein<sup>1</sup>, D. Eaton<sup>2</sup>, P. Greer<sup>3</sup>, A. Haworth<sup>4</sup>, C. Hurkmans<sup>5</sup>, S. Ishikura<sup>6</sup>, S. Kry<sup>7</sup>, J. Lehmann<sup>4</sup>, J. Lye<sup>8</sup>, A. Monti<sup>5</sup>, M. Nakamura<sup>6</sup>, C. Clark<sup>2</sup>

<sup>5</sup>European Organisation for Research and Treatment of Cancer, EORTC, Brussels, Belgium

<sup>6</sup>The Japan Clinical Oncology Group JCOG, National Cancer Center, Tokyo, Japan

<sup>7</sup>Imaging and Radiation Oncology Core, IROC, National Cancer Institute, USA

<sup>8</sup>Australian Clinical Dosimetry Service ACDS, ARPANSA, Victoria, Australia

## Purpose or Objective

Quality assurance for clinical trials is important. Lack of compliance can affect trial outcome. Different international QA groups have different methods of dose distribution verification and analysis, all with the ultimate aim of ensuring compliance. As some clinical trials are open to international recruitment, it is important to understand how different analysis techniques and tolerances translate between different groups. Therefore the aim of this study was to gain a better understanding of different process to inform potential future dosimetry audit reciprocity.

## Material and Methods

Six international radiotherapy clinical trial QA groups participated. A treatment plan, using the 3DTPS test virtual phantom (previously used in UK VMAT and Tomotherapy Audit [1, 2]), was created using a 2 Arc VMAT technique in Varian Eclipse 13.6 calculated using AAA. This phantom has similar complexity to a head & neck cancer case [1]. Each group was supplied with four datasets. The first was a TPS reference dose cube. The remaining three were simulated 'Measured' dose cubes, labelled 1 to 3. These datasets were the original TPS plan with deliberate errors introduced; including dose difference and MLC positional errors. All data was exported in DICOM format to be readable by any software. Users were blinded to the measured data detail. Each group was requested to perform an analysis on the datasets using their standard technique for a typical head & neck plan (e.g. gamma index analysis, Distance-to-Agreement (DTA), dose difference, etc.) and to create their standard audit report, including how the analysis was performed and whether the 'measurements' pass or fail.

## Results

Table 1 summarises analysis technique, software used, acceptance criteria, and results for each 'measured' dataset. All but one group used the global gamma index ( $\gamma$ ) analysis. The remaining used the DTA analysis. For the global  $\gamma$  there were differences in the normalisation method (i.e. whether to use the maximum dose, a point in a high dose low gradient region, etc.) and in pass/fail criteria. Two groups had three decision levels for analysis; optimal pass, mandatory pass and fail. The remainder had straight pass/fail decision criteria. All groups passed Measured 1 and 3. However, for Measured 2, four groups

recorded a pass, 1 passed but with further investigation necessary, and 1 recorded a fail. Figure 2 shows an example analysis of Measured 2.

Table 1 Summary of analysis technique, software, acceptance criteria, and results for each of group.

Audit group	Analysis technique used	Software	Standard Head & Neck plan Acceptance criteria	Measured 1	Measured 2	Measured 3
1	Global $\gamma$ , absolute dose	In house MATLAB software	3%/3mm -85% points with $\gamma \leq 1$ Prescription dose normalisation no low dose threshold	Pass (100%)	Pass (100%)	Pass (100%)
2	Global $\gamma$ , absolute dose	SMC Patient v6.5.1	Optimal pass: 3%/3mm -95% points with $\gamma \leq 1$ Mandatory pass: 3%/3mm -95% points with $\gamma \leq 1$ Normalised to max dose 20% threshold	Pass - optimal (97.2%) Pass - optimal (97.2%) 3%/3mm - 95.3%	Pass - optimal (97.2%) Pass - optimal (97.2%) 3%/3mm - 95.3%	Pass - optimal (97.2%) Pass - optimal (97.2%) 3%/3mm - 95.3%
3	Global $\gamma$ , absolute dose	RT version v5.0.0	3%/3mm -95% points with $\gamma \leq 1$ Normalised to a point in high dose low gradient region 20% threshold	Pass (97.5%)	Fail (85.2%)	Pass (98.8%)
4	Distance-to-Agreement	SMC Patient v6.0.0	DTA $\leq 2$ mm	Pass (Max DTA = 1.2mm)	Pass (Max DTA = 0.3mm)	Pass (Max DTA = 0.2mm)
5	Global $\gamma$ , absolute dose	PTW Verisoft v6.1.0	3%/3mm Optimal pass >97.5% points with $\gamma \leq 1$ Mandatory pass > 90% with $\gamma \leq 1$ Normalised to max dose 20% threshold	Pass - optimal (99.4%)	Pass - action level (95.4%)	Pass - optimal (98.8%)
6	Global $\gamma$ , absolute dose	In house MATLAB software	3%/3mm -90% points with $\gamma \leq 1$ Normalised to max dose 10% threshold	Pass (99.0%)	Pass (93.1%)	Pass (99.8%)

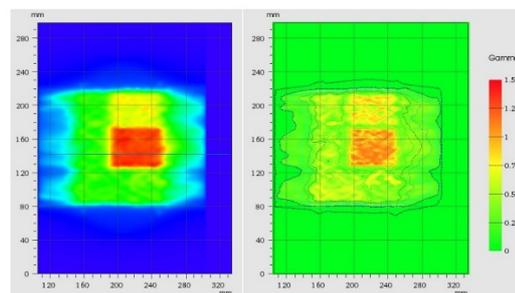

Figure 1 Example evaluation for 'measured 2' (left) using absolute gamma index analysis 3%/3mm (right).

## Conclusion

For the same dataset, different international audit groups had different analysis approaches and results. The results of this study will lead to a better understanding of methods and variability between audit groups and is informative for future work focussing on analysis techniques that are transferable between different groups.

### OC-0539 A multicentre QA study on 4DCT and IMRT/VMAT techniques for lung SBRT using a respiratory phantom

M. Lambrecht<sup>1</sup>, J.J. Sonke<sup>2</sup>, M. Verheij<sup>2</sup>, C.W. Hurkmans<sup>1</sup>

<sup>1</sup>Catharina Ziekenhuis, Physics/Radiotherapy, Eindhoven, The Netherlands

<sup>2</sup>Netherlands cancer institute, Radiotherapy, Amsterdam, The Netherlands

## Purpose or Objective

The EORTC has launched a phase II trial to assess efficacy of SBRT for centrally located NSCLC: The EORTC-LungTech trial. Due to neighbouring critical structures, these tumours remain challenging to treat. To guarantee accordance to protocol and treatment safety, an RTQA procedure has been implemented within the frame of the EORTC RTQA levels. To determine SBRT accuracy, we have performed end-to-end tests investigating both 4D-CT and IMRT/VMAT under static and respiratory conditions.

## Material and Methods

All centres audited performed 3D-CTs and 4D-CTs on the same phantom. It was successively scanned using two film inserts, one with a 15mm diameter target (15mmd) and one with a 25mm diameter target (25mmd). Three motions were tested: 20bpm/15mm amplitude (A), 10bpm/15mmA, and 15bpm/25mmA. A test procedure was developed to evaluate the impact of motion on the target volume and motion as determined using the binned CT data. These results were compared to the true volumes and motion amplitudes. Regarding the credentialing of

radiotherapy delivery, three treatment plans were made by each institution on each static 3D-CT and on the 4D-CT using the 15mmd animated by the 20bpm/15A signal. Prior to phantom measurements, a BOA was performed in water under reference conditions for the institution chosen energy. The plans were measured twice using EBT3 films and a 0.04cc ionization chamber. The films analysis was done in RIT113. Gamma analyses were performed using film dose as reference, a normalisation at the centre of the sphere, a dose threshold at 20%Dmax and 3%dose/3mm deviation as agreement criteria.

#### Results

Volume deviations (VD) (% true volume) were respectively for the 15mmd and the three motions tested: +10% (+/-7%), +1% (+/-17%), +12% (+/-12%) and for the 25mmd: +6% (+/-7%), +4% (+/-7%). VD were found higher at the end of inspiration than at the end of expiration 8% (+/-26%) insp and 1% (+/-3%) exp. The range of motion was underestimated in all cases: -0.15cm (+/- 0.07cm), the breathing pattern 10bpm presented the largest error -0.2cm (+/- 0.2cm) compared to the breathing pattern 20bpm -0.09cm (+/- 0.08cm). Regarding the dosimetric evaluation, the output dose mean deviation was 0.57% (+/- 1.42%) across institutions, agreement between chamber and point-planned doses were respectively for the 15mmd and the 25mmd static 98.9% (+/-1.3%), and 99.9% (+/-2.8%). Agreement with the planned dose (centre of PTV taken as ref. point) for the 15mmd in motion was 98.6% (+/- 0.86%). The film gamma mean pass rates were 70% for 15mmd static, 59% for 15mmd dynamic and 74% for 25mmd static.

#### Conclusion

QA of SBRT on moving targets are not yet practice routine, film dosimetry in 4D-conditions are challenging due to the absence of a consortium on where to register the films to the planned dose. Moreover we lack of consistent data to define acceptability thresholds. These results are a starting point, with more dataset we hope to correlate 4DCT and dosimetric data to propose relevant evaluation criteria.

#### OC-0540 A national cranial stereotactic radiosurgery end-to-end dosimetry audit

A. Dimitriadis<sup>1,2</sup>, R.A.S. Thomas<sup>2</sup>, A.L. Palmer<sup>3</sup>, D. Eaton<sup>4</sup>, J. Lee<sup>4</sup>, R. Patel<sup>4</sup>, I. Silvestre Patallo<sup>2</sup>, A. Nisbet<sup>5</sup>, C.H. Clark<sup>2</sup>

<sup>1</sup>University of Surrey, Department of Physics, Surrey, United Kingdom

<sup>2</sup>National Physical Laboratory, Radiation Dosimetry, Teddington, United Kingdom

<sup>3</sup>Portsmouth Hospitals NHS Trust, Medical Physics, Portsmouth, United Kingdom

<sup>4</sup>NCRI, Radiotherapy Trials Group, London, United Kingdom

<sup>5</sup>University of Surrey, Physics, Guildford, United Kingdom

#### Purpose or Objective

To assess the geometric and dosimetric accuracy of stereotactic radiosurgery (SRS) in the UK for linac-based (LB), TomoTherapy (TT), Cyberknife (CK) and Gamma Knife (GK) radiosurgery.

#### Material and Methods

26 SRS centres were visited and 28 treatment plans were assessed (16 LB, 7 GK, 4 CK, 1 TT). The audit methodology employed an anthropomorphic head phantom with realistic tissue densities with one irregularly-shaped target (PTV), modelled on a brain metastasis, located centrally in the brain and in close proximity to the brainstem (OAR). The phantom was immobilised, scanned, planned and treated following the local protocol. Previously characterised near-water equivalent dosimeters were placed inside the phantom (EBT-XD film and alanine pellets) to measure absolute dose, both inside the PTV and OAR (Figure 1), and compare with TPS

predictions. Film measurements were digitised with triple-channel-correction and compared to TPS dose planes on FilmQA Pro using  $\gamma$ -analysis for a range of global and local criteria.

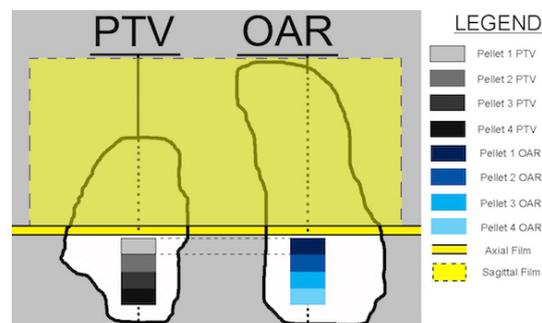

Figure 1: Schematic representation of detector positions.

#### Results

Figure 2 shows the alanine measurements inside the PTV. LB showed the largest range in percentage difference to the TPS of 5.2% (-1.3% to +3.9%) with a mean of +0.5%. CK had a range of 2.6% (+1.4% to +4%), with the highest mean difference in comparison to the other platforms (+2.5%). GK showed the smallest range at 2.4% (-0.8% to +1.5%) being comparable to that of CK, with the smallest mean percentage difference (+0.4%) comparable to that of LB. Similar trends were observed in the OAR with alanine measurements showing a range from -1% to +3.6% (mean= +1.3%), 0% to +1.9% (mean= +0.9%) and -1.1% to +0.9% (mean= +0.1%), for LB, CK and GK respectively.

The film measurements showed comparable passing rates between axial and sagittal films, regardless of the platform used. As expected, higher passing rates were observed for Global- $\gamma$  criteria. For 3%-2 mm Local- $\gamma$ , all except two films showed passing rates above 75%. For 5%-1 mm Global- $\gamma$ , all except 2 films showed passing rates above 90%.

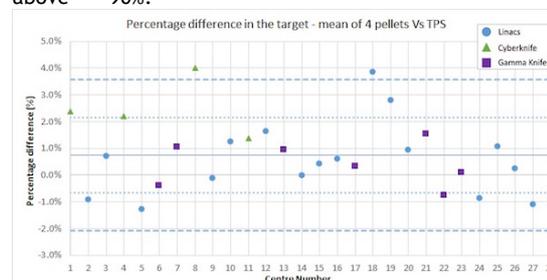

Figure 2: Results of PTV alanine pellets (dotted lines:1 $\sigma$ , dashed lines:2 $\sigma$ ).

#### Conclusion

This audit enabled the comparison of all participating centres in terms of the accuracy achieved during the delivery. The techniques used differed in many aspects. The LB group showed the largest variations in agreement to the TPS, related to more heterogeneous practices within the group, compared to small variations seen in CK, and more consistent practices seen in GK. Good overall agreement with the TPS was observed with only 3 centres falling above two standard deviations of the mean (2 centres in the target measurements and 1 in the OAR). Film measurements showed comparable  $\gamma$ -passing rates for all centres assessed with small differences between platform groups. The results suggest that good agreement with the predicted dose distributions is achievable by all treatment modalities but highlight the need for standardisation in SRS practices.

#### OC-0541 Automated treatment planning for prospective QA in the TRENDY randomized trial on liver-SBRT for HCC

<sup>10</sup>University Hospital Gasthuisberg, Radiation Oncology, Leuven, Belgium

### Purpose or Objective

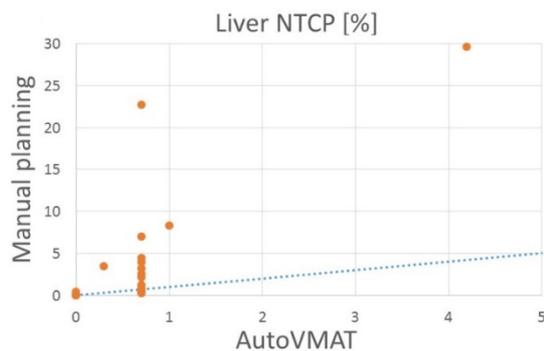

The TRENDY trial is an international multi-center phase II study in which patients with hepatocellular carcinoma (HCC) are randomized between transarterial chemoembolization in the standard arm and stereotactic body radiation therapy (SBRT) in the experimental arm. SBRT is delivered in six fractions with a total target dose of 48-54 Gy. An extensive QA program has been implemented, including prospective (prior to delivery) feedback on treatment plans, generated in the participating centers. For this feedback, the QA team uses a platform for automated treatment plan generation and planning CT-scans submitted by the centers. Here, we report on the first experiences.

### Material and Methods

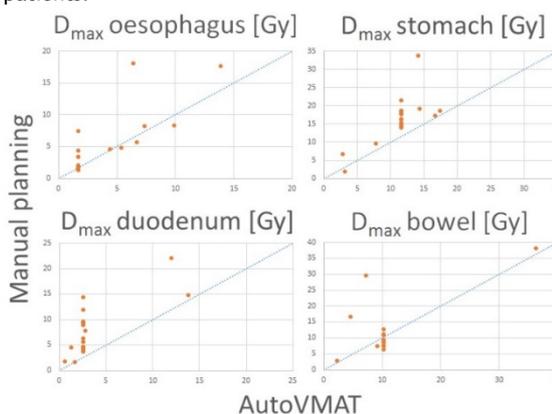

Based on the trial constraints and objectives, including a constraint on the NTCP for the healthy liver (NTCP  $\leq$  5%), fully automated plan generation for HCC has been implemented in a system for automatic prioritized multi-criteria optimization of deliverable VMAT plans (autoVMAT). Prior to treatment, participating centers send the contoured CT-scan of a new patient to the QA team. A plan is then automatically generated to be compared with the plan that was generated in the centers, using the common manual planning. Comparisons can result in improvements of the latter plan, which will be used clinically. The goal is to promote quality and uniformity of the SBRT treatment, and thereby, clinical outcome.

### Results

AutoVMAT plans are compared to 19 manual treatment plans, 12 from a dummy run, 5 from a clinical pilot, and 2 from trial patients. Since target coverage is similar for all plans, we focus on OARs. Although some non-coplanar Cyberknife plans outperform the corresponding co-planar autoVMAT plan, for most patients, autoVMAT resulted in a superior plan, with an average NTCP reduction of 4.0%. (range: -25.4% to 0.5%,  $p = 0.013$ ), a lower mean dose to the healthy liver ( $p < 0.01$ ) and lower doses to gastrointestinal OARs (see figures). As significantly suboptimal plans are easily identified, this approach is well-suited for prospective feedback on treatment planning for individual patients.

NTCP of the liver minus GTV for autoVMAT plans (horizontal) and manual plans (vertical) for the same patients.

Gastrointestinal OAR doses for autoVMAT plans and manual plans.

### Conclusion

Fully automated treatment planning has been implemented in the QA program of the randomized TRENDY trial for prospective plan QA (prior to plan delivery), and contributes to the objective evaluation of submitted treatment plans.

### Proffered Papers: Patient safety and treatment outcome

#### OC-0542 Dysphagia, Odynophagia and Globulus in Patients Receiving RT for Spinal Cord Compression

V. Gram<sup>1</sup>, M. Hemer<sup>1</sup>, A. Appelt<sup>2</sup>, H. Pappot<sup>1</sup>, P. Sjøgren<sup>1</sup>, L.S. Fog<sup>1</sup>

<sup>1</sup>Rigshospitalet, Department of Radiotherapy- Clinic of Oncology, København, Denmark

<sup>2</sup>St James's University Hospital, Leeds Institute of Cancer and Pathology- University of Leeds and Leeds Cancer Centre, Leeds, United Kingdom

### Purpose or Objective

This study aimed at determining the incidence and association of dysphagia with esophageal dose and disease localization in patients receiving radiation therapy (RT) for spinal cord compression (SCC).

### Material and Methods

This prospective study included thirty consecutive patients, who received 10 fractions of 3 Gy of RT for SCC at our clinic. Patients were irradiated using VMAT with daily CBCT. Patients were followed daily for 3 weeks, using the mBPI and ESAS questionnaires and weekly using the EORTC30 questionnaire; hereafter weekly using mBPI, ESAS and EORTC30 for 4 weeks, totaling 7 weeks. Patients were contacted by phone or personal interview. The incidence of dysphagia, odynophagia and globulus (collectively DOG) was determined. Since DOG typically

emerged after the first week of RT, patients who were not followed for at least 7 days were excluded from the analysis.

The incidence of DOG for patients with at least one treated vertebra at Th8 or above was compared to the incidence for patients treated below Th8 using Fisher's exact test. The relationships between the mean ( $D_{\text{mean}}$ ) and maximum ( $D_{\text{max}}$ ) esophageal doses and incidence of DOG was examined using the Wilcoxon rank sum test, comparing distributions of dose metrics in the two groups.

### Results

30 patients (12 women / 18 men) participated in the study, with prostate (8), breast (5) and lung (4) cancer as the most common primary diagnoses. Median number of vertebrae treated was 2 (range 1-9), with 9 patients treated to more than one site. 4 patients were excluded from this analysis due to withdrawal or inability to complete questionnaires prior to the one week mark. Out of the 26 patients, 11 reported DOG (Fig 1, Fig 2). For all 11 patients, the most cranially treated vertebra was Th8 or above; 4 of the 15 patients not reporting DOG were treated to Th8 or above ( $p < 0.001$ ). The median  $D_{\text{mean}}$  was 7.8 Gy (range 0.0-15.9 Gy) for patients reporting DOG, and 2.2 Gy (0-10.8 Gy) for patients not reporting DOG,  $p = 0.0043$ . Corresponding values for  $D_{\text{max}}$  were 24.7 Gy (0-31.4 Gy) with DOG and 9.8 Gy (0-31.4 Gy) without DOG,  $p = 0.0043$ .

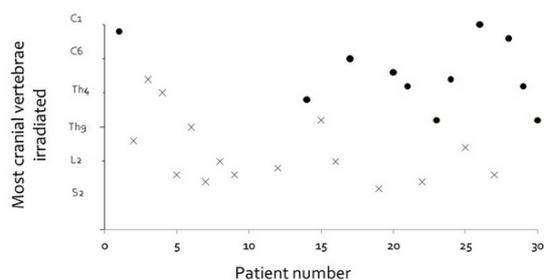

Fig 1: The most cranial vertebrae receiving radiotherapy for spinal cord compression vs patient number. The patients who experienced dysphagia, odynophagia or globulus are shown with circles; those who did not are shown with crosses.

### Incidence of dysphagia, odynophagia or globulus

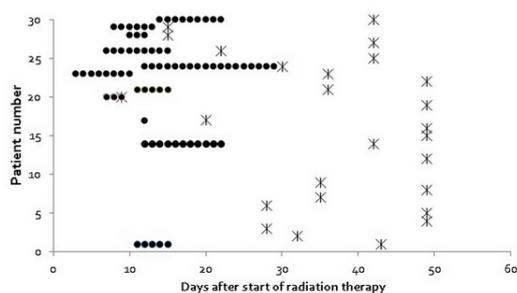

Figure 2: Incidence of dysphagia, odynophagia or globulus (DOG) in 30 patients treated with radiation therapy for spinal cord compression. The black dots indicate the days where the patients reported DOG, the stars when patient follow-up ended.

### Conclusion

There is a high incidence of patient-reported DOG in patients treated for SCC. This incidence correlates with mean and maximum esophageal dose, but also appears to depend strongly on irradiation of cranially located vertebrae. Our results indicate that it may be possible to reduce the incidence of DOG in patients with SCC by reducing the esophageal dose. This provides an argument for the use of intensity-modulated radiotherapy optimized to limit dose to the esophagus for the treatment of SCC.

### OC-0543 Acute toxicity with helical IGIMRT for head and neck cancer: Unilateral vs bilateral nodal irradiation

A.M. Bates<sup>1</sup>, D.J. Noble<sup>2</sup>, O. Young<sup>1</sup>, E. Wong<sup>1</sup>, J. Gemmill<sup>2</sup>, R.J. Benson<sup>2</sup>, S.J. Jefferies<sup>2</sup>, G.C. Barnett<sup>2</sup>,

N.G. Burnet<sup>2</sup>

<sup>1</sup>Addenbrooke's Hospital - Oncology Centre University of Cambridge, Cambridge Cancer Trials Center, Cambridge, United Kingdom

<sup>2</sup>Addenbrooke's Hospital - Oncology Centre University of Cambridge, Department of Oncology, Cambridge, United Kingdom

### Purpose or Objective

Most patients undergoing radical radiotherapy (RT) for head and neck cancer (HNC) develop severe acute toxicity, and treating physicians aim to spare uninvolved neck nodal levels where possible. This study aimed to determine rates of gr. 2+ and 3+ acute oral toxicities in patients with HNC receiving helical IMRT with daily image guidance. We compared acute oral toxicities in patients who received unilateral nodal irradiation (UNI) and bilateral nodal irradiation (BNI).

### Material and Methods

This was a sub-study of the Cancer Research UK VoxTox programme, that prospectively accrued high resolution acute and late toxicity data in patients undergoing radical RT. Selection criteria for this sub-study were: Prescription dose 65Gy/30#, concurrent weekly cisplatin (min. 4 cycles), sub-sites including oropharynx, oral cavity, larynx and hypopharynx. Patients were treated according to our local 3 dose-level protocol: macroscopic disease CTV 65Gy, high risk CTV 60Gy, lower risk CTV 54Gy (contralateral neck). Patients were reviewed at baseline, weekly during treatment, and at weeks 4 and 8 post-treatment. All data were collected using electronic clinical report forms by a specialist HNC oncologist, or experienced RTT. We collected data on 4 key oral toxicity endpoints using CTCAE v4.03: oral mucositis, dry mouth, salivary duct inflammation and dysphagia. Maximum toxicity rates of these four were also considered.

### Results

73 patients were selected; 11 had UNI, and 62 BNI. There was no reported toxicity or differences between groups at baseline. Plots of gr. 2+ and 3+ toxicity for all 4 endpoints are shown in Figure 1A-D. Maximum weekly toxicities are shown in Table 1.

Overall, there appears little difference in gr. 2+ toxicity rates between groups. Furthermore, maximum or specific toxicity rates are similar (max toxicity 83% BNI vs 80% UNI). However, table 1 and figure 1 suggest that gr. 3+ toxicity developed more quickly in BNI patients. Using 2x2 tables and Fisher's exact test, we compared rates at week 4. Overall maximum toxicity at week 4 was 33% for UNI, 56% for BNI, but this was not significant ( $p = 0.33$ ). This procedure was repeated for all 4 endpoints. Rates of mucositis were 8% (UNI) vs 33% (BNI); this trended towards significance ( $p = 0.08$ ). Week 4 gr. 3+ toxicity rates were also higher in the BNI group for dry mouth, ductal inflammation and dysphagia (0% vs 16.4%, 16.7% vs 23%, 33% vs 41% respectively). None of these differences showed statistical significance. Recovery rates post treatment appeared similar between cohorts.

### Conclusion

This study shows that gr. 2+ toxicity rates appear to be similar between patients undergoing UNI or BNI throughout treatment and recovery. Peak toxicity (ie highest proportion of patients reporting gr. 3+ toxicity) was also similar. However, our data indicate that BNI patients may develop some acute toxicity earlier in treatment and we will re-test this hypothesis once a larger cohort has been recruited.

### OC-0544 Stereotactic radiotherapy in elderly patients: age, survival and performance status

J.L. Monroy Anton<sup>1</sup>, L. Tejedor Pedrosa<sup>2</sup>, M. Soler Tortosa<sup>1</sup>, M. López Muñoz<sup>1</sup>, A. Soler Rodríguez<sup>1</sup>, A. Navarro Bergadá<sup>1</sup>, M. Estornell Gualde<sup>1</sup>

<sup>1</sup>Hospital universitario de la ribera, radiation oncology, Madrid, Spain

<sup>2</sup>Universidad catolica de valencia, facultad de enfermeria, Valencia, Spain

### Purpose or Objective

The increase in life expectancy also increases the possibility of occurrence of tumors in elderly population. Radical treatments in these patients may involve functional impairment or complications, often rejected. SBRT enables to apply a radical treatment in a few sessions, with little side effects and good results, and could be considered the technique of choice for certain patients considered elderly or frail.

Our purpose was to assess survival in function of age and performance status in a group of elderly cancer patients.

### Material and Methods

We analyzed 44 lesions treated with SBRT, in 39 patients aged 70-93 years (mean: 79.9; median: 80). Male: 32 (82.05%), female: 7 (17.95%). Performance status was determined before treatment with Karnofsky Performance Status Index (KPSI).

### Results

#### Number of fractions:

Seven fractions in 1 case (2.27%)  
Three fractions in 23 cases (52.27%)  
Two fractions in 9 cases (20.45%)  
One fraction in 11 cases (25%)

#### Survival:

Lost of follow up: 5 patients (12.82%).  
<6 months: 4 patients (10'25%)  
6-12 months : 10 patients (25'64%)  
12-18 months : 6 patients (15'38%)  
> 18 months : 14 patients (35'89%)

#### Performance status:

KPS >70 was registered in 26 patients (66.6%); ≤70 in 13 patients (33.3%)

Survival in KPSI ≤70: <6 months: 4 patients ( 11.76 %)  
6-12 months : 4 patients (11.76 %)  
12-18 months : 2 patients (5.88 %)  
> 18 months : 2 patients ( 5.88 %)

#### Survival in KPSI >70:

<6 months: 0 patients  
6-12 months : 6 patients ( 17.64 %)  
12-18 months : 4 patients ( 11.76 %)  
> 18 months : 12 patients ( 35.29 %)

#### Age and survival:

We divided the population in two groups of age, with a cut-off in 80 years.

#### Group 70-80y:

<6 months: 1 patients (2.56%)  
6-12 months : 3 patients (7.69%)  
12-18 months : 2 patients (5.12%)  
> 18 months : 6 patients (15.38%)

#### Group ≥ 80y:

<6 months: 3 patients (7.69 %)  
6-12 months : 7 patients (17.94 %)  
12-18 months : 3 patients (7.69 %)  
> 18 months : 9 patients (23.07%)

### Conclusion

- Elderly patients treated with SBRT achieved a good survival.
- A high KPS (>70) is better in terms of survival (35.29% vs 5.88% in >18 months).
- If we consider 80 years as more old patients, advanced age appeared not to be worse than younger ones in terms of survival (23% vs 15% in >18m).
- SBRT should be considered a good option of radical treatment in elderly patients because of good results in survival, which is better in patients with better performance status.

### OC-0545 Head and neck paragangliomas: preliminary results of the Protontherapy Centre of Trento (Italy)

I. Giacomelli<sup>1</sup>, D. Scartoni<sup>1</sup>, M. Cianchetti<sup>1</sup>, F. Dionisi<sup>1</sup>, D. Amelio<sup>1</sup>, S. Lemoine<sup>1</sup>, F. Fellin<sup>1</sup>, R. Righetto<sup>1</sup>, M. Amichetti<sup>1</sup>

<sup>1</sup>Azienda Provinciale per i Servizi Sanitari APSS Trento, U.O. di Protonterapia, Trento, Italy

### Purpose or Objective

Paragangliomas (PGL) are rare usually benign, slow growing but locally aggressive tumors. Overall and specific Survival analyses reveal that most patients do not die of PGLs thus local control and QoL are a meaningful endpoint for comparative decision making. Proton therapy (PT) can spare more healthy tissue than conventional and/or intensity-modulated X-ray therapy (IMRT) and it can result in fewer side effects. The aim of this study is to evaluate PT safety, feasibility and dosimetric aspects in the definitive treatment of PGL.

### Material and Methods

From December 2015 to October 2016, six pts, five females and one male, median age 55.5 years (range, 39-88 years) were treated for histological or radiological confirmed H&N PGL. Two patients (pts) had positive familiar history for PGL1 syndrome. Three patients had two PGLs treated, for a total of 9 PGLs. Locations were: jugulotimpanic (2); timpanic (1); jugular (1); vagal (2); carotid body (3). Maximum diameter ranged between 20 and 45 mm.. Five pts were irradiated with definitive intent, one pt was treated postoperatively because of gross residual disease; and one pt received PT for recurrent disease. Acute and late toxicities were evaluated according to the CTCAE scale version 4.0. Quality of Life was evaluated using the EORTC QLQ-C30 and H&N35 questionnaires.

### Results

All pts were treated with active beam scanning PT using 2-3 fields with single field optimization (SFO) technique with a total dose of 50.0 GyRBE in 25 fractions of 2.0 GyRBE. Posterior beam arrangement was preferred when allowed in order to spare as much as possible critical structures: all pts had at least one or more posterior or posterior-oblique beams, four had also one lateral beam and two had one anterior-oblique beam. Median PTV (CTV + 4mm margin) volume was 63.85 cc, median ipsilateral OARS doses were: temporomandibular joint 37.22 GyRBE, cholelea 36.72 GyRBE, parotid 22.30 GyRBE, superior constrictor muscles 19.19 GyRBE, oral cavity 2.29 GyRBE, hemimandible 7.67 GyRBE. All patients completed PT without interruptions. No acute toxicity > G2 was observed. Three pts experienced G2 skin toxicity and one pt G2 external otitis. No late toxicity was observed at the last follow-up. Two pts had improvement of symptoms related to the disease: one pt had dysphonia improvement one month after PT; in another pt improvement of VII cranial nerve paresis and reduction of tinnitus were observed. All pts reported stability or improvement in the evaluation of their health status and QoL. At the time of the analysis all patients are locally controlled

### Conclusion

Proton therapy for PGLs is a safe, feasible, and well tolerated treatment. The superiority in dose distribution compared to X-ray therapy could translate in better results in terms of long-term toxicity and QoL . A longer follow-up is needed to confirm these favourable initial results .

### OC-0546 Video Launching during Irradiation - an alternative to anesthesia in pediatric patients?

C. Palhetinha Aguas<sup>1</sup>, P. Humblet<sup>1</sup>, L. Renard<sup>1</sup>, A. Vaandering<sup>1</sup>, V. Roosen<sup>1</sup>, M. Coevoet<sup>1</sup>

<sup>1</sup>Cliniques Universitaires Saint Luc, Radiotherapy, Brussels, Belgium

### Purpose or Objective

The child's cooperation is of greatest importance during radiotherapy (RT). For very young patients, general anesthesia (GA) is often required for adequate immobilization.

GA has multiple drawbacks for the young patient, his relatives and the RTTs. VLADI (Video Launching Applied during Irradiation) project's aim is to replace the use of anesthesia with the projection of videos during treatment in order to reassure and distract the patient throughout the treatment procedure.

#### Material and Methods

Finding alternatives to general anesthesia in the treatment of children is of great interest.

Hypnosis has been known to replace anesthesia during interventions in some hospitals. This technique is very interesting but it varies from patient to patient and it's somewhat difficult to apply in children undergoing RT treatments.

As a possible alternative, VLADI project was created. It consists of a small projector which projects multimedia content in the field of view of the child throughout the treatment procedure. At this stage, this device has been specifically designed for Tomotherapy® treatment units. This project was started in late 2014 in our RT department, and we have evaluated the impact of the project on the potential reduction of the use of GA for children between the ages of 1.5 and 6 years old).

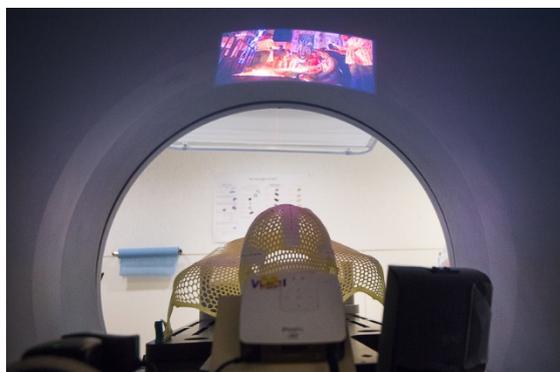

#### Results

VLADI's impact on the use of GA was evaluated by comparing 2 groups of children aged between 1.5-6 years old (n= 12): Group 1 (n=6) composed of pediatric patient treated in our RT department **before** the implementation of VLADI project and Group2 (n=6) composed of pediatric patient treated in our RT department **after** the implementation of VLADI project.

Since we implemented the VLADI project, we've diminished the use of GA from 83.3% (Group1) to 33.3% (group 2) and we've reduced the number of anxiolytics given to patients.

In total, 72.2% of the children benefited of this system instead of GA.

Also before VLADI each RT treatment with GA took at least 1h, after its implementation this has been reduced to 15-20min.

#### Conclusion

The use of VLADI as an alternative to anesthesia represents a gain both at the level of patient care (less medication) but also on a workflow level.

In our department, VLADI has almost completely replaced anesthesia resulting in reduced treatment times and reduction of stress for the young patients and their family. These first results on our pediatric patients underline the efficiency of the system and can even be extended to claustrophobic or stressed adult patients who would - without VLADI- require anxiolytics to undergo their treatment.

#### OC-0547 Acute and late morbidity in a Phase II trial of adaptive radiotherapy for urinary bladder cancer

A. Vestergaard<sup>1</sup>, L. Muren<sup>1</sup>, H. Lindberg<sup>2</sup>, L. Dysager<sup>3</sup>, K. Jakobsen<sup>2</sup>, H. Jensen<sup>3</sup>, J. Petersen<sup>1</sup>, U. Elstrøm<sup>1</sup>, A. Als<sup>4</sup>, M. Hoyer<sup>4</sup>

<sup>1</sup>Aarhus University Hospital, Department of Medical Physics, Aarhus C, Denmark

<sup>2</sup>Copenhagen University Hospital- Herlev, Department of Oncology, Herlev, Denmark

<sup>3</sup>Odense University Hospital, Department of Oncology, Odense, Denmark

<sup>4</sup>Aarhus University Hospital, Department of Oncology, Aarhus C, Denmark

#### Purpose or Objective

Large changes in bladder shape and size during a course of radiotherapy (RT) make adaptive RT (ART) appealing in the treatment of this tumour site. Patients with bladder cancer unfit for surgery and chemotherapy were treated in a multicentre phase II trial of daily plan selection with the primary aim of reducing gastro-intestinal (GI) morbidity. Acute and late morbidity is reported from the trial and the frequency of acute diarrhoea is compared to a previous cohort of similar patients treated with non-adaptive RT (non-ART).

#### Material and Methods

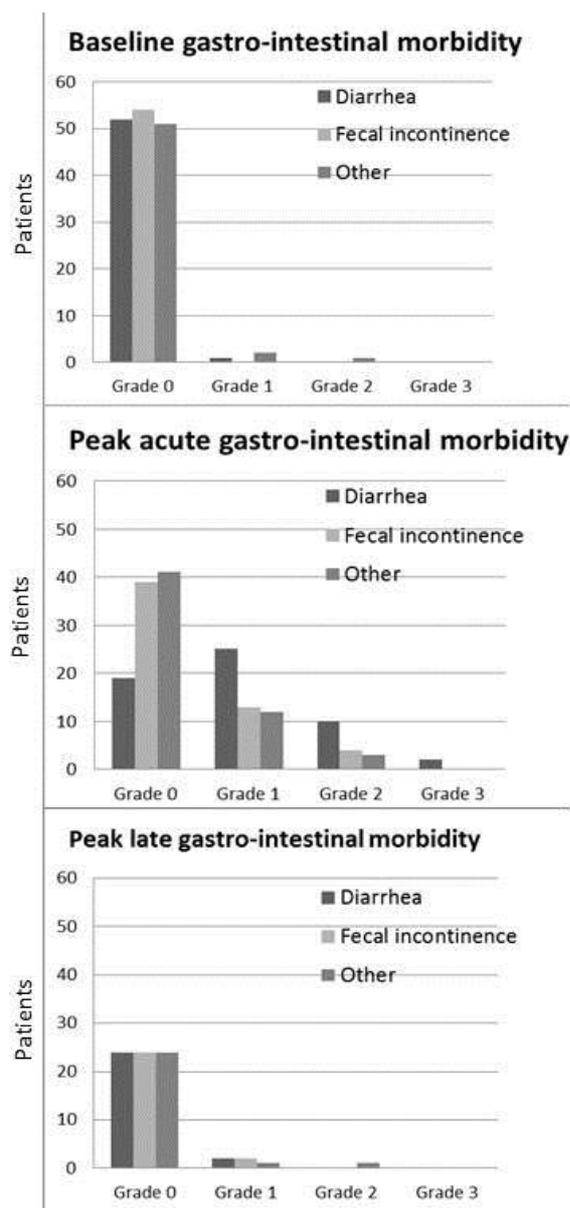

All 54 patients (median age 80 years) received 60 Gy in 30 fractions to the bladder; in 41 of the patients the pelvic lymph nodes were simultaneously treated to 48 Gy. Cone-beam CT (CBCT) image guidance was used for daily set-up and treatment was delivered by volumetric modulated arc therapy (VMAT). The first five fractions were delivered using large, population-based margins (non-ART: 20 mm sup and ant; 15 mm post; 10 mm lat and inf); the bladder contours from the CBCTs acquired during the first four daily treatment sessions were used to create a library of three plans, corresponding to a small, medium and large size bladder. From fraction six all patients were treated using daily online plan selection, where the smallest plan covering the bladder was selected prior to each treatment delivery. Morbidity scoring was performed at baseline, every second week during RT and two weeks as well as 3, 12 and 24 month after RT using CTCAE v. 4.0. The frequency of any grade 2 or higher GI morbidity was evaluated at treatment completion. Peak acute morbidity was assessed using the scorings until 3 months after RT and peak late morbidity was evaluated after 12 months of follow up. The frequency of peak acute diarrhoea was compared to the cohort treated with non-ART. Acute and late genito-urinary (GU) morbidity was also recorded. Median follow-up was 12 months.

#### Results

Frequency of use of small size plans was 46%, medium 25% and large 31%. The median volume ratio of PTV-ART vs. non-ART across the treatment course was 0.68 (range: 0.46-0.93 for individual patients). Any GI morbidity grade 2 or higher was reported by 11 patients (20%) at treatment completion and returned to baseline level at the 3 months follow-up. Peak acute grade 2 or higher diarrhoea was reported by 12 patients (22%). In the previous cohort of patients treated with non-ART, 15 (30%) reported grade 2 or higher diarrhoea. An expected increase in acute GU morbidity during RT was observed compared to baseline scoring, but primarily grade 1. Late GU morbidity was comparable to baseline.

#### Conclusion

Daily adaptive plan selection in RT of bladder cancer results in a considerable dose sparing of normal tissue. This phase II trial indicates that adaptive RT can be delivered with low risk of morbidity.

Poster Viewing : Session 12: Gynaecology and prostate

**PV-0548 The role of adjuvant therapy in stage IA serous and clear cell uterine cancer: a pooled analysis**

<sup>6</sup>McMaster University, Oncology, Hamilton, Canada

<sup>7</sup>University of Alberta, Oncology, Edmonton, Canada

<sup>8</sup>Henry Ford Hospital, Gynecology/Oncology, Detroit, USA

**Purpose or Objective**

The optimal adjuvant management of Stage IA endometrial cancer with serous or clear cell histology is controversial. The objective of this study is to explore the role of adjuvant therapy in this population and identify patient characteristics of those suitable for observation.

**Material and Methods**

Retrospective chart reviews for consecutive patients who underwent hysterectomy for FIGO Stage IA endometrial cancer with serous or clear cell histology between 2004-2015 were conducted in 6 academic centres. After excluding patients who were upstaged following surgery, a pooled analysis was performed for relevant endpoints.

**Results**

A total of 414 patients with a median age of 67 years (range 41-90) met the inclusion criteria. The most common histology were pure serous (64%, n=266) followed by mixed (27%, n=112) and pure clear cell (9%, n=36). Myometrial invasion was identified in 54% (n=222). Most patients underwent some surgical staging including sampling of pelvic lymph node (LN) (81%, n=335), para-aortic LN (45%, n=146), omentum (58%, n=239) and peritoneal washing (62%, n=219). Only 23% of patients (n=95) were considered to have adequate staging (pre-defined as  $\geq 10$  pelvic LN, sampled para-aortic LN and omentum). Thirty-four percent of patients (n=140) received adjuvant chemotherapy and carboplatin/paclitaxel was most commonly used (77%, n=108). Adjuvant RT was delivered to 47% (n=178) of patients (external beam alone 16%, n=29; brachytherapy alone 56%, n=99; both 28%, n=50). The median follow-up was 2.7 years (range 0-12). Among patients who did not receive any adjuvant treatment, 5-year actuarial estimates were as follows: local control (LC) 88%, regional control (RC) 93%, distant failure (DF) 15%, disease free survival (DFS) 74%, cancer specific survival (CSS) 91% and overall survival (OS) 82%. Adequate staging was associated with better CSS in patients who did not have adjuvant treatment (100% vs. 87%, logrank p=0.0035). Adjuvant RT was associated with better LC (5-year 96% vs. 84%, HR 0.32, logrank p=0.014). The 5-year RC was 93%, which was not found to be significantly improved by external beam RT. Adjuvant chemotherapy was associated with better LC (5-year 94% vs. 84%, HR 0.29, logrank p=0.0079), DFS (5-year 79% vs. 71%, HR 0.47, logrank p=0.033), but not for RC, DF or CSS. The delivery of at least 5 cycles of chemotherapy, was associated with a trend towards better LC (4-year 98% vs. 88%, HR 0.18, logrank p=0.090). Myometrial invasion, lymphovascular invasion, histological subtypes and the proportion of type II component were not found to be significant prognostic factors for LC, RR, DF or CSS.

**Conclusion**

Adjuvant radiotherapy and chemotherapy were associated with better LC and DFS but not for RC, DF or CSS for stage IA serous and clear cell uterine cancer. Observation may be an acceptable strategy in patients who have had adequate surgical staging.

**PV-0549 National Cancer Data Base Analysis of SBRT, IMRT, and Brachytherapy Boost for Cervical Cancer**  
 M. Ludwig<sup>1</sup>, M. Bonnen<sup>1</sup>, J. Shiao<sup>2</sup>, B. O'Donnell<sup>3</sup>, T. Pezzi<sup>1</sup>, N. Waheed<sup>1</sup>, S. Sharma<sup>1</sup>

<sup>1</sup>Baylor College of Medicine, Radiation Oncology, Houston, USA

<sup>2</sup>University of Texas San Antonio, Radiation Oncology, San Antonio, USA

<sup>3</sup>University of Texas Houston, Radiation Oncology, Houston, USA

**Purpose or Objective**

Brachytherapy is a vital component of curative radiotherapy for cervical cancer, but in certain patients, brachytherapy is not feasible because of inaccessibility of brachytherapy comorbidities, patient refusal, or unfavorable anatomy. Our objective was to determine if

stereotactic body radiotherapy (SBRT) and intensity-modulated radiation therapy (IMRT) boost techniques have comparable overall survival (OS) with brachytherapy boosts for patients with cervical cancer when adjusted for known prognostic factors.

#### Material and Methods

We used the National Cancer Data Base to study women who received radiation between 2004 and 2013 diagnosed with squamous cell carcinoma, adenocarcinoma or adenosquamous carcinoma of the cervix. Biological effective doses (BED) were calculated for both SBRT and IMRT treatments. A logistic regression model was built to identify factors associated with the receipt of SBRT and IMRT. Correlates of OS were determined using Kaplan-Meier and propensity score matching.

#### Results

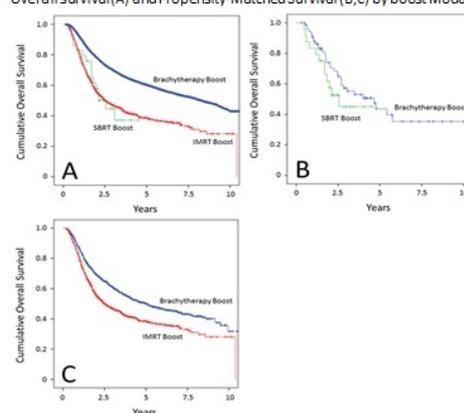

Binary Logistic Regression: Predictor of SBRT and IMRT vs Brachytherapy

Variable	Multivariable Predictor of IMRT			Multivariable Predictor of SBRT

OR = 1: More likely to receive SBRT or IMRT as compared with Brachytherapy

Of all 15,905 patients, 14,394 (90.5%) received brachytherapy, 42 (0.8%) received SBRT, and 1468 (9.2%) received IMRT. A multivariable binary logistic regression model identified the following factors associated with receipt of SBRT: advancing age, higher income status, Asian ethnicity, and FIGO Stage III cervical cancer. The following factors were associated with receipt of IMRT: advancing age, treatment at an academic/research program, treatment at an integrated network cancer program, private insurance, lower income status, FIGO Stage III, IVA, and IVB cervical cancer, positive nodal status, metastatic disease, and not receiving chemotherapy as part of the first course of treatment. Median BED was 63.7 Gy for patients treated with IMRT and 75.5 Gy for SBRT ( $p < 0.001$ ). The median follow-up was 4.8 years. Median survival was 99.1 months (95% CI: 94.4 - 103.8 months), 30.6 months (95% CI: 20.5 - 40.6 months), and 29.8 months (95% CI: 26.0 - 34.7 months) for patients who received brachytherapy, SBRT, and IMRT boost, respectively. Using propensity score matching, there was no significant difference in OS for patients who received SBRT boost vs. brachytherapy boost (HR 1.477; 95% CI 0.746 - 2.926;  $p = 0.263$ ). IMRT boost patients were also matched and did significantly worse than those who received brachytherapy boost (HR 1.455, 95% CI 1.300 - 1.628;  $p < 0.001$ ).

Overall survival (A) and Propensity-Matched Survival (B,C) by boost Modality

#### Conclusion

BED was significantly higher in patients who received SBRT compared with IMRT. Patients who receive non-brachytherapy boosts tend to have factors correlated with poor prognosis. In a propensity matched analysis, those who received SBRT had equal OS in compared with brachytherapy, but those who received IMRT had worse OS than patients who received brachytherapy boost. Prospective studies are needed to validate the use of SBRT as boost technique in selected patients who are not candidates for brachytherapy.

<sup>6</sup>University Hospital Leuven, radiotherapy and oncology, Leuven, Belgium

Leuven, Belgium

#### Purpose or Objective

Tyrosine kinase inhibitors (TKIs) targeting vascular endothelial growth factor are currently standard of care for patients with metastatic renal cell carcinoma (RCC) in first and second line. Nevertheless, durable responses are rare and most patients eventually develop progressive disease. New therapeutic approaches are needed to improve durable disease control. We studied a combination of high-dose radiotherapy and TKIs because of the immunomodulatory properties of both therapies. The primary endpoint was to determine the maximum tolerated radiotherapy doses. Secondary endpoints were local control and tumour response in non-irradiated lesions as per RECIST 1.1 or as per MD Anderson (MDA) criteria for bone lesions next to progression-free survival.

#### Material and Methods

Treatment-naïve patients with clear cell metastatic RCC, who had undergone cytoreductive treatment of their RCC at least 6 weeks prior to inclusion, were treated with a first line TKI, pazopanib, during a 1-week run-in period. Stereotactic body radiotherapy (SBRT) was delivered to the largest metastatic lesion concurrently with pazopanib administration at day 8. SBRT doses were escalated in 3

dose levels (24 Gy, 30 Gy and 36 Gy all in 3 fractions) using a time-to-event continuous reassessment method design. Pazopanib was continued post-radiotherapy as maintenance therapy until disease progression.

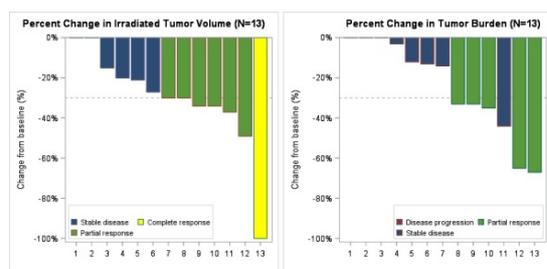

### Results

Thirteen patients were enrolled, with a median follow-up of 19 months. Their median age was 66 years, with 54% male and 46% female patients. No dose-limiting toxicities were noted at dose levels 1 or 2. Of 7 patients at dose level 3, 1 patient experienced a dose-limiting toxicity consisting of grade 4 hypoglycemia. Grade 3 to 4 pazopanib-related adverse events (AEs) occurred in 38% of patients (8%, 0%, 32% for respectively dose level 1, 2 and 3).

Table: Treatment-related adverse events

<b>AEs, grade 3-4</b>				
Hypertension	1	0	2	3

Local control was achieved in all irradiated lesions, we noted a complete local response in 1 irradiated lesion (8%), partial response in 6 irradiated lesions (46%), and stable disease in 6 irradiated lesions (46%) as best response. Mean duration of local control was 23 months (95% confidence interval 16 - 31). Assessment of responses outside the radiation field revealed that 5 of 13 patients (38 %) developed a partial response, 7 patients (54 %) had stable disease and 1 patient (8%) had progressive disease as best response. Median progression-free survival (PFS) was 6.7 months (95% confidence interval 3 - 10). Figure: Local control of irradiated lesions and distant response of non-irradiated lesions: best response

### Conclusion

SBRT in combination with pazopanib treatment is well-tolerated with long-term local control and favourable response rates outside the radiation field. Larger trials are

needed to study the impact of the combination on overall survival and PFS.

### PV-0551 PSMA PET/CT vs MRI for GTV delineation in prostate cancer: a comparison with histology

<sup>6</sup>Medical Center - University of Freiburg, Department of Radiology- Medical Physics Division, Freiburg, Germany

### Purpose or Objective

The exact delineation of the intraprostatic tumour burden is crucial for treatment planning in primary prostate cancer (PCa). We compared <sup>68</sup>Ga-HBED-CC-PSMA PET/CT with multiparametric MRI (mpMRI) for gross tumour delineation in patients with primary PCa based on slice by slice correlation with histopathological reference material.

### Material and Methods

Patients with histopathologically proven primary PCa underwent <sup>68</sup>Ga-HBED-CC-PSMA PET/CT (n=10) and MRI (n=7) followed by radical prostatectomy. Resected prostates were scanned by ex-vivo CT using a special localizer and prepared for histopathology in a customized cutting device. Invasive PCa was delineated on a HE stained histologic tissue slide and matched to ex-vivo CT to obtain gross tumor volume (GTV)-histo. Ex-vivo CT including GTV-histo and MRI data were matched to in-vivo CT(PET). Consensus contours based on MRI (GTV-MRI), PSMA PET (GTV-PET) or the combination of both (GTV-union/-intersection) were delineated. In each in-vivo CT slice the prostate was separated into 4 equal segments (total 340 segments) and sensitivity and specificity for PSMA PET and mpMRI were assessed by comparison with histological reference material. Furthermore, the spatial overlap with GTV-histo was measured. In the case of multifocal PCa (4/7 patients), SUV values (PSMA PET) and b-values (diffusion weighted MRI) were obtained for each lesion.

### Results

GTV-histo was detected in 225 of 340 segments (66%). Sensitivity and specificity for GTV-PET, GTV-MRI, GTV-union and GTV-intersection were 75% and 87%, 70% and 82%, 82% and 67%, 55% and 99%, respectively. GTV-histo had on average the highest overlap with GTV-union (57±22%), which was significantly higher than overlap with GTV-MRI (p=0.016) and GTV-PET (p=0.016), respectively. In every patient with multifocal PCa there was one lesion which had both the highest SUV and the highest b-value (mean and max), which was always the largest lesion in histology.

### Conclusion

<sup>68</sup>Ga-HBED-CC-PSMA PET/CT and mpMRI showed high sensitivity and specificity in detection of primary PCa. The combination of both methods performed even better in terms of sensitivity (GTV-union) and specificity (GTV-intersection). A good spatial overlap with GTV-histo was observed for PSMA PET/CT and mpMRI alone which was significantly improved by GTV-union. Further studies are warranted to analyse the impact of these preliminary findings for therapeutic (focal therapy) strategies in primary PCa.

**PV-0552 Urethra-sparing SBRT for prostate cancer: acute toxicity results from a randomized phase II trial**  
T. Zilli<sup>1</sup>, S. Jorcano<sup>2</sup>, S. Bral<sup>3</sup>, C. Rubio<sup>4</sup>, A. Bruynzeel<sup>5</sup>, A. Oliveira<sup>6</sup>, U. Abacioglu<sup>7</sup>, H. Minn<sup>8</sup>, Z. Symon<sup>9</sup>, R. Miralbell<sup>1,2</sup>

<sup>2</sup>Teknon Oncologic Institute, Radiation Oncology, Barcelona, Spain

<sup>3</sup>Onze-Lieve-Vrouwziekenhuis, Radiation Oncology, Aalst, Belgium

<sup>4</sup>Hospital Universitario Sancharro, Radiation Oncology, Madrid, Spain

<sup>5</sup>VU University Medical Center, Radiation-Oncology, Amsterdam, The Netherlands

<sup>6</sup>Portuguese Institut of Oncology, Radiation Oncology, Porto, Portugal

<sup>7</sup>Neolife Medical Center, Radiation Oncology, Istanbul, Turkey

<sup>8</sup>University Hospital Turku, Radiation Oncology, Turku, Finland

<sup>9</sup>Sheba Medical Center, Radiation Oncology, Ramat Gan, Israel

#### Purpose or Objective

To present the acute toxicity results from a prospective multicenter phase II randomized trial of short or protracted urethra-sparing stereotactic body radiotherapy (SBRT) for localized prostate cancer (PCa).

#### Material and Methods

From 08/2012 to 12/2015, 170 patients (pts) from nine European centers with cT1c-3a N0 M0 PCa and a low risk of nodal involvement ( $\leq 20\%$ , according to Roach et al.) were recruited and randomized according to two different overall treatment time (OTT) schedules: either 9 days (arm A, 84 pts), or 28 days, once-a-week, the same weekday (arm B, 86 pts). The prescribed dose was 36.25 Gy in 5 fractions of 7.25 Gy to the prostate  $\pm$  seminal vesicles in both arms. The prostatic urethra, with a surrounding margin of 3 mm, received a lesser dose of  $5 \times 6.5 \text{ Gy} = 32.5 \text{ Gy}$ . All patients were treated either with a VMAT or IMRT technique under stereotactic conditions using Novalis linacs and ExacTrac image-guided technology. Genitourinary (GU) and gastrointestinal (GI) toxicity (CTCAE v4.0 grading scale), IPSS, and QoL scores (EORTC QLQ-PR25) were assessed at baseline, at the 5<sup>th</sup> fraction (5fx), and 12<sup>th</sup> weeks (12W) since SBRT start.

#### Results

82 (median age 70 years) and 83 (median age 69 years) pts, respectively, from arms A and B, were retained for this analysis. Low-, intermediate-, and high-risk presentation was respectively 22%, 63%, and 15% (arm A) and 22%, 64%, and 14% (arm B). A 6-months androgen deprivation was used in 44% and 45% of the pts in arm A and B, respectively. The toxicity stopping rule of the study during the first 3-months was never activated. In both arms, Grade 1 GI toxicity increased from baseline to 5fx (from 19.5% to 38% and from 23% to 32% for arms A and B, respectively) returning back to baseline by W12 (18% for Arm A and 25% for Arm B). Only 2 cases of grade 2 GI toxicity (2.5%) were observed at 5fx in arm A. Grade 2 GU toxicity rates at baseline, 5fx, and W12 were 2%, 17%, and 11% vs. 5%, 19% and 6% in arms A and B, respectively (mainly moderate irritative and voiding symptoms). Only one grade 3 GU toxicity was observed at W12 in arm B (desobstructive TURP in a patient with a preexisting history of acute urinary retention). Median IPSS scores at the same endpoints were 6, 10, and 6 vs. 6, 10, and 7 for arms A and B, respectively, with similar IPSS-based QoL rates at baseline and W12 (80% of pts satisfied). No changes in EORTC QLQ-PR25 scores for GU, GI, and sexual domains were observed in both arms between baseline and W12.

#### Conclusion

Preliminary results of this trial demonstrate for both study arms the feasibility, tolerance, and acceptable toxicity profile of this treatment approach. Longer follow-up is needed to assess the impact of OTT and urethra-sparing on outcome, late toxicity, and QoL.

**PV-0553 Prognostic significance of Testosterone Level in prostate carcinoma patients treated with TAB and RT**

G. Ozyigit<sup>1</sup>, F. Akyol<sup>1</sup>

<sup>1</sup>Hacettepe University- Faculty of Medicine, Department of Radiation Oncology, Ankara, Turkey

#### Purpose or Objective

The aim of this study is to evaluate the prognostic significance of testosterone levels measured during total androgen blockade (TAB) in intermediate risk (IR) and high risk (HR) non-metastatic prostate adenocarcinoma patients treated with three dimensional conformal radiotherapy (3D-CRT) or intensity modulated radiation therapy (IMRT).

#### Material and Methods

The clinical data of 329 eligible T1-3N0M0 (AJCC 2010) prostate adenocarcinoma patients treated at our department between 1996-2011 with either 3D-CRT or IMRT were evaluated. The median age was 67 years. D'Amico 1998 risk classification was used, and 80 patients were in IR, as 249 patients were in HR group, respectively. The total 3D-CRT and IMRT dose was 70 Gy, 76 Gy respectively in 2 Gy daily fraction doses. All patients received TAB (combined LHRH agonist and bicalutamide), and 61% of patients were given less than 12 months of TAB. Total testosterone levels were measured in every 3 months during hormonal therapy. The castration level for testosterone was accepted as  $\leq 20 \text{ ng/dL}$  according to the European Association of Urology (EAU) criteria; and patients were categorized as castrated group (C) and non-castrated group (nC), accordingly. Log-rank test was used for univariate analyses (UVA), and Cox-regression model was used for multivariate analyses (MVA).

#### Results

Median follow-up was 9.2 years. There were no statistically significant differences between C and nC groups in terms of age, RT technique, TAB duration, risk group, Gleason score, PSA levels, T stage and RT dose. Five and 10 year overall survival (OS) rates were 97%, 91% for C group, and 90%, 75% for nC group ( $p < 0.001$ ). Five and 10 year biochemical relapse free survival rates (BRFS) were 87%, 83 % for C, and 71%, 51% for nC group ( $p < 0.001$ ). MVA revealed that testosterone level above 20 ng/dL ( $p = 0.001$ ) and Gleason score of 8-10 ( $p = 0.01$ ) were found to be independent significant poor prognostic factors in predicting OS and BRFS.

#### Conclusion

The prognostic significance of testosterone levels was previously demonstrated in metastatic prostate cancer patients receiving hormonal therapy, but not for non-metastatic patients receiving TAB and radiotherapy. In a median follow-up of 9.2 years, we found that non-castrate levels of testosterone ( $> 20 \text{ ng/dL}$ ) measured during TAB had significant detrimental effects both on overall and biochemical relapse free survival in intermediate-high risk non-metastatic prostate cancer patients. Thus, we recommend to continuously monitor testosterone levels during TAB in order to measure the efficacy of castration.

**PV-0554 Patient-reported outcomes from the phase III prostate HYPRO trial: urinary toxicity**

R.C. Wortel<sup>1</sup>, L. Incrocci<sup>1</sup>, F.J. Pos<sup>2</sup>, R.J. Smeenk<sup>3</sup>, A.D.G. Kroil<sup>4</sup>, S. Aluwini<sup>1</sup>, M.G. Witte<sup>2</sup>, B.J.M. Heijmen<sup>1</sup>, W.D. Heemsbergen<sup>2</sup>

<sup>1</sup>Erasmus MC Cancer Institute, Radiation Oncology, Rotterdam, The Netherlands

<sup>2</sup>Netherlands Cancer Institute, Radiation Oncology,

Amsterdam, The Netherlands

<sup>3</sup>Radboud University Medical Center, Radiation Oncology, Nijmegen, The Netherlands

<sup>4</sup>Leiden University Medical Center, Radiation Oncology, Leiden, The Netherlands

#### Purpose or Objective

In the Dutch phase III HYPRO trial (39x 2 Gy vs. 19x 3.4 Gy), the postulated non-inferiority of the hypofractionation arm with respect to the incidence of grade  $\geq 2$  late urinary toxicity was not shown. Moreover, a significant increase in grade  $\geq 3$  urinary toxicity was observed. In the current analysis we evaluated patient-reported urinary symptoms and possible relationships with hypofractionation and hospital of treatment.

#### Material and Methods

Patients with intermediate or high-risk prostate cancer from four hospitals applying image-guided IMRT protocols and recruiting >70 patients were analyzed, excluding patients with a baseline catheter. Long-term hormonal treatment (36 months) was prescribed to high-risk patients in hospital A-C but not in hospital D. A total of 561 patients (n=275 for standard fractionation (SF), hypofractionation (HF) n=296) with  $\geq 1$  follow-up symptom questionnaire were eligible (n=2355 total questionnaires). Treatment arm was balanced within hospitals. Local guidelines were applied for dose (in)homogeneity, margins (5-8 mm), and optimization. One hospital used MRI for prostate delineation (hospital A) and another hospital applied a rectal balloon (D). Hospital B and C varied in the applied safety margins of 5-6mm and 8mm, respectively. The study protocol did not provide dose constraints for the bladder; bladder delineation was done retrospectively. We calculated bladder and urethra dose (EQD2) with  $\alpha/\beta$  ratios of 3 Gy and 5 Gy, and analyzed incidences of urinary symptoms between 6 months and 5 year. The impact of treatment arm and hospital on late urinary toxicity endpoints was calculated in a multivariate model including time and hormonal therapy.

#### Results

Dose to structures within the target volume (urethra, base of trigone area) was 78 Gy for SF vs 82.7 Gy for HF with  $\alpha/\beta=3$  Gy, and 78 Gy for both schedules with  $\alpha/\beta=5$ . Average mean bladder dose was 29.2 Gy (SF) vs 29.9 Gy (HF) for  $\alpha/\beta=3$ , (p=0.4), and 30.2 Gy vs 29.1 Gy ( $\alpha/\beta=5$ , p=0.2), for SF vs. HF, respectively. Planned dose to the bladder varied significantly (p<0.05) between hospitals and was relatively low for hospital A and D ( $\approx 25$  Gy vs.  $\approx 33$  Gy for hospital B and C, based on  $\alpha/\beta=3$  Gy). Symptoms of incontinence, straining, and weak stream were on average significantly more reported in the HF arm during follow-up (FIG 1A-C) and varied significantly between hospitals (FIG 2A-C). Hormonal treatment was not predictive in the current models. We established that baseline levels of urinary complaints were considerable as well (FIG 1).

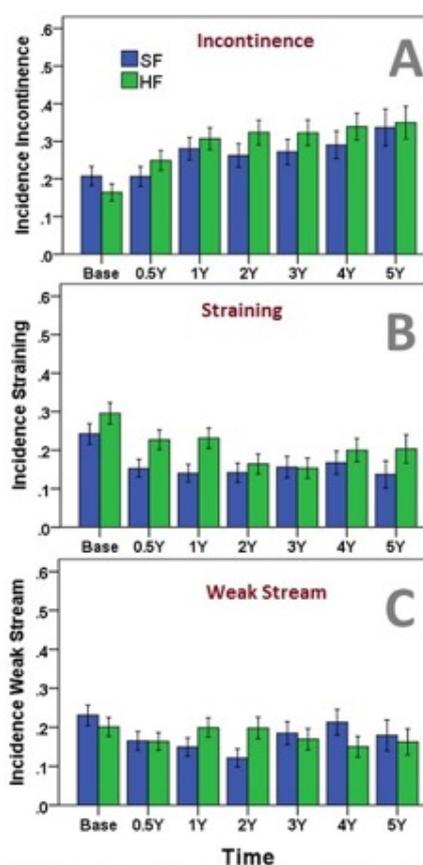

FIG 1. Incidence Urinary symptoms (1SE) per arm

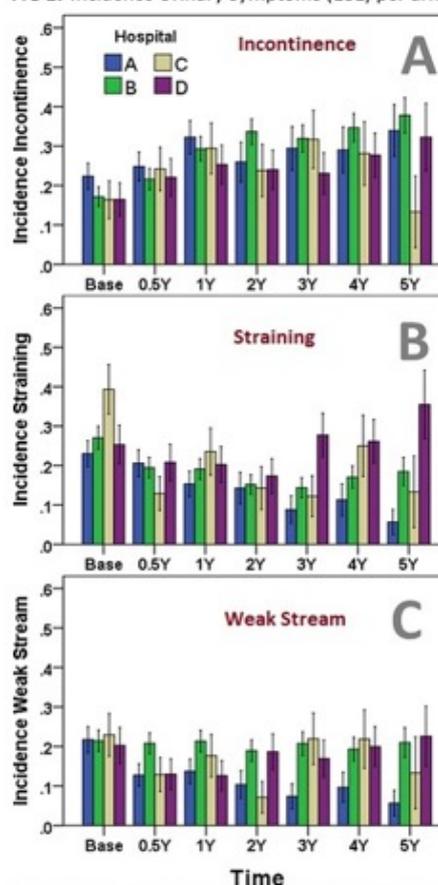

FIG 2. Incidence Urinary Symptoms (1SE) per hosp

Conclusion

We conclude that significant differences in late urinary symptoms exist between the HF and SF schedule and between hospitals. This observation needs further study since little is known about underlying mechanisms and possible dose-effect relationships.

TUESDAY, 9 MAY 2017

**Teaching Lecture: New radiotherapeutic horizons in soft tissue sarcoma treatment**

**SP-0555 New radiotherapeutic horizons in soft tissue sarcoma treatment**

R. Haas<sup>1,2</sup>

<sup>1</sup>Netherlands Cancer Institute Antoni van Leeuwenhoek Hospital, Radiotherapy, Amsterdam, The Netherlands

<sup>2</sup>Leiden University Medical Center, Radiotherapy, Leiden, The Netherlands

The field of radiotherapeutic indications and techniques is evolving. In this teaching lecture several aspects will be highlighted:

- The NCIC-SR2 trial and its implication for current daily practice.
- Balancing wound complications versus late morbidity and local relapse.
- The consequences of refraining from radiotherapy.
- Alternatives in fraction size and total dose as compared to conventional fractionation to 50 Gy.
- Combined modality regimens with conventional chemotherapy and modern targeted agents.
- The evidence for centralization of sarcoma care.

**Teaching Lecture: Clinical evidence for hypofractionation in prostate cancer what is the optimum?**

**SP-0556 Clinical evidence for hypofractionation in prostate cancer what is the optimum?**

P. Blanchard<sup>1</sup>

<sup>1</sup>Institut Gustave Roussy, Villejuif, France

Technological improvements in treatment planning and delivery allow to safely deliver high radiation doses in small volumes over a short period of time with high conformality. Hence, the pendulum of radiotherapy fractionation is moving back toward a small number of fractions. This is true for most cancer types where large prophylactic fields are not required, and especially for prostate cancer. The justification is that prostate cancer cells might be more sensitive to large doses per fraction than surrounding normal tissues, as demonstrated by their estimated low alpha/beta ratio. Multiple clinical randomized trials have evaluated the safety and efficacy of moderate hypofractionation for prostate cancer, which is now widely considered a viable alternative to conventional fractionation regardless of cancer risk group. More extreme forms of hypofractionation, such as high dose rate brachytherapy or stereotactic body radiotherapy (SBRT) are rapidly emerging as a novel treatment modality for this disease. Obviously, patient convenience and costs, which are improved with these treatments, are important aspects to take into consideration prior to administering a treatment, but efficacy and safety should always be demonstrated first. So far, clinical data for prostate SBRT suggest good short-term outcomes but follow-up remains short for a disease where patients have an extended survival after their treatment. Data on brachytherapy have more follow-up, but are limited to selected tertiary institutions. The goal of this presentation is to review the current clinical evidence for hypofractionation in prostate cancer, and to discuss appropriate regimens for routine clinical use according to patient risk group, as well as future areas of research and development.

**Teaching Lecture: Extracellular vesicles in radiation oncology**

**SP-0557 Extracellular vesicles in radiation oncology**

K. Røe Redalen<sup>1</sup>

<sup>1</sup>Norwegian University of Science and Technology, Department of Physics, Trondheim, Norway

Extracellular vesicles (EVs), once considered as cellular “garbage dumpsters”, are now recognised as important mediators of intercellular communication and key players in the transmission of signals regulating a diverse range of biological processes. Additionally, recent knowledge on the pathophysiologic roles of EVs in cancer progression highlights their potential in biomarker development as well as targets for therapeutic intervention. As determined by their biogenesis, there are three main classes of EVs: exosomes, microvesicles and apoptotic bodies. The lecture will focus on exosomes, which are the smallest EVs, ranging between 30 - 100 nm. Unlike microvesicles, which are generated by outward budding of the plasma membrane, exosomes are derived from inward budding of late endosomes released into the extracellular environment upon fusion with the plasma membrane. Several cell types can produce exosomes, including dendritic cells, B cells, T cells, mast cells, epithelial cells, and tumour cells. Although initially considered as byproducts of a pathway releasing unwanted material from cells, exosomes are now believed to perform a variety of extracellular functions involving interactions with the cellular microenvironment. For instance, it is shown that exosomes are capable of mediating matrix remodelling, and triggering tumour progression and angiogenesis via induction of proliferation and communication with the surrounding stromal tissue, as well as promoting immune escape by modulating T cell activity and horizontal transfer of genetic material (1). Importantly, several studies have also implicated exosomes as key components in the formation of pre-metastatic niches. Hence, exosomes have emerged as important constituents of the tumour microenvironment and main contributors to tumour progression and development of metastasis.

It has been shown that the exosome cargo comprises complex biological information (mRNAs, microRNAs (miRNAs), proteins, etc.) from their cells of origin (i.e., tumour cells), which is then transferred to recipient cells (2). These constituents are remarkably stable when enclosed in exosomes (3). They remain intact during sample preparation and following freezing and thawing, altogether additional reasons for why development of novel, circulating, tumour-originating cell biopsies based on exosomes isolated from biofluids, such as blood and urine, has become attractive.

With regards to their relevance in radiation oncology, recent studies have revealed that hypoxic cancer cells produce higher amounts of exosomes than their normoxic counterparts (4), and that more than half of the secreted proteome from hypoxic tumour cells are associated with exosomes (5). Furthermore, the biological content in normoxic and hypoxic cells differs, and recent evidence supports a central role for exosomes in the aggravated biology elicited by tumour hypoxia and metastasis (6). In glioblastoma multiforme, cell-derived hypoxic exosomes were found to induce angiogenesis through phenotypic modulation of endothelial cells (7). Together, these findings indicate that tumour-derived exosomes may, at least in part, mediate the hypoxic evolution of the cancer microenvironment through their transported genetic cargo. Relevant to these investigations, our research group has identified exosomal miRNAs from plasma sampled from rectal cancer patients, which at baseline were predictive of both chemoradiotherapy response and

clinical outcome. The majority of the implicated miRNAs were found to be involved in angiogenic processes, and in particular the PI3K-Akt signalling pathway.

The first part of the lecture will focus on challenges and recent recommendations for isolation and characterisation of exosomes and their cargo in preclinical models and human biofluids, while the second part will present the latest developments within exosome research relevant to radiation oncology.

#### Teaching Lecture: Update on molecular radiotherapy

---

#### SP-0558 Update on molecular radiotherapy

G. Flux<sup>1</sup>

<sup>1</sup>*The Institute of Cancer Research and The Royal Marsden NHS Foundation Trust, Department of Nuclear Medicine, Sutton, United Kingdom*

Molecular radiotherapy was first developed following a meeting 80 years ago between the clinician Saul Hertz and the physicist Karl Compton after a lunchtime symposium on 'What Physics can do for Biology and Medicine'. Radioiodine was synthesised and used to study thyroid metabolism and to treat both benign and malignant thyroid disease. In the first treatments, full dosimetry was performed by the physicist Arthur Roberts, using the best technology available at the time, 10 years before the development of the Anger camera. The use of radiotherapeutics for oncology continues to expand. In particular Ra-223, used to treat bone metastases from castration resistant prostate cancer, has now been approved in some countries. In the UK alone, treatments doubled in the year before approval. Administrations continue to be performed without imaging or patient specific dosimetry, although there are an increasing number of studies to show that this is feasible and that there exists a correlation between the absorbed doses delivered and response. A recent retrospective study of Re-186 HEDP demonstrated that survival was improved with the administration of higher activities and that the absorbed doses delivered to whole-body and to tumours correlated inversely with survival. This is due to the uptake being a marker of tumour burden, indicating the challenging potential of theragnostics. Lu-177 PSMA is being used increasingly for the treatment of bone metastases. Initial trials have shown safety and efficacy, and it is likely that its use will increase dramatically in the coming years. This follows results from the NETTER study where Lutathera was found to significantly improve PFS when compared with Sandostatin LAR (Octreotide LAR) in patients with advanced midgut neuroendocrine tumors (NETs). The treatment of liver metastases with Y-90 microspheres continues to expand. Internal dosimetry is playing a larger role for both glass and resin microspheres and a dosimetry software package has been developed by BTG for Theraspheres. Following many years of ad hoc treatment regimens, without specific international guidelines, a number of dosimetry-based clinical trials are now in progress or development, focussed on radioiodine treatment for thyroid cancer, Lu-177 DOTATATE for adult and paediatric neuroendocrine tumours, and I-131 mIBG for neuroblastoma. The European basic safety standards,

mandating dosimetry based treatments and verification for molecular radiotherapy as well as for external beam radiotherapy, are due to be enacted in February 2018. The EANM has a task force specifically addressing this issue and have recently conducted the first European survey of MRT. This has found a wide discrepancy in practice. As the treatment of cancer with radiotherapeutics is acknowledged to be a form of radiotherapy, many scientific, logistical and political challenges must be addressed. This field epitomises the need for a multidisciplinary approach to improve clinical practice for the benefit of the patient.

---

#### Teaching Lecture: Basics, implementations, applications and limitations of Monte Carlo dose calculation algorithms

---

#### SP-0559 Basics, implementations, applications and limitations of Monte Carlo dose calculation algorithms

F. Verhaegen<sup>1</sup>

<sup>1</sup>*Maastricht Radiation Oncology MAASTRO GROW - School for Oncology and Developmental Biology- University Maastricht, Maastricht, The Netherlands*

Monte Carlo (MC) simulations are potentially the most accurate and powerful techniques to calculate dose in radiotherapy, in addition to other quantities of interest, e.g. particle fluence. They are increasingly being used in treatment planning systems (TPS) for photon, electron and proton therapy. In addition, they are also increasingly encountered in preclinical research that involves precision irradiation of small animals, which nowadays use dedicated MC TPS available for radiobiology research. This lecture will cover the basics of MC particle transport: transport mechanisms, sampling from cross sections and definition of complex geometries. The advantage of track visualization and particle tagging will be demonstrated. The broad applications of MC will be discussed in modelling radiation detectors, modelling radiation sources (linear accelerators, proton beam lines, brachytherapy sources), dose calculation in cancer patients, and dose calculation in imaging panels for radiotherapy. In dose calculation in cancer patients, the subject of dose reporting as dose to water or dose to medium will be mentioned. MC simulations are also used to predict e.g. the emission of prompt gamma photons or annihilation photons in proton beams, to verify the proton range, which requires knowledge of nuclear interactions. Besides radiation dose, MC simulations can easily yield particle fluence spectra, which may be used for dose conversions, or as input for calculations of biological damage and relative biological effectiveness. Other specialized applications involve using MC for modelling precision irradiators and planning the irradiation of small animals for preclinical research. The accurate dose calculations of kV photon beams are needed to mimic human radiotherapy at the scale of small animals. Also the complex interactions of secondary electrons released in photon beams with the magnetic field inside an MR-linac, requires MC modelling for accuracy. MC dose calculations also lend themselves to modelling dynamic geometries. Limitations of MC methods are that they are still relatively slow, they exhibit statistical noise and they may express dose in unfamiliar units (dose to medium instead of dose to water).

#### Teaching Lecture: RTTs roles and responsibilities to support future practice

---

#### SP-0560 RTTs roles and responsibilities to support future practice

M. Coffey<sup>1</sup>

<sup>1</sup>Coffey Mary, Dublin, Ireland

New roles in advanced practice for RTTs In a dynamic field such as radiotherapy it is essential that all professionals are equipped to assume evolving roles and responsibilities that reflect changing practice. From a professional and clinical perspective the RTT, as an autonomous member of the team, must take equal responsibility for the introduction of change in their working environment. To enable this the ESTRO RTT committee have produced the ESTRO RTT Education Qualification Framework (EQF) for level 7 and 8. This has identified a number of key areas where advanced roles and responsibilities taken by RTTs will effectively support the dynamic clinical changes in radiotherapy preparation and delivery. On a professional level 7 and 8 will support the development of research options for practice improvement placing the RTT on an equal platform with their professional colleagues. Links to the underpinning academic topics to facilitate the development of these roles have been made. Linking academic content and evolving roles and responsibilities enables the RTT to take his/her place as an equal member of the team by providing the appropriate knowledge and skills that enable critical evaluation of practice. Defining academic components at level 7 and 8 provides a framework for staged role development combining academic components with clinical experience. The descriptions of level 7 and 8 within the ESTRO EQF are consistent with the level descriptors defined in the European Qualifications Framework. Level 7 is described as “highly specialized knowledge, some of which is at the forefront of knowledge in a field of work or study, as the basis for original thinking and/or research .... a critical awareness of knowledge issues in a field and at the interface between different fields”[1]. Level 8 is described as “knowledge at the most advanced frontier of a field of work or study and the interface between fields’ providing the skills and competences of “the most advanced and specialist skills and techniques, including synthesis and evaluation, required to solve critical problems in research and/or innovation and to extend and redefine existing knowledge or professional practice”[2]. The advanced roles include treatment planning, patient support, management and research amongst others. RTTs across Europe have already embraced many of the advanced roles and responsibilities and by providing this framework it is hoped to provide a roadmap for others to follow suit. [1] <https://ec.europa.eu/ploteus/content/descriptors-page> [2] Ibid

### Symposium: Radiotherapy in the elderly

---

#### SP-0561 Radiotherapy in elderly rectal cancer patients

R. Nout<sup>1</sup>

<sup>1</sup>Leiden University Medical Center LUMC, Department of Radiotherapy, Leiden, The Netherlands

The incidence of rectal cancer is increasing in elderly patients due to effects of population screening and aging. Total mesorectal excision (TME) surgery with or without pre-operative radio(chemo)therapy is the standard treatment for rectal cancer. However, with increasing age and co-morbidity the risk of surgical complications and post-operative mortality rises. In patients older than 75 years, and especially above 80, postoperative complications occur in approximately 50% and postoperative mortality is increased. In these situations, the risks of postoperative complications and mortality may render patients unfit for surgery. For the same reasons these patients are usually also unfit for chemotherapy,

and often they are offered palliative radiotherapy. Although palliative radiotherapy is effective in symptom reduction in most patients, the duration of benefit is limited. Importantly, there are situations that patients might benefit from a more radical approach using radiotherapy alone, with the aim to provide durable local control. With standard external beam (chemo)radiotherapy (EBRT, 45-50 Gy), complete pathologic response (pCR) is reached in approximately 16%. But dose response analyses indicate that a high dose of more than 90Gy (EQD2) is needed to achieve pCR in 50% of patients. EBRT with either contact-X-ray or endorectal high-dose-rate brachytherapy have been used in these situations. Outcomes of these approaches for local control and toxicity will be reviewed followed by an update of ongoing studies.

#### SP-0562 Breast cancer

I. Kunkler<sup>1</sup>

<sup>1</sup>Western General Hospital- Edinburgh Cancer Centre, Edinburgh, United Kingdom

The evidence base for postoperative radiotherapy after mastectomy and after breast conserving surgery (BCS) and for accelerated partial breast irradiation (ABPI) is limited in older patients. This reflects in part historical exclusion of patients >70 years from many trials or trials which included but were not confined to older patients. The Oxford overview (1) shows that postmastectomy radiotherapy (PMRT) reduces local recurrence and breast cancer mortality in women with 1-3 positive nodes as well as 4 or more positive nodes. However the role of PMRT in women with 1-3 involved nodes remains controversial. The current MRC/EORTC SUPREMO trial and its translational substudy TRANS-SUPREMO (2) is addressing this issue and has no upper age limit. There is a need to refine the selection of patients for PMRT on a biological basis with the aid of molecular markers (3). There is consensus that shorter, hypofractionated schedules of whole breast RT (WBRT) in 15 or 16 fractions are appropriate for older patients. Recent 20 year follow up of the EORTC ‘boost’ trial shows no statistically significant advantage in local control from the addition of a 16 Gy boost to the site of excision after WBRT (4) in women over the age of 60. There is a developing level 1 evidence base to suggest that omitting postoperative WBRT in ‘low risk’ older patients after BCS is an option but the issue remains controversial. The CALGB 9343 trial in T1,NO women =>70 yrs showed a 3% reduction in loco-regional recurrence at 5 years (1% vs 4%) and 7% at 10.5 years (2% vs 9%)[5,6]. However, while the early results changed NCCN guidelines to allow the omission of WBRT in patients meeting the eligibility for the CALGB trial, international practice has not changed substantially with WBRT remaining standard, irrespective of risk category. The recent PRIME 11 trial in a higher risk of group of patients =>65 years (T1-2 [up to 3cm],NO) showed a modest but statistically significant reduction in ipsilateral breast tumour recurrence from WBRT after BCS at a median follow up of 5 years (1.3% vs 4.1%) [7]. Whether this difference is sufficiently small to change practice remains to be seen. Current studies such as PRIME-TIME (8) in the UK and PRECISION (9) in the US focus on assessing the role of biomarkers to refine the selection of ‘low risk’ patients for omission of postoperative radiotherapy after BCS in older patients. None of the four published trials on ABPI to date, using a variety of techniques (brachytherapy, external beam, intraoperative irradiation) were confined to older patients, allowing limited conclusions in this age group.

#### SP-0563 Radiotherapy in older patients with GBM

G. Minniti<sup>1</sup>

<sup>1</sup>Azienda Ospedaliera Sant' Andrea, UOC Radioterapia, Rome, Italy

The incidence of glioblastoma in the elderly population has increased over the last few decades. Current treatment includes surgery, radiotherapy (RT) and chemotherapy, but the optimal management of disease remains a matter of debate. RT remains an effective treatment in elderly patients with GBM and either standard RT or hypofractionated RT are associated with longer survival than supportive care only. Randomized studies comparing standard RT versus hypofractionated radiation schedules show similar survival benefits, although short-courses RT are associated with a better safety profile. Hypofractionated RT should be chosen in older patients with newly diagnosed GBM, especially in those with poor performance status or older than 70 years old. Temozolomide (TMZ) is a safe and effective treatment option alternative to RT. Recent randomized studies indicate that chemotherapy with the alkylating agent temozolomide is a safe and effective therapeutic option in patients of 60 years or older with newly diagnosed glioblastoma. Decisions regarding the choice between RT and TMZ chemotherapy should be based on the assessment of O6-Methylguanine-DNA methyltransferase (MGMT) promoter gene. Patients with MGMT methylated tumors receive the most significant survival benefit from treatment with TMZ; by contrast, chemotherapy produces no benefit in patients with MGMT unmethylated tumors, suggesting that RT is a better option in these patients. Few studies have reported survival benefit in elderly patients treated with a combination of standard RT with concomitant and adjuvant TMZ. Although this may represent a feasible therapeutic approach in selected patients of 60-70 years old with good performance status, the potential toxicity of standard RT and chemotherapy for large irradiated brain volumes, and the modest survival

advantages in this age group as compared with younger patients, do not support the use of aggressive treatments in the majority of elderly patients. An abbreviated course of RT plus TMZ may represent a feasible treatment associated with similar survival benefit and improved quality of life. Results from an EORTC large randomized study comparing a short course of RT (40 Gy in 15 daily fractions) with or without concomitant and adjuvant TMZ in elderly patients older than 65 years old with newly diagnosed GBM indicate that RT+TMZ is a safe and effective treatment in older GBM patients. Currently, several questions regarding the risks and benefit of combined chemoradiation remains unanswered.

#### SP-0564 Lung

J. Van Loon<sup>1</sup>

<sup>1</sup>MAASTRO Clinic, Maastricht, The Netherlands

Lung cancer is a problem of the elderly: 30% of the lung cancer patients are older than 75 years. Due to underrepresentation of elderly patients in clinical trials there is a lack of evidence to select the optimal treatment strategy. For the subgroup of elderly presenting with stage I peripheral lung cancer, stereotactic radiotherapy has shown to be an effective and well tolerated treatment option. For the other patients with stage I or II disease, fractionated radiotherapy is generally offered for elderly that are considered inoperable.

With respect to the 35% of elderly patients with stage III disease, pulmonologists and radiation oncologists are faced with the challenge to judge which treatment option would be best for each individual patient. Although concurrent radiochemotherapy (RCHT) is the standard treatment for stage III disease, evidence for this treatment was gained in clinical trials that mostly excluded elderly patients.<sup>1</sup> Furthermore, the survival gain obtained with combined RCHT comes with a significant increase in toxicity. The lack of evidence on the optimal treatment strategy in elderly stage III NSCLC patients contributes to the difference between treatment guidelines and the treatment offered in routine clinical practice.

Subgroup analyses of the limited number of elderly stage III NSCLC patients included in clinical trials indicate that fit elderly patients may benefit from intensified treatment such as concurrent RCHT, but their value is limited due to a restricted number of patients and potential selection bias. Data on the influence of age on treatment induced toxicity are conflicting. A recent retrospective study reflecting current clinical practice showed that despite the fact that relatively fit and younger elderly were assigned to concurrent RCHT, tolerance was worse and OS was not significantly better compared to sequential RCHT<sup>2</sup>. Since limited information on geriatric characteristics was available in this retrospective study, prospective studies including geriatric assessments are urgently needed to gather evidence on treatment options, quality of life and survival. Different geriatric assessments have been developed to discern frail, vulnerable and fit elderly patients that may help in the selection of the most appropriate treatment<sup>3,4</sup>, but these have not been validated for RCHT in elderly lung cancer patients, are time consuming and difficult to implement in routine oncology practice.

These issues are largely addressed in the multicentre prospective randomized NVALT25-ELDAPT trial (NCT02284308), which has recently started in the Netherlands, focusing on treatment options for unselected stage III NSCLC patients ≥ 75 years. This trial aims to incorporate geriatric assessment strategies to guide treatment selection, build evidence on the treatment resulting in the most optimal balance between QoL and survival, and develop a short and clinically applicable geriatric screening instrument to implement in future lung cancer care. The results of ELDAPT can

facilitate treatment decision making in the elderly since patient preferences and capacities can be collected more precisely and interpreted in the light of a geriatric view.<sup>5,6</sup>

**Symposium with Proffered Papers: Selection of patients and radiotherapy technique for APBI in the light of new phase III trial data**

---

**SP-0565 Target coverage and dose to organs at risk using different techniques of APBI (EBI, IORT, BT)**

L. Marrazzo<sup>1</sup>

<sup>1</sup>Azienda Ospedaliera Universitaria Careggi, Medical Radiation Physics, Firenze, Italy

The evidence that most breast cancer local recurrences develop in close proximity to tumour bed paved the way to the introduction of APBI, an approach in which only the lumpectomy bed plus a 1-2 cm margin is treated, rather than the whole breast. Because of the small volume of irradiation, a higher dose can be delivered in a shorter period of time. Various approaches have been proposed for APBI: multi-catheter interstitial or balloon catheter brachytherapy (BT), intraoperative radiation therapy (IORT) and external beam irradiation (EBI). These techniques are intrinsically different in terms of both radiation delivery and obtainable dose distributions thus leading to different target coverage, dose conformity, and OARs sparing. A number of papers aims at exploring the differences between APBI planning with different techniques. Starting from these comparison studies, we'll go through the main differences between the treatment modalities, trying to identify subgroups of patients who would benefit from a specific approach and to see whether different results are due not only to the technique that was used but also the way it was implemented (e.g. use of non-coplanar beams, partial arcs, blocked regions). In BT no margin is applied around the CTV, which allows reducing the breast normal tissue irradiated with high doses, which seems to correlate with some adverse cosmetic effects. Moreover BT can provide highly conformal dose distribution and steep dose gradients, which allow optimal sparing of critical structures. Nevertheless, due to the shape of the dose distribution, the OARs sparing is strongly dependent on the location of the PTV. IORT could minimize some potential side effects since skin and the subcutaneous tissue can be displaced during radiation delivery. The dose distribution is characterized by a sharp dose fall-off but possibilities to shape the dose distribution are very limited. EBI is attractive since no specific manual

skills are required. Several strategies have been used: 3D conformal radiotherapy (3D-CRT), static field intensity modulated radiation therapy (IMRT), volume modulated arc therapy (VMAT), helical Tomotherapy and proton therapy. At the current state, the chosen approach mostly depends on the technical availability. A general result is that intensity modulation techniques are characterized by a better dose conformity when compared to 3DCRT. Non-coplanar beams may be used to reduce the proportion of ipsilateral breast receiving high doses. Proton beams generally show the best performances, allowing the smallest volume of ipsilateral breast to be exposed to low dose, even though scattered beam techniques may be associated to higher skin doses. Not only the planning technique, but also the delivery could affect the dose to OARs:

- image guidance could allow for margin reduction thus further reducing dose to uninvolved breast;
  - left sided lesion could benefit from using a deep inspiration breath-hold technique, which reduces heart dose;
  - real-time tracking could allow further margin reduction.
- Currently, we are far from being able to understand whether the dosimetric differences between the different treatment techniques are clinically relevant.

**SP-0566 External beam partial breast irradiation: changing patient selection based on current evidence**  
J. Meattini<sup>1</sup>

<sup>1</sup>Azienda Ospedaliera Universitaria Careggi - University of Florence, Radiation Oncology Unit - Oncology Department, Florence, Italy

Accelerated partial breast irradiation (APBI) has been introduced as an alternative treatment method for patients with early stage breast cancer (BC). APBI advantages includes shorter treatment time, decreased volume in the breast tissue treated, and cost reduction compared with the standard whole breast irradiation (WBI). The concept of APBI was introduced basing on the results of several large prospective randomized trials comparing postoperative WBI and exclusive surgery, that evidenced the majority of recurrences for patients who did not receive radiation at or in the region of the surgical cavity. The first 5-year results of the IMPORT-LOW trial were presented at the European Breast Cancer Conference (EBCC) 2016 and showed non-inferiority of PBI when compared to WBI in women with low risk early BC, with a 5-year local recurrence (LR) rate of 0.5%. The role of APBI has been investigated in large-scale prospective phase 3 clinical trials using different techniques. Main published results showed conflicting results in terms of local control of disease, while demonstrated equivalent impact in terms of survival when compared with WBI. The Cochrane Database Systematic Review on PBI for early BC published in 2016 showed an increased LR rate with PBI/APBI (small difference), but no evidence of detriment to other oncological outcomes (overall survival, distant metastases). Published data evidenced the crucial role of patient's selection in clinical outcome. Two trials have reported results of intra-operative radiotherapy (IORT) compared to WBI: the TARGIT-A trial, and the ELIOT trial. In both cases a significant higher rate of LR was observed using APBI, mainly due to high-risk BC patient's selection for treatment. Conversely, the GEC-ESTRO and the Florence trials, enrolling low risk early BC, obtained an equivalent local control. To note, patient's population of the Florence trial had a high proportion of luminal-A patients (79% in the APBI, and 73% in the WBI arm) compared to the ELIOT trial (40% and 37% in the IORT and WBI arm, respectively). In the ELIOT trial, the 5-year risk of LR was substantially higher in selected subgroups of patients including those with grade 3 tumors (15.6%), ER-negative disease (14.4%), and triple-negative BC (18.1%). The Florence trial, using a 30 Gy in 5 fractions with IMRT

technique, showed an equivalent 1.5% rate of LR at a median 5-year follow-up time. Also age could play an important role in a multifactorial patient's selection; the recently published subgroup analysis of the Florence trial concerning patients aged 70 years or older, showed an IBTR rate at 5 years of 1.9%, and significantly better results in terms of acute skin toxicity, in favor of APBI arm. Therefore, tumor biology seems to play a crucial role on patient's selection; treatment decisions should always consider disease stage, comorbidities, and tumor biomarkers. Longer follow-up of recently presented studies with appropriately selected patients will be critical to define the rates of local control, survival, and long-term toxicity before APBI could be accepted as a standard alternative to conventional WBI. Outcome results from ongoing unpublished prospective trials (e. g. RAPID, IRMA, SHARE, NSABP B-39/RTOG 0413 trials) are awaited.

**SP-0567 Partial breast irradiation with brachytherapy: changing patient selection based on current evidence**  
C. Polgár<sup>1</sup>

<sup>1</sup>National Institute of Oncology, Center of Radiotherapy, Budapest, Hungary

In the last decades accelerated partial breast irradiation (APBI) has been intensively evaluated in prospective phase II and III clinical trials as a possible alternative to whole breast irradiation (WBI). Majority of these trials - using conservative patient selection criteria and proper treatment technique - were successful in yielding an annual local recurrence rate in the range of 0 to 1%. The 10-year results of the Hungarian phase III trial and more recently the 5-year results of the GEC-ESTRO phase III trial also demonstrated non-inferiority of APBI with interstitial brachytherapy compared to WBI. Despite variability in selection criteria, the majority of women treated within these trials were >40 years old, presented with node negative invasive ductal carcinomas up to 3 cm, without extensive intraductal component (EIC), and resected with clear margins. Based on available experience international guidelines have been published by the American Brachytherapy Society (ABS), the American Society for Therapeutic Radiology and Oncology (ASTRO), and the GEC-ESTRO (Table 1.)

Table 1. International guidelines for APBI patient selection

Criterion	ABS	ASTRO	ESTRO
Age (years)	≥ 50	> 50	> 50
Tumor size (cm)	≤ 3	≤ 2 (DCIS ≤ 3)	≤ 3
Histology	All invasive subtypes and DCIS	Invasive ca. (excl. ILC) or low-risk DCIS	Invasive ca. (excl. ILC)
Margin status	Negative	Clear margin ≥ 2 mm	Clear margin ≥ 2 mm
ER status	Any	Positive	Any
LVI	Not allowed	Not allowed	Not allowed
Nodal status	pN0	pN0	pN0

DCIS: ductal carcinoma in situ; IDC: invasive ductal carcinoma; ILC: invasive lobular carcinoma; ER: estrogen receptor; LVI: lymphovascular invasion.

However controversy exists regarding the possible extension of selection criteria including patients younger than 50 years, women with invasive lobular carcinomas or DCIS, or patients with clear but close (< 2 mm) surgical margins. Ongoing clinical research actually focuses on better definition of candidates for APBI. As data from ongoing phase III trials mature, guidelines for patient selection should be revised and might be extended. However until additional long-term outcome reports of phase III trials are available, conservative patient selection criteria (as defined by the GEC-ESTRO and ASTRO) should be considered for selecting candidates for APBI.

**OC-0568 Accelerated PBI VS standard radiotherapy (IRMA trial): interim cosmetic and toxicity results**

<sup>6</sup>Università di Modena e Reggio Emilia, Department of Medical Statistic, Modena, Italy

<sup>7</sup>Radboud University Medical Center, Department of Radiation Oncology, The Netherlands, The Netherlands

**Purpose or Objective**

To report interim cosmetic and toxicity results in patients (pts) enrolled from 5 Italian centers in the randomized IRMA trial.

**Material and Methods**

Women age ≥ 49 years with invasive breast cancer < 3 cm, pN0-1, were randomly assigned after breast-conserving surgery to 3D-CRT APBI (38.5 Gy in 10 fractions twice daily) or WBI (50 Gy in 25 daily fractions ± boost). Pts received adjuvant systemic therapy according to institutional guidelines. Cosmesis was assessed according to IRMA protocol parameters. Toxicity was scored according to RTOG tables.

**Results**

From March 2007 to December 2013, 983 pts were enrolled in IRMA from 5 Italian centers (425 Bologna Bellaria, 240 Modena, 163 Reggio Emilia, 101 Bologna S.Orsola, 54 S.Giovanni Rotondo). Median follow-up was 5 years. No difference was observed in adverse cosmesis (fair and poor) among pts treated with APBI compared with WBI as assessed by physicians (20% vs 21.8% 1 year, 20% vs 19% 3 years) and by patients (14% vs 16% 1 years, 14% vs 14% 3 years). G3 acute skin toxicity was rare in both treatment arms (0% PBI vs 1.4% WBI), no further G3-4 acute toxicities were observed. G3-4 late skin toxicity was 0.42% (APBI) vs 0.79% (WBI) (p=0.4); G3-4 late subcutaneous tissue toxicity was 1.5% (APBI) vs 1.2% (WBI) (p=0.7); 2 rib fractures were observed in PBI patients; no further G3-4 late toxicities were observed. Axillary dissection (vs sentinel node) correlated with G3-4 late subcutaneous tissue toxicity (3.7% vs 0.9%, p<0.01); no correlation of toxicity with adjuvant chemotherapy was observed.

**Conclusion**

APBI with 3D-CRT resulted in similar acute and late toxicity and good/excellent cosmetic results compared with standard WBI. Additional follow-up is needed to confirm these results.

**OC-0569 Comparison of clinical outcome of APBI by interstitial brachytherapy as per ESTRO & ASTRO guidelines**

T. Telkhade<sup>1</sup>, T. Wadasadawala<sup>1</sup>, R. Upereti<sup>2</sup>, R. Sarin<sup>1</sup>, R. Jalali<sup>1</sup>, R. Badwe<sup>3</sup>, V. Parmar<sup>3</sup>, S. Gupta<sup>4</sup>, A. Budrukkar<sup>1</sup>

<sup>1</sup>Tata Memorial Hospital, Radiation oncology, Mumbai, India

<sup>2</sup>Tata Memorial Hospital, Medical Physics, Mumbai, India

<sup>3</sup>Tata Memorial Hospital, Surgical oncology, Mumbai, India

<sup>4</sup>Tata Memorial Hospital, Medical oncology, Mumbai, India

**Purpose or Objective**

Lack of consistency in recommendations given by ASTRO and ESTRO for accelerated partial breast irradiation (APBI)

with respect to clinicopathological criteria poses a dilemma for patient selection. The purpose of this study is to analyze clinical outcomes of patients treated with APBI using multi-catheter interstitial brachytherapy (MIB-APBI) stratified as per GEC-ESTRO and ASTRO guidelines for patient selection and to correlate and analyze appropriateness of these criteria for grouping patients to predict clinical outcomes.

#### Material and Methods

Two hundred and forty two women underwent MIB-APBI during July 2000- March 2013. Comparison of patient selection criteria as per GEC-ESTRO and ASTRO guidelines and their clinical outcomes was done on a prospectively maintained database. Median age was 56 years, and median pathological tumor size was 2 cm. ER, PR and HER 2 receptor positivity was seen 58.3%, 53.7% and 10.7% patients respectively. Median number of planes was 3 and median dose of APBI was 34 Gy. Kaplan Meier survival analysis was done for local control (LC), disease free survival (DFS), cause specific survival (CSS) and overall survival (OS) after sub grouping as per both GEC-ESTRO and ASTRO consensus guidelines.

#### Results

As per analyses with ASTRO consensus for patient selection, our cohort consisted of 32 (13.2%), 143 (59.1%) and 67(27.7%) patients belonging to suitable, cautionary and unsuitable group, respectively. According to ESTRO guidelines, 148(61.2%), 54(22.3%) and 40 (16.5%) patients were categorized as low, intermediate and high risk group, respectively. At a median follow up of 90 months, 7 year overall LC, DFS, CSS and OS were 94.3%, 88%, 97% and 92.2% respectively for the entire group. There was no statistically significant difference in the LC rates for both ASTRO and ESTRO consensus groups (Table 1). Thirty five patients (14%) had disease failure out of which 12 patients failed loco-regionally. The DFS ( $p=0.008$ ), CSS ( $p=0.004$ ) and OS ( $p=0.007$ ) rates were significantly correlated with GEC-ESTRO consensus guidelines for patient selection while none of our outcomes correlated with ASTRO consensus guidelines. Variable cut off for age, tumor size and weightage for presence of lymphovascular emboli in these two guidelines mainly led to differences in the distribution of risk stratification.

Outcome	GEC-ESTRO guideline			P value	ASTRO guideline			P value
	Low	Intermediate	High		Suitable	cautionary	unsuitable	
<b>Local control</b>								
5 years	97%	94%	97%	0.91	96%	95%	96%	0.67
7 years	94%	94%	97%		85%	95%	96%	
<b>Disease free survival</b>								
5 years	94%	90%	87%	0.008	97%	91%	92%	0.97
7 years	90%	90%	78%		82%	89%	89%	
<b>Cause specific survival</b>								
5 years	99%	98%	92%	0.004	100%	98%	95%	0.57
7 years	98%	98%	87%		100%	97%	95%	
<b>Overall survival</b>								
5 years	98%	98%	86%	0.007	100%	98%	91%	0.76
7 years	96%	98%	82%		100%	94%	91%	

#### Conclusion

Patient selection as per both ESTRO and ASTRO consensus guidelines do not have any impact on local control rates for patients treated with APBI using interstitial brachytherapy at long term follow up.

#### Symposium with Proffered Papers: Novel approaches in poor tumour control sites

##### SP-0570 Radiopharmaceuticals in pancreatic cancer: imaging and therapy

B. Cornelissen<sup>1</sup>

<sup>1</sup>University of Oxford- CRUK/MRC Oxford Institute for Radiation Oncology, Radiopharmaceuticals and Molecular Imaging Group, Oxford, United Kingdom

The potential of nuclear medicine imaging and therapy will be discussed, with a focus on pancreatic cancer.

Pancreas cancer patients, most of which present with late stage therapy-resistant pancreatic ductal adenocarcinoma (PDAC), still have a very poor prognosis. A mere five percent will survive for five years after being diagnosed. Throughout all stages of pancreatic cancer, from oncogenesis to treatment follow-up, using radiopharmaceuticals with PET or SPECT imaging can have significant impact on the management of pancreatic cancer patients. An overview of PET and SPECT imaging techniques will be presented, combining reports from the literature with our own recent work. Some are already in clinical use; some very novel agents have shown promise in the preclinical stage. A small segment will be dedicated to the use of therapeutic radiopharmaceuticals.

##### SP-0571 State of the art precision medicine for benign and malignant brain tumours

G. Zadeh<sup>1</sup>

<sup>1</sup>University Health Network, Toronto, Canada

Abstract not received

##### SP-0572 Circulating tumour DNA, a new tool for the early detection of poor outcome

F.C. Bidard<sup>1</sup>

<sup>1</sup>Institut Curie, Paris Cedex 05, France

Owing to the development of techniques that can detect rare variants, circulating tumor DNA is now approved or under investigation as a circulating tumor biomarker for several applications in clinical oncology. ctDNA can be used as "liquid biopsy", surrogate to tissue biopsy (such as in e.g. NSCLC for *EGFR* mutation detection), but is also investigated as a dynamic marker of tumor load which may be relevant for early detection of relapse or resistance to therapy.

This presentation will focus on how ctDNA can be used to detect early relapse/resistance, with examples from studies initiated by our group:

- *TP53* mutation detection: results obtained in locally advanced triple negative breast cancer (Riva *et al.*, in press) and ongoing "CirCA-01" study testing the early detection of relapse and new tumor growth in BRCA01 mutation carriers (NCT02608346)

- HPV detection: results obtained in metastatic patients and ongoing "CirCA-HPV" study testing the early detection of relapse in cervix and anal canal cancers

- *ESR1* mutation detection: ongoing PADA-1 phase III trial testing the utility of *ESR1* mutation detection in metastatic HR+ breast cancer

##### OC-0573 Development of hypoxia gene signatures as biomarkers for treatment stratification

C. West<sup>1</sup>, L. Yang<sup>1</sup>, D. Roberts<sup>1</sup>, B. Bibby<sup>1</sup>, L. Forker<sup>1</sup>, S. Haider<sup>2</sup>, F. Buffa<sup>2</sup>, A. Choudhury<sup>3</sup>

<sup>1</sup>The University of Manchester, Translational Radiobiology Group, Manchester, United Kingdom

<sup>2</sup>University of Oxford, Computational Biology and Integrative Genomics, Oxford, United Kingdom

<sup>3</sup>Christie Hospital NHS Trust, Clinical Oncology, Manchester, United Kingdom

#### Purpose or Objective

A promising area for the development of biomarkers for radiotherapy stratification is gene expression profiling to predict benefit from hypoxia modification. Advantages of RNA signatures versus other approaches are their good repeatability and ability to minimise intra-tumour variability. The rationale for focusing on hypoxia is that interventions are available with proven benefit when added to radiotherapy. This work investigated the transferability of published signatures across tumour types and the benefit of deriving tumour specific profiles.

### Material and Methods

Work focused on bladder and prostate cancers and soft tissue sarcoma. Published hypoxia signatures were tested by analysing transcriptomic data from public databases. Tumour samples were available from the BCON phase III trial that randomised bladder cancer patients to radiotherapy alone or with carbogen and nicotinamide (CON). Gene expression was analysed in 152 BCON tumours using Affymetrix Human 1.0 Exon arrays and used for independent validation.

### Results

Published signatures performed inconsistently and tended to do worse in bladder than prostate and sarcoma. A bladder-specific signature was derived, which was prognostic in an independent surgical cohort (n=408, p=0.00274) and in BCON patients receiving radiotherapy alone (n=75, hazard ratio [HR] for overall survival 2.80, 95% CI 1.48-5.32, p=0.0016). The signature also predicted benefit from CON (n=76, HR 0.47, 95% CI 0.26-0.84, p=0.011). Prognostic and predictive significance remained after adjusting for clinicopathological variables. A sarcoma signature was derived that was prognostic in independent Affymetrix Plus2 (n=127; HR=3.44, 95% CI 1.73-6.84; p<0.001) and The Cancer Genome Atlas (TCGA) RNAseq (n=246; HR=2.63, 95% CI 1.67-4.14; p<0.001) validation cohorts. A prostate signature was prognostic in TCGA (n=491; p<0.001) and an FFPE RNAseq (n=102; p=0.014) validation cohorts. The prostate signature was prognostic in the BCON radiotherapy arm (n=75; p=0.049) and predicted benefit from addition of CON to radiotherapy (p=0.019).

### Conclusion

Tumour-type specific signatures outperform those derived in other tumour types. Biomarker driven trials are now required to test these signatures in a prospective setting.

---

### Symposium: 4D imaging and tracked delivery

---

#### SP-0574 MLC tracking: from bench to bedside

M. Fast<sup>1</sup>

<sup>1</sup>The Institute of Cancer Research and The Royal Marsden NHS Foundation Trust, Joint Department of Physics, London, United Kingdom

Dynamic multi-leaf collimator tracking is an emerging form of real-time adaptive radiotherapy in which the treatment beam is continuously reshaped according to the target motion in beam's-eye-view. By following the regular or erratic motion of the treatment target, MLC tracking ensures its dosimetric coverage. Prominent examples for intra-fractional anatomy variations are respiration and gastrointestinal motion. Through better beam-target alignment and subsequent margin reductions, MLC tracking is utilized to reduce the size of the target volume. The reduction of dose to adjacent healthy tissue in combination with complete target coverage is especially relevant for highly conformal, hypofractionated treatment protocols.

MLC tracking was first suggested in 2001 [1]. Since then, MLC tracking has been demonstrated on linac platforms of all major radiotherapy vendors: Elekta, Siemens and Varian. Initially, the feasibility of MLC tracking was established in phantom experiments and treatment planning studies. Recently, first clinical implementation trials have started in Sydney, Australia, designed to demonstrate the safety and efficacy of tracked treatment deliveries for prostate and lung cancer patients [2]. This presentation will give a brief summary of past research activities and derive conclusions with regards to clinical implementation.

One crucial consideration when translating MLC tracking from the laboratory 'bench' to the clinical 'bedside' is quality assurance. Traditional delivery QA approximates

the patient as a static object and relies on the planned sequence of delivery control points. For MLC tracking, these approximations are too simplistic. Crucially, the interplay of patient and MLC motion is not known a-priori. A task group (TG 264) assembled by the American Association of Physicists in Medicine (AAPM) is currently developing guidelines on the "Safe clinical implementation of MLC tracking in radiotherapy". At the same time, novel online QA tools are being developed in order to accumulate dose in real-time during each treatment fraction with the same dosimetric precision achieved in clinical treatment planning systems [3]. This presentation will summarise tracking QA requirements and give preliminary recommendations for clinical implementation.

The efficacy of MLC tracking is limited by the spatial and temporal resolution of the target localisation modality, system lag times, and the mechanical performance of the MLC. Current target localisation strategies rely on x-ray imaging, often in combination with implanted radiopaque markers, or implanted resonant circuits and their detection with an electromagnetic antenna array. Less invasive and non-ionizing target localisation relying on soft tissue contrast, namely ultrasound imaging and MRI, are increasingly being investigated as drivers for MLC tracking deliveries. For tracked deliveries in the presence of a strong magnetic field, the electron-return effect could potentially introduce an additional challenge for the safe delivery of treatment. A recent treatment planning study, however, has confirmed the efficacy of MLC tracking on the Elekta MR-linac prototype [4]. The suitability of the treatment plan for MLC tracking is another important area of investigation. As an example, this presentation will provide a simple template for creating a treatment plan suitable for a tracked lung SBRT delivery.

#### SP-0575 Motions models and tracking using MR

R. Tijssen<sup>1</sup>

<sup>1</sup>UMC Utrecht, Department of Radiation Oncology, Utrecht, The Netherlands

Image guidance plays an important role in modern radiotherapy. Current x-ray based onboard imaging, however, has poor soft-tissue contrast, which challenges image guidance of mobile tumors. Particularly in abdominal regions, tumor visualization is virtually impossible on clinical CBCT images. By utilizing Magnetic Resonance Imaging (MRI) for radiation guidance, tumor and organs-at-risks (OAR) can be directly visualized and targeting can be improved. This has been the philosophy behind the development of the MRI-Linac (MRL). An MRI based workflow has the potential to shape the radiotherapy paradigm of the future: an online adaptive treatment in which positional uncertainties are mitigated and the deposited dose can be tracked in real-time making dose escalation possible while sparing healthy tissue.

In order to facilitate this new paradigm, fast MRI acquisition and processing methods are needed that accurately map the motion within the entire irradiated volume with sufficient temporal and spatial resolution.

Respiratory motion models compliment real-time imaging in two ways: 1) motion prediction models overcome the inherent latency in tracked delivery associated with the real-time feedback loop, and 2) motion estimation models alleviate the need for full 3D coverage at each time-point thus allowing dose deposition mapping in both the tumor and surrounding organs at risk. The efficacy of motion modelling relies on the available information (input) and the redundancy in the data (dimensionality reduction). Optimal results are therefore only achieved when both the acquisition strategy and motion modeling are matched. In this talk I will go through the basic requirements of an online MR-guided workflow and discuss the use of respiratory motion models for 1) tumor tracking, and 2) dose accumulation mapping. An outlook is then given, in which the foreseen advances in imaging speed are discussed and the role of motion models in the future.

**SP-0576 Tracking: present status and what to expect in the near future**

T. Ravkilde<sup>1</sup>

<sup>1</sup>Aarhus University Hospital, Medical Physics- Department of Oncology, Aarhus, Denmark

In recent years there has been a growing trend towards hypofractionation in radiation therapy. The recent surge of interest in stereotactic body radiation therapy is yet another stone on this path. With these treatment schemes large radiation doses are delivered in few fractions, making the correct delivery of every treatment fraction critical. Unfortunately, many sites in the thorax, abdomen and pelvis are subject to motion, which can significantly deteriorate the highly conformal dose distributions typical of today's standard of care. One way to restore dose conformity is by adjusting the radiation delivery to the moving anatomy on-the-fly; so-called tumour tracking. Tumour tracking was originally proposed more than 15 years ago and has been heavily investigated since, yet is very sparsely available in clinics worldwide. While dedicated machines are now commercially available, tracking on the ubiquitous standard C-arm linear accelerators is still lacking. Despite a large body of research publications and many convincing results in phantom experiments at multiple institutions tumour tracking has proven difficult to push into the clinic, with very few clinical trials existing.

Unfortunately, tumour tracking inherently presents a problem for existing pre-treatment plan-specific QA regimes as parameters of the treatment machine is continuously adjusted during beam delivery of each treatment fraction and thus cannot be known beforehand. This has shown to be a concern for many physicians and physicists with regards to the clinical introduction of tumour tracking.

This presentation will present an overview of machinery and techniques and discuss pros, cons and opportunities. It will make a brief review of the history of research and development and attempt to sum up the present status of tumour tracking while finally sharing a few thoughts on the direction it could be headed in the near future.

**SP-0577 Developments in head and neck toxicity data, models, and treatment optimisation**

A. Van Der Schaaf<sup>1</sup>

<sup>1</sup>UMCG University Medical Center Groningen, Radiation Oncology, Groningen, The Netherlands

Radiotherapy in the head and neck region plays a pivotal role in the treatment of cancer but it is also associated with a large spectrum of toxicities. In past years many studies have concentrated on xerostomia and dysphagia as

the toxicities with the most detrimental effect on quality of life, but the list of complications that are studied is expanding. Prospective data registration programs are increasingly used to collect large standardized data sets of good quality. Modelling techniques become more advanced by adopting methods from the field of (bio)statistics and machine learning, enabling data driven exploration of complicated dose response relationships and a large variety of other predictive factors, including emerging factors like genetics and image features. Also, biological experiments are narrowing down on the potential mechanisms, aiming to find anatomical targets, e.g., a stem cell rich compartment in the parotid glands. All these findings can be used to (automatically) optimise treatment planning, or to select patients that benefit most from advanced treatment modalities, such as protons. For this to be effective, however, it is required that the observed findings describe general and causal relationships, which is checked with validation studies and rapid learning methodologies. This talk will include characteristic examples from literature and details from recent developments in the Netherlands and at our department, illustrating current processes from data collection to toxicity reduction.

**SP-0578 New NTCP data in the thoracic region: probing 'dark toxicity'**

J. Deasy<sup>1</sup>, M. Thor<sup>1</sup>, J. Oh<sup>1</sup>, A. Rimner<sup>1</sup>

<sup>1</sup>Memorial Sloan-Kettering Cancer Center, Medical Physics, New York- NY, USA

Following the shocking results of RTOG 0617, it has become clear that high dose radiotherapy to the thorax can be lethal within a few months to a few years following treatment. This previously unappreciated syndrome is greater than any expected treatment benefit due to dose escalation, although it goes the wrong way. Given this new perspective, we can freshly review old and emerging data related to irradiation of central thorax structures. Although heart irradiation appears to be the likely cause of this 'dark toxicity', there are many remaining questions, such as the sensitive anatomic sub-structures. In our search for safe 'tolerance' thresholds, we will review all the data currently available to better understand this unexpected lethal toxicity in lung cancer. We will also highlight new methods of interrogating imaging data to identify local damage. In addition, we will also review recent data and risk modeling results for severe esophagitis and pneumonitis.

**SP-0579 New NTCP data in the pelvic area**

C. Fiorino<sup>1</sup>

<sup>1</sup>San Raffaele Scientific Institute, Medical Physics, Milano, Italy

The last years were very fruitful in improving our knowledge regarding the prediction of toxicities after pelvic radiation therapy (RT). Prostate cancer (PCa) patients (pts) mostly contributed to the picture; on the other hand, results came also from other fields such as gynaecological, rectal and bladder cancer RT. Compared to the pivotal reviews of the Quantec group, published in 2010, our knowledge dramatically increased for most organs. Concerning rectum, the prevalently serial behaviour when considering moderate/severe bleeding was confirmed. In addition, several clinical parameters were found to significantly modulate the risk, primarily previous abdominal/pelvic surgery and cardio-vascular disease: the existence of a relationship between acute symptoms and late bleeding was also corroborated. Other end-points were investigated such as faecal incontinence, loose stools, urgency and pain: overall, robust models were reported for faecal incontinence showing a prevalently parallel behaviour of the rectum and/or of the anal canal and a relevant impact of clinical factors such

as previous abdominal/pelvic surgery and pre-existing disease of the colon. Although much has still to be explored, bowel dose-volume effects were better quantified in recent studies showing correlation between the bowel DVH in pelvic IMRT and acute loose stools/diarrhea. The long-term effects of the inflammatory response of the bowel after RT are the object of a number of on-going trials with a careful evaluation of their impact on quality-of-life, largely underestimated in the past. The assessment of reliable predictive models of urinary toxicity is challenging, and this reflected in a heavy lack of knowledge of bladder dose-volume effects, well described by Quantec. Fortunately, major advances occurred in the last years thanks to few prospective trials, including patient-reported scoring of urinary symptoms. One of the most outstanding findings is the assessment of the existence of a dose-volume effect for several urinary symptoms typically occurring after RT for PCa. Predominantly, reducing the bladder volume receiving >75-78Gy or >8-12Gy/week (in the case of acute toxicity) may reduce acute and/or late urinary toxicity. Importantly, the impact of the (prescribed and/or maximum) dose was also confirmed in several studies both in radical and post-prostatectomy settings. Few studies also reported that the bladder trigone is more sensitive: based on these results, a value for trigone Dmax<78-80 Gy may be suggested. Many studies identified clinical factors that are correlated with urinary toxicity: the most important one is the baseline urinary functionality, which clearly modulates the response of the bladder and urethra to RT. Other major predictors are vascular problems, use of anti-hypertensives, previous transurethral resection of the prostate; interestingly, neo-adjuvant/adjuvant hormone therapy was found to be protective with respect to the onset of severe acute patient-reported symptoms: this remarkable result surely needs to be confirmed. Confirmations regarding the consequential nature of late urinary toxicity appeared, suggesting that a fraction of the late events are a "consequence" of the exuberant repair process subsequent to the acute inflammatory phase. Then, any effort to reduce acute toxicity may impact the occurrence of late events. NTCP models for haematological toxicity including dose-volume patterns of pelvic marrow were recently reported for both pts treated with radio-chemotherapy for rectal/gynecological cancer and for pts treated for PCa with RT only. NTCP models regarding sexual dysfunctions remain scarce, although the increased use of patient-reported and/or objective scores promises to get new results in the near future. As an example, the evidence that the sparing of penile bulb and the baseline erectile functionality are correlated with the insurgence of impotence in hormone-naïve pts, potent before RT for PCa, was recently reported. The continuous improvement of NTCP models in the pelvic area includes the impact of hypo-fractionation, especially for bladder: a much higher sensitivity to fractionation compared to what expected if applying the LQ-model (and alpha/beta values between 3 and 5) has been reported and modeled for several late end-points. Although relevant progresses occurred in the field, much remains to be investigated. Interestingly, the need of integrating dose-volume effects into multi-variable models including clinical (and genetic) parameters is nowadays very clear, showing that the dose distribution is only one (highly relevant) piece of the picture. Particular attention should be dedicated to the generalizability of integrated NTCP models through external validations, testing models on new data/pts/situations. First validations of NTCP models of rectal and urinary toxicity appeared in the last years, opening a pioneering, relevant field of investigation for NTCP modeling.

**SP-0580 Patient education - tools to improve patient positioning**

H. Hansen<sup>1</sup>

<sup>1</sup>*Aarhus University Hospital, The Danish Centre for Particle Therapy, Aarhus N, Denmark*

It is well-known that informing patients with cancer about treatment can help relieve anxiety. Studies in radiotherapy have focused on the use of tools in patient education. This includes the use of visual aids and exercises to facilitate knowledge about radiotherapy treatments. Use of visual aids includes the use of videos, virtual reality programmes as well as other computer programmes. A combination of virtual reality programmes and exercises has been tested in different areas as tools in rehabilitation and treatment. In our radiotherapy department, we tested a combination of exercises and 3D as means to teach patients about positioning. We hoped to reduce the residual rotational set-up errors and the number of repositions. We also wanted to improve patients sense of control by increasing self-efficacy and thus reducing distress. Bandura describes self-efficacy as believing in own capability to react to specific conditions in the environment. Knowledge of and believe in being able to control a given situation can, according to Bandura, increase belief in self-efficacy. Self-efficacy has been linked to quality of life and mood in cancer care. In our study patients were randomised to either standard care (control group) or standard care and a teaching session combining practical exercises and 3D images (intervention group). Off-line evaluation of daily images showed a reduction of residual rotational set-up errors in the intervention group compared to the control group. No differences were found in number of repositionings, distress score or self-efficacy. It was concluded that it is possible to use teaching sessions as a method to improve positioning in patients undergoing radiotherapy. Furthermore, it was concluded that teaching the patients did not seem to affect distress score or self-efficacy neither at baseline nor at the end of treatment.

**SP-0581 Public knowledge of RT saves lives: the case for RT awareness**

E. Naessens

*Dublin, Ireland*

There can be little doubt that well-structured communications between patients and healthcare professionals save time, cost, reduce risk, increase patient confidence in treatment, uncover false beliefs and misconceptions, and offer valuable insights and data into health services. Drawing upon his experience as an oncology patient, role as a patient advocate, and academic training in Mental and Moral Science, Eddie Naessens makes the case that robust healthcare communications strategies are pragmatic and essential to best practice. Oncology patients rely significantly on the quality of information and communications offered. He sets out psychological and cognitive science approaches to communications that should be considered in the design of PROMs in the RT setting.

**SP-0582 PROMs analysis to improve communication and enhance practice**

A. Lemanska<sup>1</sup>

<sup>1</sup>*University of Surrey, School of Health Sciences, Guildford, United Kingdom*

PROMs add an important dimension to the information gathered by professional assessments or clinical tests. The

patient's perspective provides a holistic and a more comprehensive assessment of treatment, and PROMs are increasingly being seen as a way to improve practice by enhancing communication, improving management of symptoms associated with disease or treatments, as well as identifying patients' care needs. With the increase in long-term remote follow-up of patients PROMs play an important role as they offer the opportunity to assess and address the health concerns or health-related quality of life (HRQOL) issues of individual patients [1]. Other important clinical applications of PROMs include aiding treatment choices as well as identifying high risk patients who may have poorer long-term health-related outcomes [2, 3]. These are all key challenges of modern oncology, and PROMs play a strategic role in this as they enable the tailoring of treatments according to the priorities, risks or concerns of individual patients.

The successful application of PROMs requires a deeper understanding of the methods for extracting information carried within PROMs [4]. PROMs data are complex, with a large number of variables (HRQOL, symptoms, function, bother, performance or health concerns) measured on different scales (with different levels, ratios or frequencies). Symptom clusters are groups of 3 or more correlated symptoms that occur together, and this is stable over time [5, 6]. Symptom clusters can be easily determined specifically to each dataset or clinical trial [7]. This can be used as a method of grouping symptoms for the purpose of summarising PROMs and extracting meaningful information. The advantage of exploring symptom clusters within a dataset is that it allows a study specific method of grouping symptoms. Because of this symptom clusters have the potential to improve sensitivity and specificity to symptom grouping. Only items that are strongly correlated, and so measure the same underlying health concern, are included in summative scores. This can be utilised in PROMs data modelling or clinical decision making.

In clinical trials PROMs are often seen as a research tool and it can be challenging to deliver real-time clinical applications. PROMs can be difficult for patients to complete, and missing data is another common problem when analysing and interpreting PROMs [8]. Some of the causes of missing data include the complexity of long and multiple PROMs questionnaires, lack of feedback following the delivery of PROMs, difficulty in understanding questions or language issues (potentially associated with migration), patients missing their appointments or dropping-out of studies, and intermittent missingness when patients fail to complete some of the questions. All this contributes to the degree of missing data and in turn a reduction in sample size, limited analytical applications or even the risk of biased results. As treatments evolve and the characteristics of patient populations change, study specific approaches to analysing PROMs are warranted. The correlation and grouping of items, missing data, and the ceiling or floor effect in collected data should all be investigated for each study when interpreting and analysing PROMs. This may advance PROMs data analysis and lead to the extraction of more relevant and meaningful information.

#### Symposium: Hypofractionation in prostate cancer

---

##### SP-0583 Moderate hypofractionation in prostate cancer: what have we learnt from phase 3 trials

D.P. Dearnaley<sup>1</sup>

<sup>1</sup>*Institute of Cancer Research, Academic Radiotherapy, London, United Kingdom*

Evidence has accumulated suggesting that prostate cancer (PCa) may be particularly sensitive to radiation fraction size. This has considerable implications for the delivery of radical radiation treatments suggesting that shorter treatments using higher dose/fraction schedules might improve the therapeutic ratio and make treatment more convenient for patients as well as using radiotherapy resource more effectively. Four large randomised controlled trials testing modest hypofractionation for localised PCa have reported efficacy and side effect outcomes within the last year<sup>(1-4)</sup>. The largest trial, CHHiP, which included 3216 patients compared standard fractionation (SFRT) using 2.0Gy daily fractions (f) (total dose 74Gy) with two experimental hypofractionated (HFRT) schedules using 3.0Gy/f (total doses of 60Gy and 57Gy)<sup>(1)</sup>. The trial used a non-inferiority design and demonstrated that HFRT at 60 Gy was non-inferior to SFRT. Five year disease control rates defined by biochemical (PSA)/clinical failure free outcome were for HFRT (60Gy) 90.6% (95% confidence intervals 88.5 - 92.3) compared with SFRT 88.3% (86.0 - 90.2) (hazard ratio 0.84, (95% CI: 0.65 - 1.07)); treatment related toxicities were low and similar. A complementary study design was used in the PROFIT trial<sup>(2)</sup> which included 1206 patients and compared SFRT using 2.0Gy/f (total dose 78Gy) with the same HFRT schedule of 3.0Gy/f (total dose 60Gy). HFRT was again shown to be non-inferior to SFRT with identical 21% biochemical/clinical failure rates at 5 years. In PROFIT gastro-intestinal side effects were increased in the SFRT group compared with HFRT group probably due to the higher SFRT dose given compared with CHHiP. Intensity modulated radiotherapy methods (IMRT) using either forward or inverse planning with a 3 part simultaneous integrated boost were used in all patients in the CHHiP trial. IMRT/IGRT methods were used in the PROFIT trial. A key difference between the trials was the use of 6 months neoadjuvant androgen deprivation therapy (ADT) in CHHiP whilst RT alone was used in PROFIT which probably explains the 11% higher biochemical control rate in CHHiP. Both investigator groups suggested that HFRT (60Gy/20f in 4 weeks) could be considered a new standard of care. In contradistinction authors of the HYPRO study<sup>(3)</sup> came to different conclusions testing dose escalated HFRT. 804 patients received either SFRT 78Gy in 2Gy daily fractions or HFRT giving 64Gy in 3-4Gy fractions but importantly treating with three fractions per week and therefore protracting overall treatment time (OTT). The gain in tumour control was smaller than might

have been expected from radiobiological models (HFRT 80.5% vs. CFRT 77.1%) and not statistically significant. The relatively unfavourable side effect profiles may be due to the higher HFRT doses delivered. The trial failed to demonstrate either superior efficacy or non-inferior side effects for HFRT. These 3 studies were undertaken in predominantly intermediate and high risk localised PCa. 1092 men were included in RTOG trial 0415<sup>(4)</sup> which tested the non-inferiority of HFRT in low risk PCa. Daily schedules of SFRT (73.8Gy/1.8Gyf) were compared with HFRT (70Gy/2.5Gyf). The cumulative incidence of biochemical recurrence at 5 years was 8% and 6% in SFRT and HFRT groups respectively which met the protocol-specified non-inferiority criterion but late gastrointestinal and genitourinary side effects were increased with HFRT. There was no certain improvement in the therapeutic ratio. Together the 4 trials provide a rich source of data to further explore the radiobiology of prostate cancer response and hint that there may be a time factor resulting from tumour repopulation. Without a time factor the CHHiP and PROFIT trials suggest the  $\alpha/\beta$  ratio is low and between 1.3-1.9 Gy although higher values of 3.5-6.9 Gy are suggested by HYPRO and RTOG-0415. However if time factors are included "best fit" estimates of the  $\alpha/\beta$  ratio increase and cluster between 3.8-5.4 Gy. These estimates are associated with wide confidence intervals and should be treated with considerable caution. Much remains to be learnt about PCa radiobiology which may have significant impact on the on-going development of more extreme hypofractionation schedules. The clinical trial results are adequately robust to recommend a change in prostate cancer fractionation to 60Gy in 20 fractions with the key proviso that high quality IMRT is delivered meeting appropriately defined normal tissue dose constraints.

**SP-0584 Extreme hypofractionation - the future of prostate care or repeating past mistakes?**

A. Loblaw<sup>1</sup>

<sup>1</sup>*Odette Cancer Centre - Sunnybrook Health Science, Department of Radiotherapy, North York- Toronto, Canada*

Based on in vivo and clinical observations, it was hypothesized in the late 1990's and early 2000's that the radiobiology of prostate cancer favored hypofractionation. There have since been a number of randomized studies published that confirm that moderate hypofractionation (doses per day of 2.1 - 5Gy) is non-inferior and isotoxic compared to conventional fractionated regimes. With the high precision available with newer stereotactic systems (non-coplanar, tomotherapy and gantry-based) interest developed in testing the feasibility, tolerability and efficacy of extreme hypofractionation (> 5Gy per day) protocols. A number of small to medium-sized prospective and retrospective studies have been published with medium follow-up. These studies suggest that with moderate doses (35-40Gy in 5 fractions), biochemical disease-free survival is similar to brachytherapy with low rates of severe toxicities. There is emerging data that rectal and bladder toxicities are highly sensitive to the volume of normal tissues in the high dose region. There are two ongoing phase 3 studies (SPCG, PACE, HEAT) which are comparing extreme and conventionally fractionated / mild hypofractionated regimes.

**Symposium: Is there any ground for boost brachytherapy in the time of high precision IGRT/IMRT?**

**SP-0586 The efficacy of IGRT/IMRT simultaneous integrated boost (SIB) in gynaecology and breast**

E.M. Ozsahin<sup>1</sup>

<sup>1</sup>*Centre Hospitalier Universitaire Vaudois, Department of Radiation Oncology, Lausanne Vaud, Switzerland*

Brachytherapy (BT) has been the standard of care for cervical cancer since the discovery of X-rays. In advanced cervical carcinoma, radiation treatment is typically external-beam irradiation (EBRT) to the pelvis followed by intracavitary brachytherapy boost to the cervix. Breast brachytherapy is increasingly used as an accelerated partial breast irradiation (APBI) modality in selected patients undergoing breast-conserving surgery. With the advent of advanced external beam radiation therapy techniques, including volumetric modulated arc therapy (VMAT), helical Tomotherapy (HT), and protontherapy (PT); and stereotactic body radiotherapy (SBRT) techniques such as CyberKnife (CK) or VMAT SBRT, many attempts have been made to substitute the BT boost with SBRT or SIB using VMAT, HT, or PT in cervical cancer; or to substitute BT with VMAT, HT, PT, or CK in APBI of breast cancer. The presentation will focus on the use of SBRT or SIB-EBRT techniques in the boost treatment cervical cancer or in APBI.

Abstract not received

**SP-0588 Why use invasive techniques for boost if IGRT is more comfortable for the patient?**

J.L. Guinot<sup>1</sup>

<sup>1</sup>*Fundación Instituto Valenciano de Oncología, Department of Radiation Oncology, Valencia, Spain*

Brachytherapy (BT) is an effective treatment with a century of antiquity but remains the best way to give a high dose of radiation to small volumes. The development of radiosurgery displaced the use of BT in brain tumors, avoiding the aggressiveness of inserting catheters through surgery. Stereotactic body radiation therapy (SBRT) is achieving new indications and optimal outcomes in small volume tumors avoiding the invasiveness and discomfort of BT. The question is open, and the debate is between invasiveness and results, comfort and accuracy. We can show that BT has always a better conformity, with a steep dose gradient, with higher doses inside the volume and shorter overall time of treatment. But the most important issue is the evidence of long-term outcomes: BT has been used for years and those data are known; SBRT must have a longer follow-up to be sure that it is an alternative and can replace BT. We will review long-term clinical evidence supporting the use of brachytherapy boost in multiple sites. BR is mandatory in cervical tumors, because higher

doses (90Gy) can be achieved in big tumours, and if it is not used local control can decrease as much as 20%. On the other hand, smaller volumes can be radiated in nasopharynx, early bronchial and oesophageal carcinomas increasing the dose in cases where the tumor control is dose-dependent. BT allows better function performing smaller glossectomies in tongue carcinomas and with less xerostomy than SBRT, and with preservation of sphincter in anal canal cancer. Organs at risk are clearly preserved in prostate carcinoma delivering lower doses to rectum and bladder, as well as allowing focal therapy. Last but not least, the biological effect of BT due to the high dose inside the treated volume, can have an influence in decreasing the risk of relapse in breast carcinoma at long-term FU. Therefore, non-invasive techniques can be more comfortable and desirable, but the main goal in oncology is long-term tumor control with minimal late effects in organs at risk, and BT in selected situations is still the best option nowadays.

**SP-0589 Molecular mechanisms of radiation-induced in situ tumor vaccination**

S. Demaria<sup>1</sup>

<sup>1</sup>Weill Cornell Medical College, Radiation Oncology and Pathology, New York, USA

Growing pre-clinical and clinical evidence supports the hypothesis that ionizing radiation applied locally to a tumor has the ability to induce the activation of tumor-specific T cells. This property of radiation, which is likely responsible for the occasional occurrence of abscopal effects (regression of tumors outside of the radiation field), has attained increasing importance in the new era of immuno-oncology with radiotherapy being tested in a large number of clinical studies as a treatment that can increase patients responses to immunotherapy (1). In fact, radiation-induced in situ vaccination could provide a relatively simple and widely available modality to achieve the personalized immunization of a patient towards mutated proteins expressed by his/her tumor (2). Proof-of-principle evidence that radiotherapy in combination with immune checkpoint inhibitors elicits powerful and durable anti-tumor responses has been obtained in several pre-clinical models (3). However, the mechanisms underlying radiation's ability to induce effective anti-tumor immune responses remain incompletely understood (4).

My lab studies the radiation-induced molecular pathways responsible for effective activation of robust anti-tumor T cells that mediate abscopal effects. Recruitment to the tumor of a Batf3-dependent subset of dendritic cells specialized in cross-presentation of tumor-derived antigens to CD8<sup>+</sup> cytotoxic T cells (CTLs) is driven by type I interferon (IFN-I) and has been shown to be essential for activation of anti-tumor CD8<sup>+</sup> T cells. We have recently found that in tumors refractory to treatment with immune checkpoint inhibitors radiotherapy induces cancer cell-intrinsic activation of IFN-I pathway and release of interferon-beta, mimicking a viral infection, and resulting in recruitment of Batf3-dependent DCs. Importantly, the dose and fractionation of radiation are critical for induction of IFN-I production by irradiated cancer cells, with a lower (doses >2-4 Gy) and an upper (doses >12 Gy) threshold for the induction of IFN-I, creating a therapeutic window that defines the immunogenicity of radiotherapy. The molecular mechanisms that regulate this therapeutic window will be presented. Fractionation, i.e., repeated (three times) daily delivery of radiation therapy at doses within this window, amplifies the IFN-I pathway activation in the carcinoma cells, an effect that requires

upregulation of IFNRA. Furthermore, the synergy of radiation with immune checkpoint inhibitors and the induction of abscopal effects are completely dependent on the ability of radiotherapy to induce cancer cell-intrinsic IFN-I. These findings have critical implications for the use of radiotherapy to increase responses to immunotherapy in the clinic.

**SP- 0590 Novel developments in paediatric cancer**

M.G. McCabe<sup>1</sup>

<sup>1</sup>University of Manchester,

Division of Molecular and Clinical Cancer Sciences, Manchester, United Kingdom

The last decade has seen only incremental improvements in survival when compared to the dramatic changes that followed the centralisation of specialist care and the introduction of multi-agent chemotherapy regimens and combination treatments during the last half century.

Although in some cases subtle, those incremental changes have been apparent across almost all types of childhood cancer, even the most refractory to change. Five-year overall survival for childhood cancer in the last EURO CARE cohort was just under 80%, and in many European countries now exceeds 80%.

The explosion in high throughput '-omics' technologies and expertise currently underway is rapidly expanding our knowledge of the mechanistic drivers of tumour growth and treatment resistance. Progress is not evenly distributed across childhood cancer; the brain tumour community has benefited particularly from molecular technologies, with the recognition of some novel tumour entities, subclassification of others and the declassification of one major tumour group altogether. More accurate recapitulation of tumour biology by *in vivo* models is also contributing to understanding of tumorigenesis and treatment effects, and holds promise for individually tailored therapies.

Whilst molecular profiling has undoubtedly increased our ability to accurately diagnose and risk stratify tumours, and in many cases identified the mutations responsible for tumorigenesis, that knowledge has yet to lead to a paradigm shift in treatment for most paediatric cancers. Childhood cancers in general have fewer mutations than their adult counterparts and could be expected to have more sensitivity to appropriately targeted therapies. The challenges, however, are multifactorial: redundancy in signal transduction pathways, a predominance of driver mutations in genes encoding proteins that are difficult to target, tumorigenesis driven by missing tumour suppressor genes rather than over-expressed oncogenes, and a commercial and legislative environment that does not foster the development of novel therapies for rare cancers.

Notwithstanding the challenges, progress is being on multiple fronts. There are examples of successful incorporation of molecular therapies into standard treatment in haematological and solid malignancies. Individual tumour profiling is becoming increasingly routine in clinical practice. Several European

countries now have paediatric stratified medicine programmes underway or in development, and the first multi-arm, multi-Pharma company European paediatric basket trial - e-SMART - is due to open for relapsed and refractory tumours. At a strategic level, consultation is underway for the EU 'Paediatric Regulation' which it is hoped will further increase access of children to novel therapies by removing the facility for Pharma companies to apply for waivers for paediatric testing. In an era of molecularly driven therapy, such waivers have no logical basis in the majority of cases.

#### OC-0591 Hypoxic cell killing by SN36506, a novel hypoxia-activated prodrug

#### Purpose or Objective

Hypoxia is a common feature of solid tumors. Conventional treatments such as chemo- and radiotherapy (RT) are less effective against hypoxic tumor cells. Hypoxia-activated prodrugs (HAPs) are specifically activated under hypoxic conditions to directly target these as well as adjacent more oxygenated tumor cells via their bystander effect. SN36506 is a newly developed nitroaromatic HAP with highly favorable properties: 1) activation under hypoxia, 2) high bystander effect, 3) excellent aqueous solubility, 4) murine oral bioavailability and 5) no off-mechanism activation by human aerobic reductases. Here we tested the cytotoxic effects of SN36506 *in vitro* and *in vivo*.

#### Material and Methods

IC<sub>50</sub> viability ratios were assessed in 2D cell culture exposed to normoxic or anoxic ( $\leq 0.02\%$  O<sub>2</sub>) conditions in a panel of human tumor cell lines. H460 lung tumor multicellular layers (MCLs) were incubated with SN36506 under aerobic (5% CO<sub>2</sub>, 95% O<sub>2</sub>) or anoxic (5% CO<sub>2</sub>, 95% N<sub>2</sub>) conditions and plated for clonogenic cell survival (CCS). In addition, H460 spheroids were incubated with SN36506, after which single cell suspensions were made and cells were plated for CCS.

Mice bearing H460 xenografts received a single i.p. dose of SN36506 (781 mg/kg) after irradiation (10 Gy) of tumors. 18 h later tumors were excised, single cell suspensions were prepared and plated for CCS.

Mice bearing xenografts of a range of tumor cell lines received one i.p. dose of SN36506 (800 mg/kg) per day on 5 consecutive days (QD5). Treatment started when tumors reached a volume of approximately 200 mm<sup>3</sup>, and tumor volumes were followed-up after treatment.

#### Results

IC<sub>50</sub> were lower in anoxia than normoxia by factors of 20.17 (SiHa), 55.11 (C33A), >7.84 (HCT116), >3.66 (DLD-1), >12.9 (MDA-MB-468), >2.67 (H1299) and >6.21 (H460). In a H460 MCL clonogenic assay, 100  $\mu$ M SN36506 caused 99% cell kill under anoxia but exhibited no aerobic cell kill. SN36506 caused a concentration-dependent decrease in survival of clonogens derived from hypoxic spheroids but had no effect on clonogenic cells from non-hypoxic spheroids, indicating hypoxia-specific cell kill. A single dose of SN36506 significantly reduced clonogenic cell survival when combined with RT in an *in vivo* excision assay (log cell kill 2.35 relative to control). Furthermore, *in vivo* 800 mg/kg QD5 of SN36506 caused xenograft growth inhibition of 99.6% (MDA-MB-468), 81% (A2780), 52% (H460) and 41% (SiHa).

#### Conclusion

*In vitro*, SN36506 preferentially kills tumor cells in hypoxic conditions and reduces clonogenic cell survival of hypoxic spheroids only. *In vivo*, SN36506 sterilizes radiation resistant hypoxic tumor cells, and strongly inhibits tumor growth. As such, SN36506 is a promising new HAP with potentially favorable properties for clinical use. Further studies to determine the antitumor effects of SN36506 as a monotherapy and in combination with RT in several preclinical tumor models are ongoing.

The excellent visualization of soft-tissue with MRI can allow direct visualization of the tumor when applied during the delivery of radiotherapy. Several designs, which combine MRI with either an accelerator or Co-60, are being developed or in clinical use. At the UMC Utrecht a clinical prototype is installed which integrates a 1.5 T MRI scanner and a 7 MV linear accelerator. When the dose is delivered in presence of a magnetic field, the Lorentz force will change the trajectories of the high energy electrons generated by the megavoltage radiation. The effect on dose distribution depends on the magnetic field strength, its direction relative to the treatment field and the energy. In our MRI-linac design this results in a decreased build-up distance and a shifted penumbra. Changes can also be observed in the dose distribution near interfaces of two materials with different densities. Especially near tissue-air boundaries electrons can be curved back into the tissue (electron-return-effect).

The influence of the magnetic field can also affect the reading of various detectors used for reference dosimetry, acceptance and commissioning, regular QA and patient QA. The change in reading of a detector depends on the field strength, orientation relative to the photon field and the magnetic field and to sources of air-layers between build-up material and detector.

An important detector is the waterproof farmer type ionization chamber, which performance in a magnetic field has been investigated thoroughly in our department. Correction factors had been derived for the magnetic field in various geometries and orientations to obtain absolute dose measurements. The performance was characterized in water as well as solid water phantoms. Also the use of other detectors such as a diamond detector have been investigated for use in magnetic fields.

To evaluate dose distributions of clinical plan delivery, patient specific quality assurance can be performed using various dedicated detectors, such as the Delta4 and

arcCHECK. The performance of a dedicated MRI compatible version of the Delta4 and the acrCHECK has been evaluated. Both devices performed well in presence of a 1.5 T magnetic field, and isocentric set-up, with no significant differences relative to conventional linac without magnetic field.

Since the MR-Linac aims for online adaptive radiotherapy, online plan QA needs to be developed additional to the offline QA procedures and devices. At the MRI-linac, an IMRT plan will be created online based on the daily anatomy while the patient is on the treatment couch. Therefore, individual plan QA via measurements can't be performed. As a solution, the use of an independent dose calculation based on 3D collapsed cone dose calculation algorithm was investigated. Although the effect of the magnetic field is not directly incorporated in this algorithm it seems to be sufficient to be used for online QA of the online generated IMRT plan.

**The role of oxygenation in tumor radio-sensitivity**

The cell damage due to radiation exposure is conveyed by means of both direct effects, and indirect ionization of DNA due to free-radicals (e.g. O<sup>-</sup>). As a consequence, tumor oxygenation affects the response to radiotherapy by enhancing the radiosensitivity, conversely, hypoxic tumors are likely to be more radio-resistant. Moreover, literature findings suggest a systemic repercussion of changes in oxygen levels in the lesion area, for example hypoxia may reduce the tumor metabolism inducing a quiescent status and preventing the mass development. Mathematical models of tumor growth and response to irradiation are able to mimic the interplay among oxygenation, volume and radiosensitivity addressing the problem as a whole. Tumor data (e.g. volume, PO<sub>2</sub>, necrotic fraction) are mandatory for an accurate and patient-specific model setting.

**Current methods to assess tumor oxygenation**
